INTRODUCTION

In the 20th century, technological innovation has progressed at such an accelerated pace that it has permeated almost every facet of our lives. This is especially true in recent developments in the field of medicine and the delivery of health care services. Although the art of medicine has a long history, the evolution of a health care system capable of providing a wide range of positive therapeutic treatments in the prevention and cure of illnesses is a decidedly new phenomenon. Of particular importance in this evolutionary process has been the establishment of the modern hospital as the center of a technologically sophisticated health care system. In the process of centralizing the support and utilization of medical technology, it became apparent that specialization of a large number of health care professionals was also necessary. In the United States, the result has been the emergence of a technologically dominated health care system focused around the activities of regional hospitals serviced by a technologically sophisticated staff.

Since technology has had such a dramatic impact on medical care, engineering professionals have become intimately involved in many medical ventures. As a result, the discipline of *biomedical engineering* has emerged as an integrating medium for two dynamic professions, medicine and engineering, assisting in the struggle against illness and diseases by providing materials, tools, and techniques (such as imaging and artificial intelligence) that can be utilized for research, diagnosis, and treatment by health care professionals. Thus, biomedical engineers serve as relatively new members of a health care delivery "team" seeking new solutions for the difficult health care problems confronting our society. The purpose of this article, therefore, is to provide a broad overview of technology's role in shaping our modern health care system, to discuss the basic aspects of the field of biomedical engineering, to review some of the contributions made by biomedical engineers including cardiovascular assist devices, med-

ical imaging, and diagnostic support systems, and to present the status of biomedical engineering education.

1. EVOLUTION OF THE MODERN HEALTH CARE SYSTEM

Before 1900, medicine had little to offer the average citizen, since its resources consisted mainly of the physician, his education, and his "little black bag." In general, physicians seemed to be in short supply, but the shortage had rather different causes than more current crises in the availability of health care professionals. Although the costs of obtaining medical training were relatively low, the demand for doctors' services was also very small, since many of the services provided by the physician could also be obtained from experienced amateurs in the community. The home was typically the site for treatment and recuperation, and relatives and neighbors constituted an able and willing nursing staff. Babies were delivered by midwives, and those illnesses not cured by home remedies were left to run their natural, albeit frequently fatal, course. The contrast with contemporary health care practices, in which specialized physicians and nurses located within the hospital provide critical diagnostic and treatment services, is dramatic.

The changes that have occurred within medical science originated in the rapid developments that took place in the applied sciences (chemistry, physics, engineering, microbiology, physiology, pharmacology, etc.) at the turn of the century. This process of development was characterized by intense interdisciplinary cross-fertilization, which provided an environment in which medical research was able to take giant strides in developing techniques for the diagnosis and treatment of disease. For example, in 1903, Willem Einthoven, the Dutch physiologist, devised the first electrocardiograph to measure the electrical activity of the heart. In applying discoveries in the physical sciences to the analysis of a biological process, he initiated a new age in both cardiovascular medicine and electrical measurement techniques.

New discoveries in medical science followed one another like intermediates in a chain reaction. However, the most significant innovation for clinical medicine was the development of x rays. These "new kinds of rays," as their discoverer W. K. Roentgen described them in 1895, opened the "inner man" to medical inspection. Initially, x rays were used to diagnose bone fractures and dislocations. In the process, this "modern technology" became commonplace in most urban hospitals. Separate departments of radiology were established, and their influence spread to other departments throughout the hospital. By the 1930s, x-ray visualization of practically all organ systems of the body had been made possible through the use of barium salts and a wide variety of radio-opaque materials.

X-ray technology gave physicians a powerful tool that, for the first time, permitted accurate diagnosis of a wide variety of diseases and injuries. Moreover, since x-ray machines were too cumbersome and expensive for local doctors' clinics, they had to be placed in health care centers or hospitals. Once there, x-ray technology essentially triggered the transformation of the hospital from a passive receptacle for the sick poor to an active curative institution for all members of society.

For economic reasons the centralization of health care services became essential because of many other important technological innovations appearing on the medical scene. However, hospitals remained institutions to dread, and it was not until the introduction of sulfanilamide in the mid-1930s and penicillin in the early 1940s that the main danger of hospitalization, i.e., cross infection among patients, was significantly reduced. With these new drugs in their arsenals, surgeons were permitted to perform their operations without the prohibitive morbidity and mortality due to infection. Furthermore, even though the different blood groups and their incompatibility were discovered in 1900 and sodium citrate was used in 1913 to prevent clotting, full development of blood banks was not practical until the 1930s when technology provided adequate refrigeration. Until that time, "fresh" donors were bled and the blood transfused while it was still warm.

Once these surgical units were established the employment of the available technology assisted in further advancing the development of complex surgical procedures. For example, the Drinker respirator was introduced in 1927 and the first heart-lung bypass in 1939. By the 1940s, medical procedures

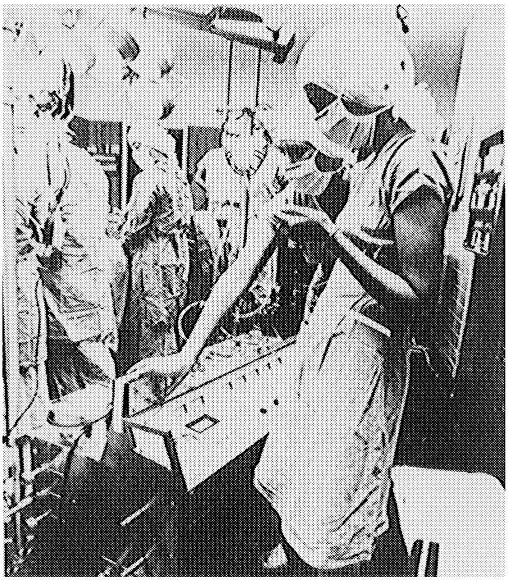

FIG. 1. The operating room scene during the early 1950s illustrates the invasion of medical technology into the clinical theater of operation. (Courtesy of Hartford Hospital.)

heavily dependent upon medical technology such as cardiac catheterization and angiography (the use of a cannula threaded through an arm vein and into the heart with the injection of radio-opaque dye for the x-ray visualization of lung and heart vessels and valves) were developed. As a result, accurate diagnoses of congenital and acquired heart disease (mainly valve disorders due to rheumatic fever) became possible, and a new era of cardiac and vascular surgery was established.

Following World War II, the development of medical devices accelerated rapidly and the medical profession benefited greatly from this rapid surge of "technological finds" (Fig. 1). Consider the following examples:

1. Advances in electronics made it possible to map the subtle electrical behavior of the fundamental unit of the central nervous system—the neuron—as well as to monitor various physiological parameters, such as the electrocardiogram (ECG), of patients in intensive care units.
2. Nuclear medicine—an outgrowth of the atomic age—emerged as a powerful and effective approach in detecting and treating specific physiological abnormalities.
3. Diagnostic ultrasound based on sonar techniques became so widely accepted that ultrasonic studies are now part of the routine diagnostic workup in many medical specialties.
4. "Spare parts" surgery also became commonplace. Technologists were encouraged to provide prosthetic devices, such as artificial heart valves and artificial blood vessels, and the artificial heart program was launched to develop a replacement for a defective or diseased human heart.
5. Computers similar to those developed to control the flight plans of the Apollo capsule were used to store, process, and cross-check medical records, to monitor patient status in intensive care units, and to provide sophisticated statistical diagnosis of potential diseases correlated with specific sets of patient symptoms (Fig. 2).
6. Development of the first computer-based medical instrument, the computerized axial tomography (CAT) scanner, revolutionized clinical approaches to noninvasive diagnostic imaging procedures which now include magnetic resonance imaging (MRI) and positron emission tomography (PET) as well.

The impact of these discoveries and many others was profound. The health care system consisting primarily of the "horse and buggy" physician was gone forever. It was replaced by a clinical staff operating primarily in hospitals which began to change to accommodate the new medical technology. The "modern hospital," therefore, in its contemporary, familiar form is essentially less than sixty years old (Crichton, 1970; Knowles, 1973; Bronzino, 1977, 1986).

2. WHAT IS BIOMEDICAL ENGINEERING?

Many of the problems confronting health professionals today are of extreme interest to engineers because they involve the design and practical application of medical devices and systems—processes that are fundamental to engineering practice. These medically related design problems can range from very complex large-scale constructs, such as the design and implementation of automated clinical laboratories, multiphasic screening

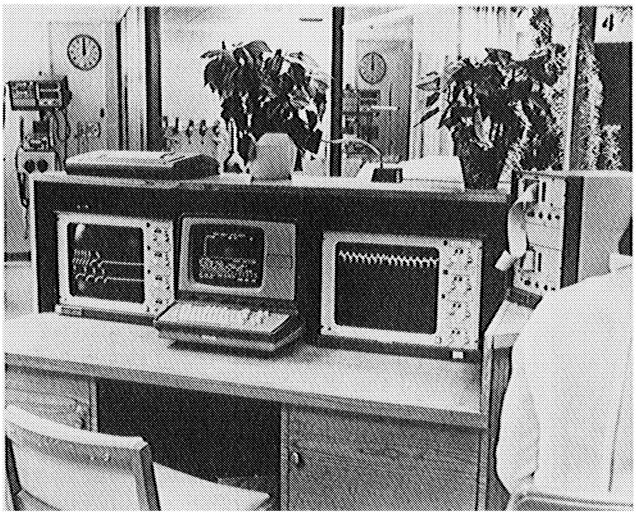

FIG. 2. Computer-based monitoring systems scan the vital signs of patients in hospital intensive care units. (Courtesy of Electronics for Medicine, Inc., White Plains, NY.)

facilities (i.e., centers that permit many clinical tests to be conducted), and hospital information systems, to the creation of relatively small and "simple" devices such as recording electrodes and transducers that may be used to monitor the activity of specific physiological processes in either a research or clinical setting. They encompass the many complexities of remote monitoring and telemetry, including the requirements of emergency vehicles, operating rooms, and intensive care units. The American health care system, therefore, encompasses many problems that represent challenges to certain members of the engineering profession called biomedical engineers.

Since biomedical engineering involves applying the concepts, knowledge, and approaches of virtually all engineering disciplines (e.g., electrical, mechanical, and chemical engineering) to solve specific health-care-related problems, the opportunities for interaction between engineers and health professionals are many and varied.

Biomedical engineers may become involved, for example, in the design of a new medical imaging modality or development of new medical prosthetic devices to aid the handicapped. Although what is included in the field of biomedical engineering is considered by many to be quite clear, many conflicting opinions concerning the field can be traced to disagreements about its definition (Plonsey, 1973; Johns, 1975). For example, consider the terms *biomedical engineering*, *bioengineering*, and *clinical* (or *medical*) *engineering* which are defined in the *Bioengineering Education Directory* (Pacela, 1990). While Pacela defines "bioengineering" as the broad umbrella term used to describe this entire field, bioengineering is usually defined as a basic-research–oriented activity closely related to biotechnology and genetic engineering, that is, the modification of animal or plant cells, or parts of cells, to improve plants or animals or to develop new microorganisms for beneficial ends. In the food industry, for example, this has meant the improvement of strains of yeast for fermentation. In agriculture, bioengineers may be concerned with the improvement of crop yields by treatment of plants with organisms to reduce frost damage. It is clear that bioengineers of the future will have a tremendous impact on the quality of human life; the full potential of this specialty is difficult to imagine. Typical pursuits include the following:

- development of improved species of plants and animals for food production;
- invention of new medical diagnostic tests for diseases;
- production of synthetic vaccines from clone cells;
- bioenvironmental engineering to protect human, animal, and plant life from toxicants and pollutants;
- study of protein-surface interactions;
- modeling of the growth kinetics of yeast and hybridoma cells;

- research in immobilized enzyme technology;
- development of therapeutic proteins and monoclonal antibodies.

The term *biomedical engineering* in this author's opinion has the most comprehensive meaning. Biomedical engineers apply electrical, chemical, optical, mechanical, and other engineering principles to understand, modify, or control biological (i.e., human and animal) systems. When a biomedical engineer works within a hospital or clinic, he or she is more properly called a *clinical engineer.* However, this theoretical distinction is not always observed in practice; many professionals working within U.S. hospitals today continue to be called biomedical engineers. In the field of biomedical engineering there are seven major career areas which include application of engineering system analysis and modeling (computer simulation) to biological problems; measurement or monitoring of physiological signals; diagnostic interpretation via signal processing techniques of bioelectric data; therapeutic and rehabilitation procedures and devices; prosthetic devices for replacement or augmentation of bodily functions; computer analysis of patient related data; and medical imaging, i.e., the graphic display of anatomical detail or physiological function. Typical pursuits include the following:

- design of instrumentation for human physiology research;
- monitoring astronauts and maintenance of life in space;
- research in new materials for implanted artificial organs;
- development of new diagnostic instruments for blood analysis;
- computer modeling of the function of the human heart;
- writing software for analysis of medical research data;
- analysis of medical device hazards for the U.S. government;
- monitoring the physiological functions of animals;
- development of new diagnostic imaging systems;
- design of telemetry systems for patient monitoring;
- design of biomedical sensors for measurement of human physiological systems variables;
- research on artificial intelligence (AI) (*q.v.*) and development of expert systems for diagnosis of diseases;
- design of closed-loop control systems for drug administration;
- modeling of the physiological systems of the human body;
- design of instrumentation for sports medicine;
- development of new dental materials;
- design of computers and communication aids for the handicapped;
- research in pulmonary fluid dynamics (see BIORHEOLOGY);
- study of the biomechanics of the human body.

The above list is not intended to be all-inclusive. There are many other applications that utilize the talents and skills of the biomedical engineer. In fact, the list of activities of biomedical engineers depends upon the medical environment in which they work. This is especially true for the "clinical engineers," biomedical engineers employed in hospitals or clinical settings. Clinical engineers are essentially responsible for all the high-technology instruments and systems used in hospitals today; for the training of medical personnel in equipment use and safety; and for the design, selection, and use of technology to deliver safe and effective health care (Fig. 3).

Hospitals that have established centralized clinical/biomedical engineering departments to meet these responsibilities, therefore, use clinical engineers to provide the hospital administration with an objective opinion of equipment function, purchase, application, overall system analysis, and preventive maintenance policies. With the in-house availability of such talent and expertise, the hospital is in a far better position to make more effective use of its technological resources (Jacobs, 1975; Bronzino, 1977, 1986).

In the past, industry has been reluctant to make large investments in biomedical engineering research and development. The lack of a clearly defined and predictable market for successful technologies is the major culprit here. Competent clinical engineers, however, as part of the health care system, can help create a more unified and predictable market. By providing health professionals

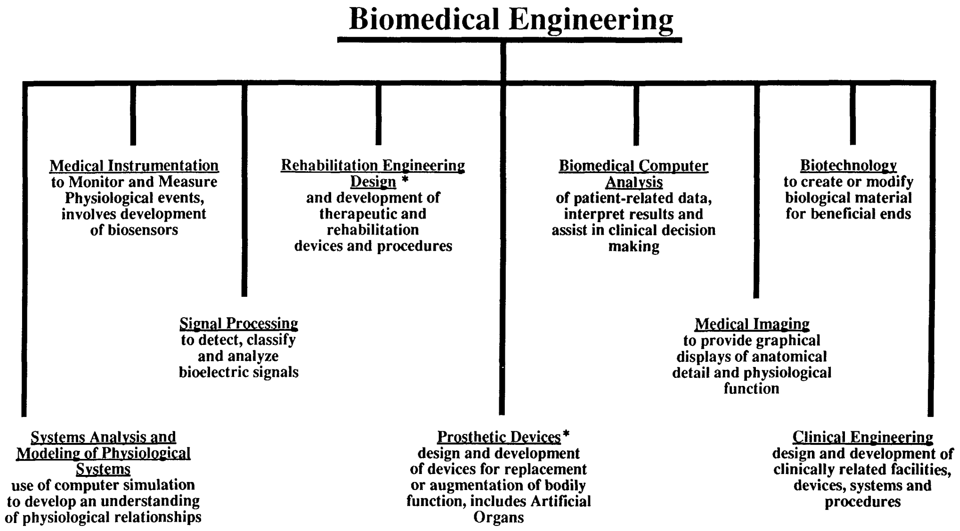
with needed assurance of safety, reliability, and efficiency of new and innovative equipment, they can, in the process, identify poor-quality and ineffective equipment much more readily. These activities can lead to a faster and broader acceptance of new technology and provide a natural incentive for greater industry involvement, a step that is an essential prerequisite to widespread utilization of any technology (Neuman *et al.*, 1989).

Typical pursuits of clinical engineers, therefore, include the following:

- supervision of a hospital clinical engineering department;
- design, modification, or repair of sophisticated medical instruments or systems within a hospital;
- evaluation of a new noninvasive monitoring system during a clinical research program;
- prepurchase evaluation and planning for new medical technology;
- cost-effective management of a medical equipment repair service;
- safety testing of medical equipment;
- risk management and liability control within the hospital;
- coordination of outside services and vendors;
- supervision of biomedical engineering technicians;
- providing training for medical personnel in the safe and effective use of medical devices and systems;
- custom modification of medical devices for clinical research.

Of all of the definitions discussed above, the term *biomedical engineering* provides the broadest meaning (Fig. 4). Biomedical engineering is an interdisciplinary branch of engineering heavily based both in engineering and in the life sciences. It ranges from theoretical, nonexperimental undertakings to state-of-the-art applications. It can encompass research, development, implementation, and operation. Accordingly, like medical practice itself, it is unlikely that any single person can acquire expertise that encompasses the entire field. As a result, there has been an explosion of biomedical engineering specialists to cover this broad spectrum of activity. Yet because of the interdisciplinary nature of this activity, there is considerable interplay and overlapping of interest and effort between them. For example, biomedical engineers engaged in the development of biosensors may interact with those interested in prosthetic devices to develop a means to detect and use the same bioelectric signal to power a prosthetic device. Those engaged in automating the clinical chemistry laboratory may collaborate with those developing expert systems to assist



Biomedical Engineering
Medical Instrumentation to Monitor and Measure Physiological events, involves development of biosensors
Rehabilitation Engineering Design * and development of therapeutic and rehabilitation devices and procedures
Biomedical Computer Analysis of patient-related data, interpret results and assist in clinical decision making
Biotechnology to create or modify biological material for beneficial ends
Signal Processing to detect, classify and analyze bioelectric signals
Medical Imaging to provide graphical displays of anatomical detail and physiological function
Systems Analysis and Modeling of Physiological Systems use of computer simulation to develop an understanding of physiological relationships
Prosthetic Devices* design and development of devices for replacement or augmentation of bodily function, includes Artificial Organs
Clinical Engineering design and development of clinically related facilities, devices, systems and procedures

* Both of these activities involve the fields of Biomechanics and Biomaterials

clinicians in making clinical decisions based upon specific laboratory data. The possibilities are endless.

Perhaps a greater potential benefit occurring from the utilization of biomedical engineers is the identification of problems and needs of our present health care delivery system that can be solved using existing engineering technology and systems methodology. Consequently, the field of biomedical engineering offers hope in the continuing battle to provide high-quality health care at a reasonable cost. If properly directed towards solving problems related to preventative medical approaches, ambulatory care services, and the like, biomedical engineers can provide the tools and techniques to make our health care system more effective and efficient.

3. PRESENT AND FUTURE RESEARCH DIRECTIONS IN BIOMEDICAL ENGINEERING

Biomedical engineering research has taken place in a number of important areas in the basic life sciences and clinical medicine (Table 1). Modifying the categories of biomedical research presented in a recent review by Neuman *et al.* (1989), we have the following:

1. systems science and integrated biology,
2. cardiovascular assist devices,*
3. biomaterials,
4. rehabilitation engineering and prosthetic devices,
5. instrumentation and sensors,
6. medical imaging technology, and
7. biomedical computing.

In keeping with this classification, let us review some of the research activities in each category.

3.1 Systems Science and Integrated Biology

The application of engineering systems analysis and modeling to biological problems is perhaps one of the earliest recognized research areas in biomedical engineering. The quantification of physiological relationships and the building of mathematical models, i.e., simulations, based upon these relationships have not only been central to the field of biomedical engineering, but have been signifi-

[a] Taken from Neuman *et al.* (1989).

cant aids to life scientists in their effort to understand basic physiological mechanisms better.

The relevance of simulation to biological research lies in its utility, which suggests to biological researchers the most efficient, meaningful, and creative avenues of investigation. Knowledge about a particular biological system is usually pieced together from facts gathered in a variety of laboratories, using many different experimental procedures in many different environments; in some instances attention is given to microscopic experimentation and in other instances to macroscopic experimentation. It is not surprising then, that comprehensive understanding does not necessarily correlate well with the number of "facts" available about the system being studied.

As the various small bits of information are synthesized into a meaningful composite, the level of complexity of the description becomes greatly increased. The language of mathematics, assuming the data under consideration are quantitative in nature, allows the biological investigator to contemplate complex interrelationships that appear to be beyond comprehension when viewed casually. In turn, modern high-speed computing machinery can manipulate such mathematics often with dramatic effect which improves understanding of the biological system under study. The mathematical description (and any resultant solutions) forms a compact, exact language that can easily be communicated to others.

Successful simulation demands that the experimenter have a certain talent in model building and a grasp of the physical principles that are pertinent to his field of research. It is, therefore, important that a continual interaction take place between experimentation and simulation (Fig. 5 suggests several modes of interaction). The ultimate objective is to increase the knowledge of a particular system. If we start a study by doing simulation there are several pathways that lead to "knowledge." After a simulation is performed, the questions "Has the simulation been a creative experience?" or "Does the solution prove new insight into the system's performance?" must be answered. If the answer is "yes," then appropriate experimentation is in order. If the answer is "no" the simulation activity was not completely successful and alterations in the model are required. In a similar fashion, the next step is either more experimentation or more simulation.

Today, new modeling approaches, such as parallel processing and neural networks, are opening new horizons in enabling life scientists to understand complex cognitive function as well as the interaction of processes occurring at the cellular or even subcellular levels. At the same time further advances in computing technology may allow investigators to reduce the need of using animals in a wide variety of experiments.

3.2 Cardiovascular Assist Devices

Biomedical engineering has played an important role not only in increasing our understanding of the cardiovascular system, but also in the development of diagnostic and therapeutic devices that are routinely used in the care of cardiac patients. Since this is such an important area of research and involves many biomedical engineering disciplines, such as biomaterials and instrumentation, let us explore it in more detail.

3.2.1 Cardiac Pacemakers. The use of artificial cardiac pacemakers is well established in medical practice. Since its development in 1960, over 500 000 pacemakers have been implanted into patients in the United States alone, making this the most common of all cardiovascular therapeutic procedures. The most common indication for a pacemaker is very slow heart rate or bradycardia due to a failure of the natural pacemaker or a component of the conduction system. Patients with bradycardia are prone to loss of consciousness as their hearts cannot speed in response to stress and their brains do not receive adequate blood flow.

Modern pacemakers can sense the heart's own electrical activity and pace appropriately. For patients with sinus atrium (SA) node dysfunction the pacemaker can pace the atrium directly through an atrial electrode and allow the heart's own conduction system to function normally. For patients with a blockage of impulse conduction between the atria and ventricles, a condition called heart block, the heart's own atrial activity can be sensed by the pacemaker and a stimulus sent directly to the ventricle. This type of physiological pacing allows the patient's own SA node to set the rate. Many patients have widespread conduction system disease. At various points in their conduction system, problems may occur and flexibility is needed to control the situation. These patients may initially experience SA node dysfunction but subsequently develop heart block. To deal with this problem of change in the status of the heart, biomedical engineers developed a dual-chamber programmable pacing system. After implantation, the functions of these units can be controlled and reprogrammed by an external device using radio-frequency commands. The functions that can be controlled are the selection of the chambers to be paced, the chambers to be sensed, and the mode of response. Furthermore, all of the above functions and battery status are presently monitored by telemetry.

Typically, a pacemaker unit will be installed in a patient and programmed by a cardiologist (Fig. 6). The status of the unit will be monitored by telemetry, increasingly via the telephone, on a monthly basis, and periodic reprogramming of the pacemaker will take place as needed. Present pacemakers are so

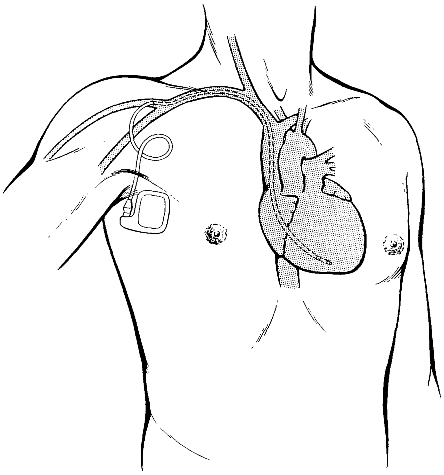

FIG. 6. Sketch illustrating the placement of a cardiac pacemaker. (Courtesy of Medical Systems Division, General Electric Company, Milwaukee, WI.)

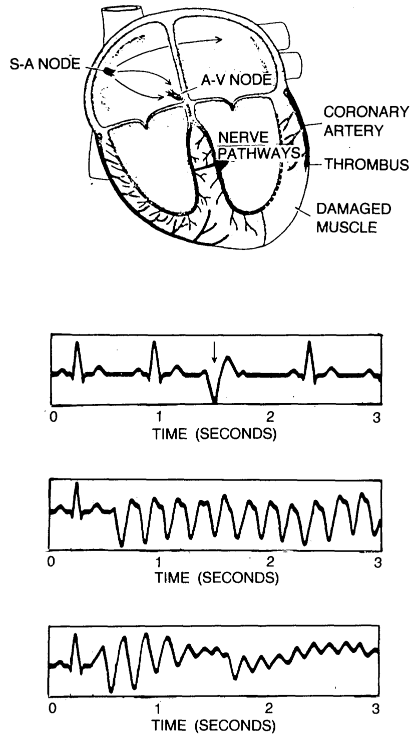
durable they even can be reused. In the future, it is almost certain that more-advanced pulse generators will be developed to provide even more flexibility.

3.2.2 Defibrillation Techniques. The normal heart normally contracts in a rhythmic fashion. In the diseased heart, especially in the case of coronary artery disease when the heart muscle does not receive adequate blood flow through the blocked coronary arteries, rhythm disturbances occur. These are usually limited to occasional extra beats called ventricular extrasystoles, but can progress to the potentially lethal rhythm called ventricular fibrillation. In this state, there is no orderly beat and the ventricle is overstimulated electrically to the point where mechanical activity ceases and there is no effective cardiac pumping. Death occurs in a few minutes if the condition persists (Fig. 7).

In 1962, Dr. Bernard Lown of Harvard, a cardiologist, developed the direct current (dc) defibrillator in which a capacitor is charged to the desired dc voltage and then discharged through large metal paddles placed on the patient's chest. This method is still being used today.

Today the defibrillator is carried as part of the ambulance equipment in most areas. The paramedical team, which arrives at the home



ELECTRICAL ACTIVITY OF DAMAGED HEART is erratic because nerve impulses can no longer flow smoothly from the atrioventricular node through the pathways that feed impulses to the ventricular muscles. Most heart-attack patients develop one or more of the arrhythmias shown below.

FIRST SIGN OF ARRHYTHMIA in the heartbeat, following a coronary heart attack, usually takes the form of a premature ventricular beat (arrow).

MORE SERIOUS ARRHYTHMIA is tachycardia, or fast heartbeat, in which ventricular impulses occur at two or three times the normal rate. If not halted, they can cause death.

FATAL ARRHYTHMIA known as fibrillation can develop from tachycardia or when premature beats fall within a critical part of the T wave.

FIG. 7. Electrical activity of damaged heart. Redrawn from Lown (1968).

of a patient who is thought to be suffering from a heart attack, promptly attaches electrocardiogram (ECG) leads to the patient, observes the ECG, and sends a copy of the signal by radio to the physician at the hospital base. If ventricular fibrillation is seen, cardiopulmonary resuscitation is started and, by remote direction of the physician, the defibrillator paddles are placed on the patient's chest. Ventricular fibrillation is again confirmed by analysis of the ECG signal sensed by the paddles.

One paddle is placed over the upper chest and the other over the lower chest. The discharge switches are located in the handles of the paddles and both must be pressed at the same time to allow the defibrillator to discharge. Within seconds, the ECG trace hopefully reveals a return to a normal rhythm. The patient can then be safely transported to the hospital for further care. This system of portable monitoring, telemetry, and defibrillation is a major reason that patients who have heart attacks now survive in greater numbers.

At present there also exist automatic, implantable defibrillators. In patients with very unstable rhythm which is only partially controlled by medication, this type of device can be used to allow them to leave the hospital and resume a more normal lifestyle. This new electronic device can even be programmed to monitor cardiac electrical activity and to recognize ventricular fibrillation. If ventricular fibrillation is sensed, an internal discharge of the device can be triggered.

3.2.3 Artificial Heart and Cardiac Assist Devices. It has always been clear to many researchers that many patients with heart disease could not always be aided by medication or surgical repair of their damaged hearts. The heart valves could be replaced with artificial devices but the heart muscle or myocardium was often so damaged that it required replacement or the patient would die. As a result, two separate avenues of research to the problem were begun.

First, research into cardiac transplantation was initiated. Kidney and cornea transplants from other humans had proven so successful that cardiac transplantation was studied. Although many problems such as rejection, donor organ procurement, and infection remain, considerable progress has been made and this approach has now become an accepted part of cardiac therapy.

The second area of research in the area of cardiac replacement was the development of the artificial heart. This effort was subdivided into two areas: the left ventricular assist device and total cardiac replacement (Bernard and LaFarge, 1969). Both approaches require close cooperation between the biomedical engineer and the surgeon. The relative successes that have been achieved to date are testament to the accomplishments possible from these joint ventures.

The first temporary use of a mechanical device to sustain life while the heart was unable to function was the pioneering effort of J. H. Gibbon, Jr. and C. W. Lillehei at the University of Minnesota (Allen and Lillehei, 1957). In 1953 their group began the use of the techniques of cardiopulmonary bypass, enabling the current practice of open-heart surgery to evolve. The device they developed consisted of a pump to maintain blood flow and an oxygenator to permit gas exchange when the heart and lungs were removed from the path of circulation.

The modern heart-lung machine typically consists of a double-roller pump which propels the blood forward by a squeezing action and either a bubble or membrane oxygenator. The roller pump is quite effective as a generator of flow, but prolonged use causes mechanical damage to the red blood cells (hemolysis). This damage can be tolerated for the short periods (several hours) which are typical in open-heart surgery but not for prolonged periods as the damaged red cells release hemoglobin into the bloodstream which eventually causes kidney failure. To permit support for longer periods of time, pumps that compress the blood between the walls of flexible chambers in a way similar to the natural process are more desirable. As new types of pumps are developed they are being utilized.

It is important to note that the materials in these devices are sensed as foreign to the body. While they are not rejected as unacceptable biological tissue (a problem that occurs in the case of heart transplants), the body does attempt to form clots on their surface. Such clotting is to be avoided since it could cause the mechanism to fail. Patients with these devices must therefore be given drugs called anticoagulants to prevent clotting, and the use of anticoagulants has to continue as long as the mechanical device is sustaining circulation. Care must be taken, however, to avoid overuse of anticoagulants since spontaneous bleeding in such vital organs as the brain or the gastrointestinal tract can take place.

Both the artificial heart and the left ventricular assist devices are extensions of earlier efforts to develop the heart-lung machine for open-heart surgery. In many patients, the left ventricle is damaged during an episode of coronary artery blockage. The left ventricle, which is the pump for the entire body, can be revascularized by coronary artery bypass, but often requires time to heal. As the body must be served by the ventricle immediately after surgery, there can be no rest period. What many patients require, therefore, is temporary assistance for the left ventricular function. The development of a left ventricular assist device (LVAD) was led by Dr. John C. Norman and colleagues (Norman and Huffman, 1974; Norman, 1975a, 1975b). Such assist devices are designed to provide partial or total support of the circulation.

The second and more highly publicized effort has been in the development and use of the *total artificial heart*. These devices are designed to replace completely the damaged heart and to support the circulation on a permanent basis. Unlike the LVAD where the patient's own heart can recover and the support device can be removed, the artificial heart is implanted in place of the patient's own heart, which is then discarded.

In 1963, the National Advisory Heart Council recommended giving priority to this type of research, as well as the necessary federal funding, focusing on such areas of research as biomaterials, pumping mechanisms, and control systems.

In 1969, sufficient progress had been made to permit Dr. Denton Cooley of the Texas Heart Institute in Houston to implant an artificial heart in a patient awaiting a heart transplantation whose own heart had failed. The device sustained the patient for 64 h until a suitable donor heart was found and the heart transplant took place. A similar type of temporary artificial heart was again used in a similar circumstance by Dr. Cooley in 1981 to sustain a patient for 54 h. In both these cases, the use of the artificial heart was described as temporary, i.e., providing assistance until a heart transplant could be performed. The work of Dr. William C. DeVries and Dr. Robert K. Jarvik, supported initially by Dr. W. J. Kolff at the University of Utah, and initially and subsequently by the Humana Heart Institute in Louisville, Kentucky, has led to the use of a *permanent artificial heart* to sustain a patient (DeVries *et al.*, 1984; DeVries, 1986).

On 2 December 1987 Dr. Barney Clark became the first legal recipient of a permanent artificial heart—the Jarvik-7—after the U.S. Food and Drug Administration approved the device in 1982 (Fig. 8). Dr. Clark suffered from cardiomyopathy, a disease that causes the heart muscle to deteriorate and has no known cure. He showed no chance of recovery through any heart surgery and was very close to death—conditions required by the FDA before approval to implant the artificial heart could be given. At 61, he was considered too old to receive a transplanted heart, even if a donor had been available.

The Federal Food and Drug Administration has given the University of Utah Medical Center permission to implant the Jarvik-7 heart and its driving system in seven patients. However, while the implantation of the Jarvik-7 heart continues, the design team of

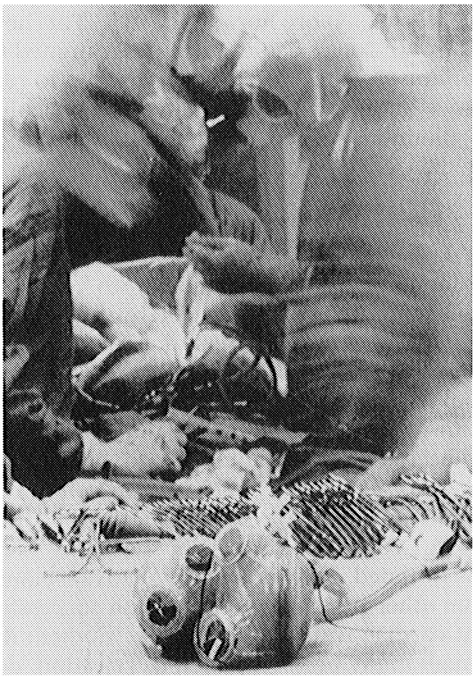


FIG. 8. The Jarvik heart being implanted.

Symbion, the firm in Salt Lake City headed by Dr. Robert Jarvik, works on the successor model, the Jarvik-8. The major problems of the Jarvik-7—clotting, size, durability, and "mass" production—are being addressed in the redesign.

Both the total artificial heart and the LVAD face similar engineering problems (Galioto, 1986). Materials for their construction must be durable as they are truly life sustaining. Their mechanisms must safely pump blood but should not damage the delicate cellular elements of the red blood cells. Blood can be protected by nonocclusive pumps and anticoagulants but the patient's own long-term responses to such devices must be borne in mind at all times. Most important, these devices should allow for a reasonable and tolerable lifestyle.

3.3 Biomaterials

The use of surgical implants and invasive medical therapies has expanded greatly in recent decades. Devices ranging in complexity from chronic infusion catheters and lens implants to total hip prostheses, to implantable pacemakers/defibrillators, heart-lung machines, and hemodialyzer systems are now routinely used. These devices are employed on a vast scale: tens to hundreds of thousands are used each year in the United States alone. On the medical horizon are numerous devices (such as the artificial heart discussed above) of increasing sophistication and complexity. Common to all these devices is the use of biomaterials.

What are these biomaterials and how do they differ from other engineering materials? They are metals, plastics, and ceramics, some of which are merely purified forms of industrial materials. Some are new formulations with specific properties found to be advantageous in medical applications. Others are surface modifications of, or bulk additives to, conventional materials. Still others are processed natural (biological) materials (Eberhart, 1989).

Research efforts in biomaterials include understanding the biological and physical properties of naturally occurring materials, such as bone, connective tissue, keratin, etc., and creating new artificial materials or generating "natural" materials with similar properties to their natural counterparts. Since biomaterials are used to replace or augment natural tissues, it is also important to understand and control the biology of the interface between artificial and natural biomaterials in the body.

There are three main classifications of artificial biomaterials: metals, ceramics, and polymers. Each class has specific properties that make it especially suitable for some function in the body, but in many cases it cannot perform today as well as its natural counterpart. It is hoped that through research, new and improved materials can be developed that meet or even exceed the capabilities of the natural substances (Neuman *et al.*, 1989).

3.3.1 Metals. A major component of bone and joint prostheses are metals, used because of their strength and ability to absorb energy before fracture. Table 2 presents properties of some commonly used biomaterial metals. Their major drawback, however, is associated with the propensity of the elements responsible for their resistance to corrosion (chromium, nickel, cobalt) to induce a cell-mediated hypersensitivity. Today, work is under way to utilize titanium-based alloys because there has yet to be any record of hypersensitivity response from these materials.

3.3.2 Ceramics. The class of materials called "ceramic" includes a variety of substances that are nonmetallic and inorganic in nature, and generally consist of clay or other silicates. Although ceramics are the oldest manmade materials and plaster of Paris ($CaSO_4$) has been used for casts in fracture immobilization for many years, the use of ceramics for biomedical applications only started in the mid-1960s (Saha, 1989).

Compared to the large number of different ceramic materials that are used for industrial purposes, only a few classes of these materials have been found suitable for implantation and clinical use, in spite of the fact that they are highly inert and elicit a minimum foreign-body reaction. These classes include

1. oxide ceramics and ceramics of calcium phosphate salts,
2. various types of glass or enamel, and
3. crystalline or glassy forms of carbon and its compounds (Heimke, 1986).

The oxide ceramics are known by the metals from which they are formed. Alumina

[a] From Tarjan and Gold (1988).

(Al_2O_3) is the most commonly used and most biocompatible ceramic material for orthopedic implants. Other oxides of calcium and phosphorus, such as hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] and hydroxylapatite [$Ca_4H(PO_4)_3OH$] have also been used. Among these, hydroxyapatite (HA) is of particular interest as its chemical composition is very similar to that of the mineral content of bone.

The glasses that have been studied for implantation are based on silica (SiO_2) and sometimes contain a small amount of other crystalline phases. Bioglass, developed by Hench and co-workers (1988), is perhaps the most common among these types of ceramics.

The carbons that are primarily used in prosthetic devices include low-temperature isotropic (LTI) pyrolitic carbon (Pyrolite), biotite carbon, and carbon or graphite fibers. LTI pyrolitic carbon has been used in the DeBakey heart valve since 1969 and has also been used to make coatings for other valves, vascular access devices, and dental implants. Carbon fibers are being used to replace or augment ligaments and tendons. Carbon-fiber-based composites are also being developed to manufacture orthopedic implants.

During the last twenty years, ceramics have also been used as a material for total joint-replacement implants as well as a coating on metal implants for improved biological fixation with the host bone (Christel, Meunier, and Lu, 1986).

Total joint replacement is one of the great orthopedic advances of this century. Sir John Charnley introduced the metal-on-plastic total hip replacement in the mid-1950s, and since then this orthopedic procedure has revolutionized the treatment of painful arthritic hip disorders. This procedure is highly successful with rates of success between 80% and 98%, depending upon the type of implant, surgical technique, patient selection, and, particularly, follow-up time. In long-term follow-up studies, it has been found that aseptic loosening is the significant cause of failure of total hip replacement. This failure rate is estimated to be 7%–24% for a 5–10 yr follow-up (Russotti, Coventry, and Stouffer, 1988). The enormity of the problem is evident from the fact that in the United States alone, over 120 000 total hip replacement arthroplasties are performed each year. Worldwide, over 2.5 million people are estimated to have artificial hip joints.

To improve the long-term results of total hip replacement (THR), a large number of new prosthesis designs have been proposed. These include use of a low-modulus metal such as titanium alloy to reduce the stress shearing effect on bone. Ceramics have also been used to make the whole or parts of a THR and in coating on metal implants to obtain a chemical bond between the implant and surrounding bone.

In the future, it is anticipated that ceramics will become a major component for hermetic sealing of implantable microelectronic devices and sensors because of a combination of their properties. Of major importance is their transparency to electromagnetic radiation, as well as their impermeability to water. It has been suggested that sealing processes using laser technology will solve the problem of packaging implantable electronic devices without damage and that modification of the surface charge on such ceramic packages will help to control their thrombogenicity, thus allowing their use in packages for sensing applications in blood.

3.3.3 Polymers. Polyurethanes are generally formed by the addition of a polyglycol to an isocyanate. Typically, the isocyanate is part of an aromatic molecule that gives rigidity or hardness to this portion of the polymer chain, while the polyglycol is the part of an aliphatic molecule that produces a less rigid or soft portion of the polymer chain. Most polyurethanes, therefore, have hard and soft segments and are called segmented polyurethanes (McMillin, 1989).

Polyurethanes can be readily tailored for many biomedical applications by either changing the chemical used in any of the components or by changing the length of the prepolymer or extended chains of the polyurethane. Thus, polyurethanes are in themselves a wide class of materials. Ether-based polyurethanes are known to be less susceptible to hydrolytic cleavage than ester-based polyurethanes and have therefore been used for most biomedical applications. Polyurethanes are usually strong, flexible, transparent, or translucent, tissue compatible, and reasonably blood compatible, and are used for a variety of applications requiring these properties, such as peristaltic pump tubing, parenteral solution tubing, balloon pumps, and catheters.

Much of the research on biomedical polyurethanes focuses on a relatively few commercial polymers. For competitive reasons, the chemical composition of these polyurethanes are sometimes trade secrets. The known compositions of some urethanes are shown in Table 3.

Polymers of biological origin such as collagen and elastin appear to be a logical solution for implant applications. The major problem is how to remove their antigenic properties while maintaining their desirable properties. It is important to make progress in using materials of biological origin as scaffolds for the reconstruction of certain tissues. Probably the major advance in this area will be in the use of synthetic polymers as scaffolding structures that will degrade, and therefore be repopulated by body cells, to construct the appropriate collagen network to give structural integrity to the system as a whole.

A major limitation in the use of synthetic polymers as biological materials is their tendency to fatigue. More fatigue-resistant polymers with isotropic mechanical properties need to be developed. These materials are needed as the basis of the diaphragms for pumps in total artificial heart and heart assist systems, as well as polymeric valves that will replace the artificial heart valves used today.

3.4 Rehabilitation Engineering and Prosthetic Devices

Engineering devices have been applied to helping disabled individuals return to more useful lives. The design of prosthetic devices and artificial organs frequently involves mechanical principles, and therefore these areas lie partly in the province of biomechanics.

Biomechanics has traditionally been concerned with the analysis of macroscopic biological structures such as bones, blood vessels, other soft tissues, and blood and other biological fluids. In the past, computer modeling techniques have been applied to help understand not only normal function but also the pathophysiology of various diseases and conditions. For example, computer simulations have provided great insights into the mechanics of lifting as it applies to lower back pain, optimization of athletic performance, mechanics of bone healing, and transport processes in various organ systems. Biomechanics has also led to the development of procedures in diagnostic medicine, such as gait analysis, and the design of various prosthetic devices ranging from joint replacements to artificial organs. This field has contributed to the design and optimization of

man-machine interfaces, such as improved sports equipment, safety of automobiles and aircraft, and specialized equipment for space exploration.

As physiologists and other biological scientists increasingly turn their attention to studies at the cellular and molecular levels, it becomes clear that mechanics has important applications in these areas as well. Atherosclerosis remains a major clinical problem, and only preliminary exploration of the effects of blood fluid mechanics on endothelial cells has been done. Other cellular and molecular aspects of biomechanics remain relatively unexplored. There are many phenomena at the microscopic level in which mechanics is likely to play a role. Among these are

1. atrophy and hypertrophy of muscle,
2. regulation of blood pressure,
3. the origin of atherosclerosis,
4. microscopic processes in bone healing, and
5. bone remodeling and osteoporosis.

The roots of rehabilitation originate in the historical use of prosthetic devices (wooden limb substitutes) and orthotic devices (crutch-like aids) (see PROSTHETICS AND ARTIFICIAL ORGANS). In modern times, visual orthoses (eyeglasses) have become ubiquitous. Technological advances in medical treatment were developed during World War II at the same time as technological applications to weaponry leaped forward. Thus, society believed that the people maimed by the war and saved by medicine had to be helped to lead fuller lives.

After the war, the Veterans Administration (VA) was founded and began to apply engineering solutions to some of the physically disabling problems which patients in VA hospitals presented—principally in the areas of wheelchair development and prosthetic limbs. Around 1970, several *Rehabilitative Engineering Centers* were funded by the U.S. government to increase the application of engineering techniques in the solution of problems related to rehabilitation. However, it was not until about 1980 that the idea developed, in major centers of rehabilitation, that engineers could be useful in direct service to patients along with the more usual deliverers of patient care.

Recently, the idea that people with technical training in engineering can help in the patient care process has spread outside of the major rehabilitation hospitals to smaller hospitals with rehabilitation departments. The Rehabilitative Engineer, trained in engineering and biology, has a capacity to act as the interface between the patient, the rehabilitative team, and technology.

Although many orthotic and prosthetic devices have been developed to help individuals regain some form of functionality, many opportunities remain for future research. In the future, rehabilitation research will probably be more in the direction of utilizing existing but nonfunctional biological structures, such as a paralyzed limb, to regain function rather than by employing external orthoses. Functional electrical stimulation of intact nerves and muscles will allow patients to control contraction of paralyzed muscles. To control such motor prostheses effectively, it will be necessary to obtain a better understanding of the body's natural control systems and to determine what constitutes minimal processing to regain particular functions. Sensory input to such systems will be important, and research into making use of intact but disconnected natural sensors, as well as the development of implantable artificial sensors, will continue to be important research areas.

The computer has already played an important role in helping individuals with disabilities to be viably employed and to perform tasks that were once thought to be impossible. The interface between the patient and the computer, however, still remains crude. Research is needed to develop more effective interfaces, as well as processing algorithms for these interfaces. Advances in the neural sciences should help to establish connections between a patient's nervous system and external electronic devices. By understanding natural signal processing in the nervous system, it should be possible for computers to emulate this human function and to control both internal body structures and external devices.

3.5 Instrumentation and Sensors

Instrumentation is involved throughout the field of biomedical engineering. This certainly becomes clear when one reviews the number and diversity of biomedical quantities measured by biomedical instruments in Table 4. In practice, however, the transducers which convert signals in one form of energy into signals in another form of energy are incorporated in an instrumentation package or system. The most general instrumentation system then consists of the transducer or biosensor, a signal processing component which amplifies and filters the signal and performs some preprocessing to permit the measured quantity to be stored, to be displayed, to activate some device, or to be processed further.

The biosensor, therefore, serves as the interface between the biological system being measured and the electronic system of the in-

Table 4. Biomedical electronic measurements.[a]

Measured quantity	Principle or devices used	Biomedical applications
	A. Physical parameters	
Electrical potential	Voltage	Nerve and muscle activity, ECG, EEG, EMG, EOG, etc.
Impedance	*Z* bridge	Skin condition, respiration rate, peripheral blood flow
Temperature	Thermistor, *p-n* junction, infrared	Inflammation, cancer location, blocked circulation
Sound	Microphones	Heart and breathing sounds, blood pressure measurement, fluid flow
Light	Transmission, refraction, absorption	Physiology research, clinical laboratory, gas and ion sensors
Magnet	Permeability, field	Blood flow, heart activity, proximity
Force and pressure	Piezoresistance, capacitance deformation	Pressure of blood, CSF, urine, etc.; locomotion
Displacement, velocity, acceleration	Capacitive, magnetic, laser, ultrasound, acceleration force	Body movement, physiology research, orthopedics
Flow: blood, fluid, air	Electromagnetic, optical ultrasonic Doppler, pressure drop, streaming potential	Blood, air, body fluid; heart, lung, kidney function
Volume	Displaced volume, dye dilution	Physiology research, cardiac output
Time	Delay, response time	Alertness, nerve signal transmission, signal transmission in heart and other organs
	B. Chemical parameters	
Gas concentration	Gas-sensitive electrodes, chromatography, chemical analysis	Blood gas (H^+, O_2, CO_2, O_2 saturation), respiration, perfusion, anesthesia, hospital operations, clinical laboratory
Humidity	Dew-point temperature, resistance and capacitance change due to condensation or absorption	Pediatric, respiratory research, intensive care
Ions	Ion-selective electrodes, ISFET, chemical analysis	Clinical laboratory, intensive care unit, acid-base balance
Biomolecules	Enzyme electrodes, chemical analysis	Clinical laboratory, research laboratory, patient monitoring

---

[a] Modified from Ko (1988).

strumentation. Work during this century has been devoted to developing new types of sensors of physical and chemical variables and incorporating these sensors into instrumentation systems. The application of technologies such as microelectronics and optoelectronics to biomedical sensor problems has shown that imaginative solutions are possible. For example, a few years ago transducers for measuring biomedical pressures were based on handmade, unbonded strain gauge technology. These devices were expensive and had to be individually calibrated for the electronic system with which they were used. Today, semiconductor electronics allows mass produced biomedical pressure transducers to be sold at less than 5% of the price of the earlier devices. This makes it possible to have disposable pressure sensors for clinical applications at a cost that would have been impossible in the past (Neuman *et al.*, 1989).

Future research in sensors will certainly follow corresponding improvements in technology, as well as the feasibility of developing bioanalytical sensors for complex biochemical substances that are found in the body in only very small concentrations. Substances such as neurotransmitters, tumor markers, and local and systemic hormones are important analytes for future biomedical sensors. The availability of such sensors would make it possible to measure these biochemicals directly and continuously within the body itself.

It is important to note that creative ways to present and summarize large amounts of patient-related data for busy physicians and nurses need to be incorporated into modern instrumentation systems. Furthermore, providing instrumentation packages to monitor patients in their homes will become more and more important as health care becomes decentralized and the need for larger data samples becomes important. Coupled with these efforts is the need to develop communication systems to tie such monitoring devices into central facilities.

3.6 Medical Imaging Technology

Developing noninvasive tools that can "look into" the human body while posing minimal risks for the patient has been given an extremely high priority in the post 19th century scientific era of medical research and practice (see IMAGING TECHNIQUES, BIOMEDICAL). Diagnostic and therapeutic techniques that remove the need for invasive (surgical) exploration often both reduce patient risk and lower the costs of health care. However, until recently the health care profession "black bag" has contained only a relatively small number of noninvasive diagnostic tools that provided images of the body. None were available until the end of the 19th century.

We now know that x rays

1. are part of the electromagnetic spectrum, that have relatively short wavelengths,
2. are generated by collision of atomic particles,
3. travel in straight lines in all directions from the point of origin, and
4. are capable of penetrating many forms of matter opaque to ordinary light.

Therefore, the classical medical imaging technique, radiology, uses high-energy electromagnetic waves or x rays as a tool to "look" into the patient to view certain anatomical structures. During the early part of the 20th century additional improvements in the field of radiography involved advances in technology related to particular components of the system including intensifying screens and rotating anode tubes.

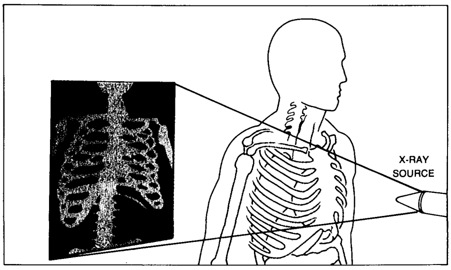
It is interesting to note that after 1930, profound improvements in radiology were achieved by developing procedures for selectively opacifying regions of interest in the body. These developments were achieved through a variety of approaches, such as the injection of dyes, often invasive to the body, to facilitate visual representation of otherwise invisible organs.

Since 1960, through the marriage of computers and sophisticated imaging processing techniques, medical imagery has been able to pursue totally new directions. Images of the internal structures of the body are now created that are often of startling clarity, significantly enhancing the ability of the clinician to arrive at an appropriate diagnosis.

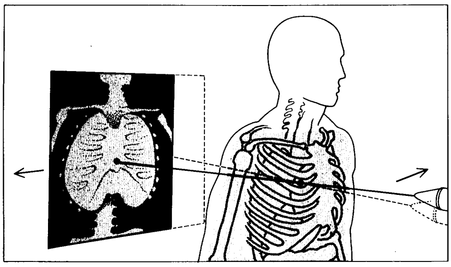
Although modern medical imaging takes many forms, systems of most practical interest today include the following: nuclear medicine, diagnostic ultrasound, computerized tomography, and magnetic-resonance imaging. These imaging devices enable doctors to avoid exploratory surgery and still watch vital organs at work, identify blockages and growths, and detect the warning signs of possible future disorders. Since these techniques, for the most part, do not involve penetrating the skin, they have been classified as noninvasive. However, patients may face other consequences of their use (e.g., the possible destruction of body tissue caused by the radioactive materials used in nuclear medicine, or the increase in tissue temperature as a result of high-frequency ultrasound). Bearing this in mind, it may be more precise to consider the relative degree of direct surgical intervention that certain devices entail. Thus the term noninvasive will be used here to refer only to specific techniques developed in radiology, nuclear medicine, and ultrasound.

Major advances in medical diagnostic procedures were made during the 1980s that greatly enhanced image quality and expanded the types of tissues that could be visualized with good resolution. Even with this advanced technology and the integration of computer and image processing techniques into medical imaging devices, problems and opportunities remain for biomedical engineering researchers. These include instrumentation not only for visualizing internal structures but for assessing their function.

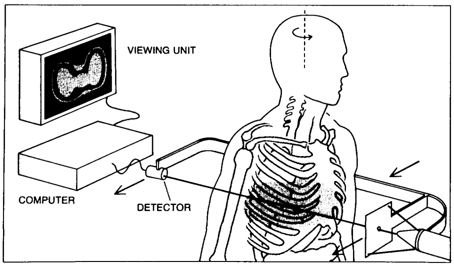
3.6.1 Radiography. Radiography, the classical medical imaging technique routinely applied to nearly all hospitalized patients whether or not there is a direct need, uses high-energy electromagnetic waves or photons (x rays), as a tool to "look" through the patient to obtain information on anatomical structures (Fig. 9). The propagation of x rays, characterized by wavelengths that are shorter than the atomic diameters of the penetrated matter, is dominated by corpuscular ray properties rather than by the wave character of light. The velocity of propagation is essentially constant for all kinds of biological tissue; thus the refractive index of all such structures is unity. As a consequence, the only mechanisms of interaction are absorption and scattering; no reflection or diffraction takes place. So, unlike ultrasonic waves, x rays travel in straight lines through the body, unaffected by tissue interfaces, and provide undistorted images of high resolution (see BIOMEDICAL USES OF RADIATION).



CONVENTIONAL X-RAY PICTURE is made by allowing the X rays to diverge from a source, pass through the body of the subject and then fall on a sheet of photographic film.



TOMOGRAM is made by having the X-ray source move in one direction during the exposure and film in the other direction. In projected image only one plane in body remains stationary with respect to moving film. In the picture all other planes in body are blurred.



RECONSTRUCTION FROM PROJECTIONS is made by mounting the X-ray source and an X-ray detector on a yoke and moving them past the body. The yoke is also rotated through a series of angles around the body. Data recorded by detector are processed by a special computer algorithm, or program. Computer generates picture on a cathode-ray screen.

FIG. 9. Image reconstruction from x-ray projections.

The term radiography is sometimes misleading because it applies to various x-ray techniques. Its original definition referred only to the recording of x-ray projection images on photographic film. Use of a fluoroscopic screen as the x-ray detector (instead of film), called fluoroscopy, provided the ability for continuous x-ray monitoring. The use of TV systems for electronically monitoring the fluoroscopic screen is called x-ray television. Because all of these systems, including film recording, use fluoroscopic screens as image converters, and all of them are based on the same physical principle of imaging (i.e., the projection of body absorption onto a single plane), the terminology is illogical and arbitrary. So, with the development of an imaging principle called computed tomography (CT) (Ledley, 1976), a renaming took place, in which all possible imaging techniques using x rays are called radiography (Nagel, 1988).

Since its introduction, computed tomography has undergone continuous refinement and development. Significant improvements have been made in

1. x-ray tube performance,
2. reduction of scan times,
3. reduction of image reconstruction time,
4. reduction and, in some cases, elimination of image artifacts,
5. reduction of patient dose.

Present CT scanners are usually integrated units consisting of three major elements (Fig. 10):

1. *the scanning gantry*, which takes the readings in a suitable form and quantity for a picture to be reconstructed;
2. *the data handling unit*, which converts these readings into intelligible picture information, presents this picture information in a visual format, and provides various manipulative aids to enhance the image and thereby assist the doctor in forming a diagnosis, and
3. *a storage facility*, which enables the information to be examined or reexamined at any time subsequent to the actual scan (Walmsley, 1979).

The objective of the scanning system is to obtain enough information to reconstruct an image of the cross section of interest. All the information obtained must be relevant and accurate, and there must be enough independent readings to reconstruct a picture with sufficient spatial resolution and density discrimination to permit an accurate diagnosis. The operation of the scanning system is therefore extremely important.

During the past decade, the CT scanner has undergone several design changes. The earliest generation of gantries used a system known as "traverse and index." In these systems, the tube and detector were mounted on a frame and a single beam of x rays traversed the slice linearly, thereby providing absorption measurements along one profile. At the end of the traverse, the frame indexed through 1° and the traverse was repeated. This procedure continued until 180 single traverses were made and 180 profiles were measured. Using the "traverse and index" approach, the entire scanning procedure took approximately 4–5 min. The images it provided had excellent picture quality and hence high diagnostic utility. However, this approach had several disadvantages. First of all it was relatively slow, resulting in relatively low patient throughput. Second, streak arti-

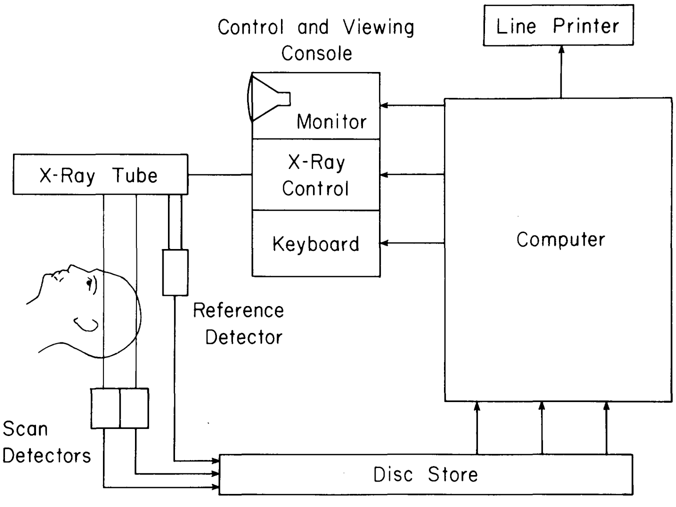


FIG. 10. Basic components of a CT scanner.

facts, i.e., lines in the image, were common, and although these artifacts normally were not diagnostically confusing, the image quality did suffer. Finally, perhaps the biggest drawback was that since the patient had to remain absolutely still during the scan, its use was restricted solely to brain scans.

In an attempt to solve these problems, several generations of gantries have evolved over the past 15 years (Fig. 11). Initially new scanning procedures included a translation step as in the first generation but permitted the scanning gantry to go around the patient (180°) in 10° steps. With use of this 10° fan beam, it is possible to obtain a full set of 180° profiles by making only 18 traverses. At the rate of approximately 1 s for each traverse, scanning systems of this type usually operate in the range of 18–20 s while still retaining picture quality.

However, very shortly a major redesign ensued and a third generation of gantries evolved consisting of a pure *rotational system.* In these systems the source/detector unit, with a pulsing, highly collimated wide-angle (typically 20°–50°) fan beam and a multiple detector array, is rotated 360° around the patient. This single 360° smoothly rotating movement decreases scan time to approximately 3 s, increases appreciably the reliability of the data since it is taken twice, and increases the quality of the reconstructed image. A by-product of this design is that the pulsing x-ray source can be synchronized with physiological parameters enabling

rhythmically moving structures, such as the heart, to be accurately imaged.

The main advantages of this type of system are its simplicity and its speed; however, its fixed geometry system with a fan beam, usually established for the largest patient, makes it inefficient for smaller objects, in particular head scanning. Consequently a fourth generation gantry system consisting of a continuous ring of fixed detectors (usually numbering between 500 and 700) was developed. In this system the x-ray source rotates as before, but the detectors remain stationary, arranged in a full circle around the gantry. The fan beam is increased slightly so that the detectors on the leading and trailing edge of the fan can be continuously monitored and thereby adjust the data in case of shifts in detector performance (Maravilla and Pastel, 1978).

Recently the bulky, noisy electromechanical rotation mechanism has been eliminated and, in its place, a magnetic induction system is employed to rotate the source. This has enabled designers to attain a long sought goal: the 1-s scan.

The whole purpose of the scanning procedure is to take thousands of accurate absorption measurements through the body. Taken at all angles through the cross section of interest, these measurements provide an enormous amount of information about the composition of the section of the body being scanned.

In conjunction with the operation of the scanning and detection system, the data obtained must be processed rapidly to permit producing and viewing an image or scan as quickly as possible. The first stage of this computation process is to analyze all of this raw data and convert it into the set of profiles, normally 180 or more, and then convert these profiles into information which can be displayed as a picture and used for diagnosis. Here we have the heart of the operation of a CT scanner, that element which makes CT totally different from conventional x-ray techniques and most other imaging techniques. The algorithms or computer programs for reconstructing tissue x-ray absorption presently fall into one of the following categories: simple back projection (sometimes called summation), Fourier transforms, integral equations, and series expansions. The choice of an algorithm for a CT scanner depends upon its speed and accuracy (Nagel, 1988).

To facilitate the utilization of these computational processes significant advances had been made in the development of data acquisition and conversion systems by the late 1970s. One of the most important of these developments was the design of the array processor which has become an integral part of the data acquisition and conversion systems used in the most recent CT systems.

Once the image is displayed and initially reviewed, it is often important that this information be retained. Consequently, present CT systems have a variety of storage media such as floppy disks or magnetic tape available. The type of storage facility employed depends to a large extent on the length of time the information is required to be held.

The availability of various storage media, therefore, provides a means of recording, storing, and viewing patient scans independently of the scanning system's operational viewing unit. Consequently, health professionals are provided with around-the-clock access to existing patient scans, irrespective of the in-use status of the basic scanner. With present CT systems, patient records can be stored on floppy disks or magnetic tape in less than 1 min. These magnetic storage devices can serve as a means of permanent storage of patients' records or may be erased and then used again.

Although there have been technological improvements of methods for generating x rays during this century, for the most part medical x-ray sources are basically the same today as they were in the early years. There is a need to develop new methods of generating x rays, including tunable, steerable, and coherent beams. Improved detectors are also needed. Photographic film will no longer be used for detection and archiving in medical imaging systems of the next century. High-resolution, two-dimensional detectors with high sensitivity and capable of rapid sequence imaging and energy resolution are needed. New methods of practical and efficient picture archiving, image communication, and three-dimensional image display will also be important areas for significant work to be done.

3.6.2 Nuclear Medicine. Nuclear medicine has been defined as the application of radioactive materials (tracers) to medical diagnosis and treatment (see NUCLEAR MEDICINE). It is a classic example of a medical discipline that has embraced and utilized concepts developed in the physical sciences. Conceived as a "joint venture" between the clinician and physical scientist, nuclear medicine has evolved into a science with its own body of knowledge and techniques. In the process, the domain of nuclear medicine has grown to include studies pertaining to

1. the creation and proper utilization of radioactive tracers (or radiopharmaceuticals),
2. the design and application of appropriate nuclear instrumentation to detect and display the activity of these radioactive elements, and
3. the determination of the relationship between the activity of the radioactive tracer and specific physiological processes (Wagner, 1975).

The gamma camera system, one of the most basic instruments for diagnostic nuclear medicine (Spencer and Hosain, 1986), converts the radioactive emissions into an image (Fig. 12). Interfacing this device with a digital computer enables clinicians to perform data collection, storage, and analyses.

The gamma camera systems are large and heavy and cannot be moved easily. They are regarded as stationary cameras. However, relatively mobile versions are available with computer interface especially for cardiac studies. Gamma cameras often have capabilities for obtaining whole-body images by linearly moving the camera head or the patient bed. Often called scanning cameras, they have replaced rectilinear scanner systems. A major innovation in gamma camera design has been the addition of an extra camera head with rotational capabilities which is used with a computer system known as single-photon-emission computed tomography (SPECT) for carrying out optional tomographic work. The technique is known as computer-assisted reconstruction tomography (CT) scanning. Tomograms represent the images of isolated cross-sectional slices of the body. They facilitate identification of abnormalities that are otherwise difficult or impossible to identify in a two-dimensional image covering overlying and underlying tissues (Spencer and Hosain, 1986).

With the discovery of artificial radionuclides, the "modern era" of nuclear medicine began. The availability of these radioactive elements increasingly encouraged pioneers in this discipline to employ radioactive tracer techniques to gain information regarding biological and physiological systems. One of the first physiological systems to be studied in both animal and man was the metabolism of phosphorus. Using the cyclotron-produced tracer ^{32}P, several investigators observed the

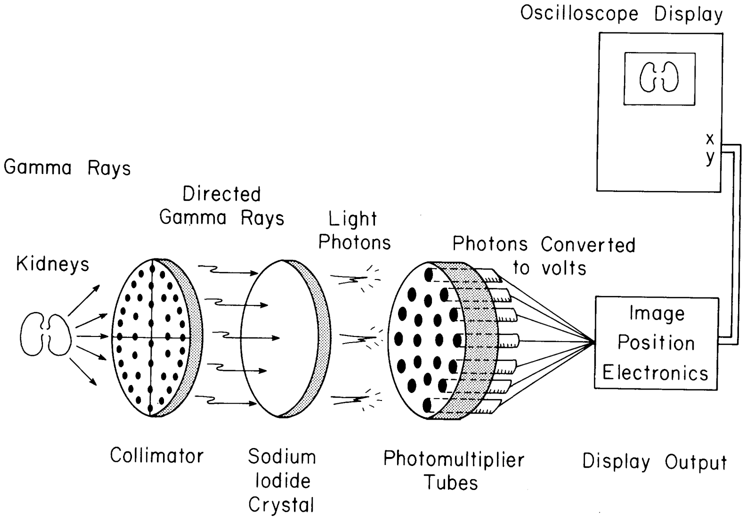

FIG. 12. Basic steps in obtaining an image in nuclear medicine.

great efficiency with which the body absorbed inorganic phosphorus and preferentially utilized it in rapidly multiplying tissues, such as those associated with malignancies. In 1936, John Lawrence, recognizing the therapeutic implications of these findings, acted. He used ^{32}P in the treatment of leukemia, and in the process inaugurated the therapeutic employment of artificial radionuclides (Wagner, 1975).

Although the early uses of radioactive materials in medicine were chiefly in radiation therapy, today most radioactive materials are used to provide useful diagnostic information. These radionuclides can be monitored within the patient (*in vivo*) or in various bodily fluids removed from the patient (*in vitro*). For example, it is possible to inject a patient with a radioactive substance that is "taken up" by a particular organ such as the kidney. By placing a detector over the kidneys, the amount of radioactive material accumulated by the kidney can actually be measured. This uptake test allows the clinician to monitor the activity of specific organs and determine whether they are functioning properly. Another example of an *in vivo* study involves imaging the distribution of a radionuclide within an organ. This can be very important, especially since it has been demonstrated that abnormal tissue tends to accumulate more or less of the radionuclide administered than the normal tissue surrounding it. In this way, *in vivo* measurement can help the clinician delineate the presence of these tissue abnormalities.

The *in vitro* category, on the other hand, includes tests made outside the body. These tests are used to study various chemical, as well as physiological, processes. Today, *in vitro* tests are capable of detecting extremely small amounts of various hormones and chemicals in the blood and have been used to determine

1. insulin dosage in diabetics,
2. whether individuals are immune to specific diseases such as hepatitis, and even
3. the proper dosage of digitalis required by cardiac patients.

Recent developments in this area have indicated that this is an area of application that will continue to grow in importance over the next decade.

The major thrust of the current application in nuclear medicine lies primarily in the use of radioactive tracers in both *in vivo* and *in vitro* studies to evaluate various physiological systems within a patient. The key to success in this application is the specificity of the radioactive material utilized (Bronzino, 1977). That is, the more closely the radionuclide can be tied to a specific function, then the easier it is to examine the dynamic physiological system under study. Clearly, it is beyond the scope of this text to provide a complete outline of all the possible applications presently being utilized. However, some of the most common clinical applications of nuclear technology in studying major organs are summarized in Table 5. Obviously, these applications are only representative of the type of information available using nuclear instrumentation techniques.

Although the initial notion of developing radioactive "magic bullets" capable of seeking out and destroying diseased tissue in the human body has not been realized, it is increasingly evident that the techniques embodied in current nuclear medicine (NM) clearly allow the acquisition of quantitative information not available by other means (Spencer and Hosain, 1986). The utilization of radionuclides makes possible the measurement and visualization of the regional function. As a result, it is possible to use nuclear technology to determine both the site and activity (rate of change) of essential biological processes, thereby permitting abnormalities, i.e., regions of dysfunction, to be detected.

Since most physiological processes within the body are usually in a dynamic state insofar as they exhibit continual change, radioactive tracer techniques have enabled the clinician to monitor accurately the activity of a variety of different physiological systems. These systems range from the pulmonary and cardiovascular systems, to renal function, to the microvascular circulation of the eye. Today, several of these procedures are widely used in clinical medicine, whereas others are conducted only in research laboratories. As has been the case in other fields of medicine, procedures that are presently being viewed as "ancillary" may become an essential part of the routine medical examination conducted in the future.

Although NM will continue to be an important imaging modality, improved radiation

Table 5. Clinical application of nuclear medicine imaging technology.

1. Brain scanning
   a. Detection of intracerebral-space-occupying disease: primary or secondary neoplasms, abscesses, arteriovenous malformations
   b. Evaluation of cerebrovascular disease
   c. Detection and localization of intracranial injury after trauma
2. Lung scanning
   a. Diagnosis and management of pulmonary embolism
   b. Evaluation of regional function in emphysema and other forms of chronic obstructive lung disease
   c. Evaluation of pulmonary venous hypertension
3. Thyroid scanning
   a. Evaluation of thyroid size, position, and function
   b. Functional assessment of thyroid nodules
   c. Diagnosis of functioning metastatic lesions in patients with known carcinoma
4. Liver scanning
   a. Evaluation of liver size, configuration, and position
   b. Preoperative search for metastatic disease when a primary neoplasm exists elsewhere
   c. Functional evaluation of cirrhosis and other diffuse parenchymal processes
5. Spleen scanning
   a. Evaluation of spleen size, shape, and position
   b. Evaluation of spleen function
   c. Detection of intrasplenic-space-occupying disease
6. Pancreas scanning
   a. Carcinoma of the pancreas
   b. Pancreatitis
   c. Miscellaneous pancreatic problems such as pseudocysts

sources and detectors with higher resolution need to be developed. The development of nuclear probes for use in the operating room during surgery would also be of extreme assistance to the surgeon to visualize structures during complex operations.

3.6.3 Ultrasonic Imaging. The application of ultrasound as a noninvasive diagnostic tool is presently widely accepted within the medical community (see IMAGING TECHNIQUES, BIOMEDICAL). As a matter of fact, diagnostic ultrasound studies are often the method of choice because they provide information otherwise not available. The term ultrasound is used to describe sound waves (mechanical vibrations) that are beyond the range of human hearing, that is, above 20 000 Hz. Since sound waves of any frequency are essentially vibratory phenomena, their transmission from one point to another requires the presence of matter. As a result, substances best suited for transmission of sound waves are those with a significant number of molecules. Consequently, solids are better transmitters of sound waves than gases, in which there are fewer molecules. In a vacuum where there are no molecules present, the conduction of sound waves becomes impossible.

Since the composition of each substance varies, these ultrasonic or high-frequency sound waves travel through each of them at different velocities. Thus it is possible to investigate the internal composition of many materials simply by studying the transmission of ultrasound through them. In addition, just as audible sound under correct conditions produces echoes that can be heard, ultrasound, also under the correct conditions, produces echoes that can be detected with appropriate instruments, and then processed and displayed. The application of these basic concepts of ultrasound transmission and echo-ranging led to the development of nondestructive testing techniques in industry and eventually to the utilization of ultrasonic techniques in the conduction of noninvasive testing in medicine today. However, although the discovery of ultrasound preceded the discovery of x rays by 12 years, x rays found almost immediate clinical application, while the use of ultrasound did not become widespread until much later. The primary reason for this delay is that the application of ultrasound had to await the development of appropriate technologies to detect the presence of echoes and display the information in a meaningful manner.

Real-time ultrasonic examinations are being used diagnostically to characterize normal and abnormal anatomical structures accurately in many areas of the body (Peura, 1986). Ultrasonic images of the fetus, for example, are especially useful in fetal examinations since there is no electromagnetic radiation danger, and they can be used to guide a needle to harvest ovary material for pathological tests. Today, it is estimated that from one-half to two-thirds of the pregnant women in the United States have at least one fetal ultrasound scan, while in Great Britain and Germany fetal examination by ultrasound is required by law.

Fetal ultrasound scans are used to view the fetus and to determine whether the fetus is normal. Fetal anatomical features including the width of the fetal head, size of brain ventricles to monitor possible hydrocephalus, crown-to-rump length to determine the age of the fetus, spinal examination to check for abnormalities, the femur length to correlate with biparietal diameter to assess proper physical development of the fetus, and detectable fetal anomalies can be determined.

Real-time ultrasound has been used to perform interventional therapeutic techniques on the fetus *in utero.* Fetal transfusions have been performed using real-time ultrasonic visualization. Also, ultrasonic guidance has been used to drain hydrocephalus, posterior urethral valves, and chylothorax *in utero.*

The introduction of ultrasonic examinations of the heart (Fig. 13) has had great impact on the field of cardiology since the present real-time two-dimensional ultrasound images or echocardiograms provide an almost unlimited number of cross-sectional image planes. Furthermore, using real-time scanners, additional spatial resolutions of the valve morphology as well as the cardiac chambers is now possible. The recent addition of Doppler flow measurements to echocardiography imaging also holds great promise for the future, since the cardiologist will be able not only to visualize the movement of cardiac structures but also to measure the blood-flow velocity in the heart chambers and great vessels as well.

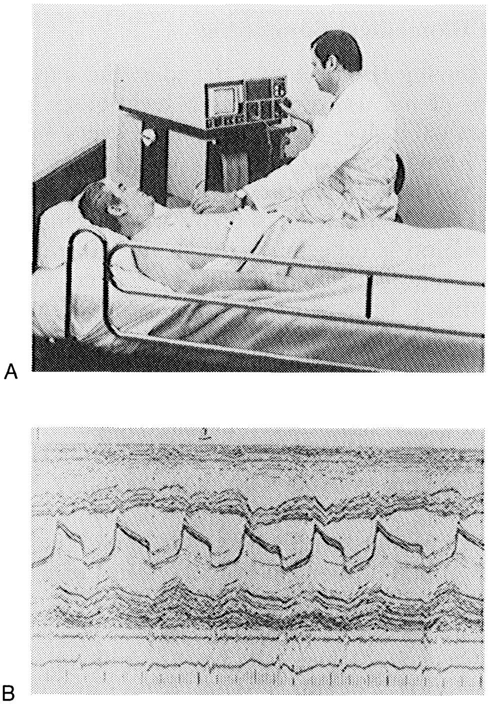

FIG. 13. (A) Diagnostic ultrasound being used to assess cardiac function. (B) Once trained, the physician can interpret the ultrasonic images shown here to detect the presence of any abnormalities. (Courtesy of Pecker Corporation, Cleveland, OH.)

Superficial structures, located less than 5 cm from the skin surface, can also be imaged in real time using ultrasound techniques. Since depth penetration is not a requirement, high-frequency transducers with resultant submillimeter anatomic resolution are used, thereby permitting very small lesions (2–3 mm) to be observed. Superficial anatomical structures which can be imaged include the thyroid, carotid arteries, eye, scrotum, breast, and subcutaneous tissue.

Ultrasonic examinations of the eye are important especially when an ophthalmologist cannot visually examine the eye (in situations in which opaque material such as blood is present or when the patient has cataracts). It would be unfortunate to have a situation in which a cataract was removed only to find that the patient had a retinal detachment or a large melanoma. The major application of ultrasonic examinations of the eye is in the evaluation of nonmetallic foreign bodies, retinal detachment, and intraocular tumors. The availability of high-frequency transducers makes evaluating the eye for periorbital and intraorbital disorders possible.

The future of the medical applications of diagnostic ultrasound is tied to the progress of electronic and computer technology. As electronic and computer circuits become more powerful for the same hardware volume and cost, more sophisticated ultrasonic imagers will be developed and new medical applications will be found. Furthermore, the future of diagnostic ultrasonic applications in medicine is contingent on the development of improved digital processing of the ultrasonic data. New image processing algorithms will handle and quantify the large amounts of ultrasonic data. In present-day systems, once the data are stored in relatively inexpensive digital memory devices, they can be manipulated to improve the image quality and to make simple calculations of tissue dimensions. Further work remains in terms of improving the image quality, extracting information about the nature of the tissue, and making accurate calculations of tissue dimension, including volumes, from three-dimensional measurements.

Perhaps one of the most exciting and challenging areas of ultrasonic imaging deals with tissue characterization. Wells (1977) reviewed the early work in this area and indicated that the ultrasonic signal (or signature) can distinguish between normal or abnormal tissue. A number of ultrasound parameters have been investigated, including attenuation, scattering, and velocity of propagation. These parameters now need to be tested to determine, e.g., from an appropriate ultrasonic scan of the heart, whether a myocardial infarction has taken place, and if so, how severe it was. Similar questions need to be posed for benign and cancerous tissue.

Another area of future development deals with the development of specialized transducers that would be placed inside the body for better imaging of a specific organ. For instance, approximately 30% of all men aged 50 or over have prostate cancer. It has been proposed that a high-resolution ultrasonic transducer operating at 10 MHz, when placed in the rectum, could provide high-resolution ultrasound images of prostate cancer. This should give more definitive results than those available with the normal digital examination for prostate cancer.

3.6.4 Magnetic Resonance Imaging. Tissue variations can be measured by methods other than those using x rays. For example, protons, neutrons, high-frequency sound waves, or nuclear magnetic resonance can also be employed. Each of these energy-containing sources can be used to generate sets of measurements or projections at different angles across the body, and, in a similar manner, a picture can be reconstructed from them.

In recent years, attention has focused on body-scanning devices capable of providing information on specific chemicals as well as structural information about soft tissues. Employing magnetic resonance imaging (*q.v.*) (MRI) techniques instead of x-ray radiation, several systems have produced images that permit the detection of healthy bone, organs, and tissue, as well as areas of chemical and structural irregularity (Lauterbur, 1973). This method is noninvasive, penetrates bony structures without attenuation, does not use ionizing radiation, and appears to be without hazard. As a result, MRI has become an essential and well-established technique for analytic, structural, and dynamic investigations of matter in many disciplines, especially chemistry and physics, and in recent years has made significant inroads in the field of medicine (Taylor, 1986).

Although MRI is still a relatively new technology, it has already changed the definition of optimal diagnostic care in several clinical areas, particularly the brain, spinal cord, and musculoskeletal system. Thus, many radiologists, neurosurgeons, neurologists, and orthopedists are incorporating MRI scanning into their practices, either as a single diagnostic test or as a complement to other modalities such as computed tomography (CT).

3.7 Biomedical Computing

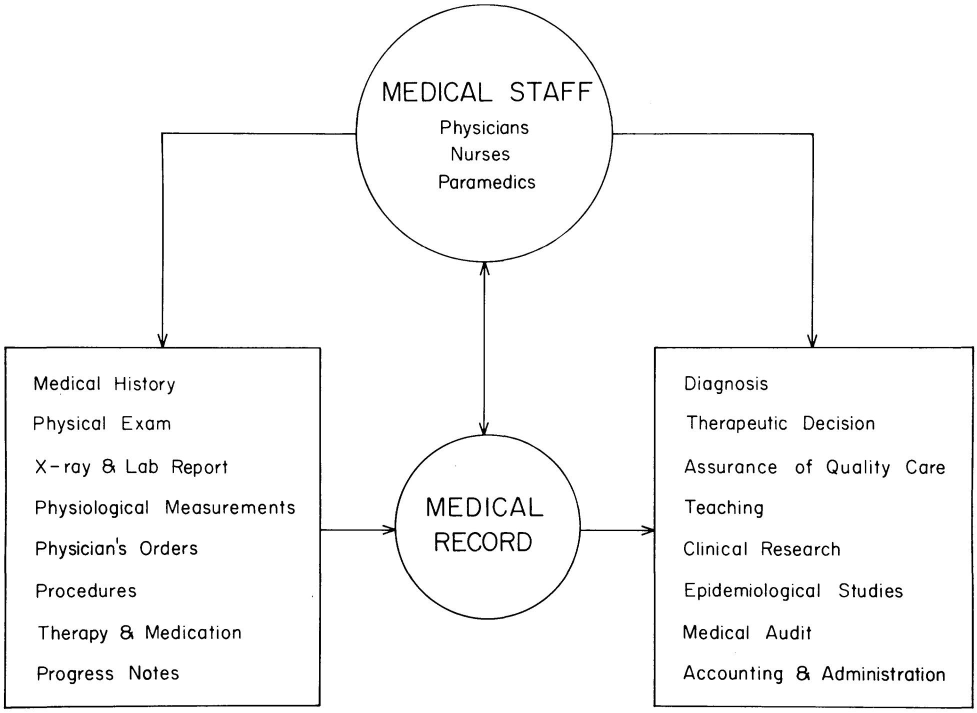
During the past two decades, the expansion of the use of computer technology has been explosive, involving almost every facet of human activity. Today computers are nearly everywhere, and yet these devices are still considered to be in their infancy. This observation is especially true in the utilization of computer technology in the clinical environment. In recent years, the introduction of computerized systems into the medical environment has greatly accelerated, and there is every indication that this will continue. In the future, it is almost certain that computer systems will be even more extensively utilized by health care systems than they are today. Major areas that have been and will continue to be important include patient care and the development of medical expert systems to assist clinicians in the diagnosis and treatment of their patients. As a result, these evolving computer technologies will have significant impact on U.S. health care procedures and policies into the 21st century.

The digital computer is clearly the linchpin for modern state-of-the-art information processing systems. This is especially true in modern health care institutions. The techniques actually used to collect, store, retrieve, and analyze data on the status of a patient, however, have been until recently quite slow and inefficient, even rudimentary. Since the quality of patient management and care depends on the rapid processing of accurate information about the patient's status, comprehensive computer-based health care information management systems have been increasingly used for these purposes. In spite of the progress to date, it is still the case that in many hospital and other health care facilities, patient management and care could be further enhanced by the adoption of current hardware and software data processing systems. Moreover, in the future, the types of information processing tasks that could be carried out by health care professionals will be even further expanded as new applications of computer-based technologies are developed.

Since the early 1960s, health care technologies based on the digital computer have become more and more pervasive. Advances in almost all types of medical research have come to depend heavily on computer-based technologies, either through the acquisition of accurate data from experimentation or the analysis of that data. Efficient financial management of health care facilities has also become increasingly dependent on high-speed data collection and retrieval of patient-related information. Only with such systems is it possible to achieve economic management of hospital inventories of drugs and equipment and provide accurate accounting of patient care costs and billing.

Since the 1970s, patient care computing systems have been developed to provide comprehensive information about the health care status of the patient (Fig. 14). These systems utilize computer hardware and software to collect, retrieve, and present clearly a wide variety of patient-related information (Jenkins, 1978; Bronzino, 1982). The development of such patient care systems has significantly altered and improved the way in which health care professionals utilize information about the patient's health care status. For example, patient care computing systems do the following:

1. provide clinicians with access to sophisticated and often widely dispersed resources,



MEDICAL STAFF
Physicians
Nurses
Paramedics
Medical History
Physical Exam
X-ray & Lab Report
Physiological Measurements
Physician's Orders
Procedures
Therapy & Medication
Progress Notes
MEDICAL RECORD
Diagnosis
Therapeutic Decision
Assurance of Quality Care
Teaching
Clinical Research
Epidemiological Studies
Medical Audit
Accounting & Administration

FIG. 14. Block diagram of medical information systems.

2. simplify the assembly of patient-related data for review by all types of health care professionals, and
3. assist health care professionals in making fundamental decisions about patient health care strategies.

As current systems are more widely adopted, the scope of the services they provide expands, and patient care computing will enhance both clinical performance and patient care.

Specific patient-care-related computer applications can be (approximately) allocated to the following categories (Bronzino, 1982):

- clinical laboratory analysis;
- acquisition of patient data and the evolution of automated multiphasic testing systems;
- computer-based medical-record data collection, storage, and information retrieval systems for patient management;
- automated patient monitoring;
- diagnostic support systems (such as electrocardiographic interpretive systems);
- medical imaging;
- artificial intelligence and expert systems.

The application of computers in biology and medicine has been important, and there have been many advances in applying computer technology to problems in the basic life sciences and clinical medicine. Even so, problems remain where computer technology can have a significant effect.

One class of these problems revolves around record keeping in clinical medicine. A hospital chart today does not look much different from what it did ten or twenty years ago, with the exception that it is thicker because of additional diagnostic procedures and patient monitoring data available. Trying to extract information from one of these records remains a problem for anyone other than those intimately involved in the patient's care and the production of the record in the first place. There is little standardization, and storage and retrieval techniques are not at the frontiers of technology. Yet the medical chart is becoming increasingly important in the patient's care, as well as for medical-legal reasons. Change in this feature of clinical medicine has been slow and will probably continue to be slow until such time that truly useful systems are developed and clinicians become more comfortable with computer technology. It is anticipated that these conditions will evolve in the 1990s, and opportunities for developing new methods of medical record keeping on a national and perhaps even an international basis will be best at the beginning of the next century. Such computer systems will have to incorporate advances in computer science such as artificial intelligence and expert systems, high-density data storage, more direct input and output from human beings (such as computer recognition of speech), and a combination of alphanumeric and pictorial data.

Computers will continue to play an important role in medical instrumentation, as they have begun to do in the late 1980s. No longer will instruments be concerned only with data gathering. Signal processing, including specific pattern recognition, self-calibration, preventative maintenance, data transmission, and multiple instrument control, will continue to offer research opportunities. As instrumentation and computer technology both become more complex, it will be important to develop software to keep the technology within reasonable bounds for human users and to optimize the application of the hardware to medical problems.

While computer engineers are just beginning to find the value of electronic systems for parallel processing as a means of speeding up complex computer operations, biological systems have been using this technique all along. Complex pattern recognition routines play an important role in biochemical reactions, such as between enzyme and substrate or antigen and antibody. Although investigators have explored the possibility of harnessing these complex processes into computational hardware, this field still remains at the frontier of technology, and many problems will need to be solved before techniques can be demonstrated and applied.

4. STATUS OF BIOMEDICAL ENGINEERING EDUCATION

The first undergraduate programs in biomedical engineering were initially organized as options in the traditional engineering undergraduate departments (such as electrical and mechanical engineering). As the field of biomedical engineering matured, separately accredited programs in biomedical engineering emerged. Today there are 18 organized undergraduate programs which have been accredited by the Accreditation Board for Engineering and Technology (ABET). A list of the presently accredited programs with the year of initial accreditation is shown in Table 6.

A significant number of undergraduate "option" programs, however, have not moved to separate department status. Since growth in enrollments and in the demographic projections for college-age youth has nearly ceased, it is expected that few, if any, new departments will be formed (Pilkington *et al.*, 1989).

The first formal programs in biomedical engineering began at the master's level, the program at Drexel which began in 1959 being a prime example; Johns Hopkins and the University of Pennsylvania began Ph.D. programs shortly thereafter. Graduate programs, because they are either research oriented or in some cases clinically oriented, are very much cast in the "image" of the particular faculty forming the program. In this respect, graduate programs often have different directions, and thus offer very different areas of specialization to the student. For example, some institutions have a basic research effort in physiological system modeling, others emphasize instrumentation and devices, while still others may have a clinically based program or one that emphasizes rehabilitation engineering. This diversity is appropriate because no one program can possibly provide the depth of education and training required to be competent in all fields (Pilkington *et al.*, 1989).

Table 6. Bioengineering group accredited programs (IEEE Lead Society, with AIChE, ASAE, ASME, and NICE). (Programs in this group are accredited according to the program criteria for bioengineering and similarly named engineering programs. Year of accreditation is shown.[a])

enrolled both in engineering and in biomedical engineering (BME) for the B.S., M.S., and Ph.D. is shown. It will be noted that at the undergraduate level, the total engineering enrollment peaked in 1983, and that biomedical engineering represents 1% of the total number. On the other hand, the percentage of BME students has remained fairly steady in recent years on both the graduate and undergraduate levels, and on this basis the expectation is for BME to follow engineering enrollments as a whole.

Finally, in Table 8 are listed the biomedical engineering undergraduate and graduate programs by state (Browneller, 1986a–f). It will be noted that the field of biomedical engineering is represented in almost every state and has indeed become an important component of the engineering profession.

[a] Details not received in time for publication.

GLOSSARY

Aliphatic Molecule: A molecule belonging to that series of compounds characterized by open chains of carbon atoms rather than by rings.

Artificial Intelligence: The science of making machines do things that would require intelligence if done by men.

Atherosclerosis: A form of arteriosclerosis characterized by a variable combination of changes to the intima of arteries, not arterioles, consisting of the focal accumulation of lipids, complex carbohydrates, blood and blood products, fibrous tissue, and calcium deposits; associated with changes in the media of the arteries.

Digitalis: The dried leaves of the *Digitalis purpurea* plant which are powdered into tablets or capsules. Cardiotonic glycosides, especially digitoxin and digoxin, are obtained from various species of the Digitalis plant. Use of these glycosides increases cardiac output and results in diuresis.

Etiology: The study of the causes of disease.

Hemodialyzer: Instrument for removal of chemical substances from the blood by passing it through tubes made of semipermeable membranes.

Hemolysis: The destruction of red blood cells with the liberation of hemoglobin which diffuses into the fluid surrounding them.

Hermetic: Airtight.

Hydrolytic Cleavage: The splitting of a molecule into two or more simpler ones through the addition of water.

Isotropic: 1. Possessing similar qualities in every direction. 2. Having equal refraction.

Left Ventricular Assist Device (LVAD): Implantable device used to assist in those instances where the major contractual muscle of the heart, the left ventricle, is not performing satisfactorily.

Morbidity: 1. State of being diseased. 2. The number of sick persons or cases of disease in relationship to a specific population.

Morphology: Science of structure and form without regard to function.

Mortality: 1. State of being mortal. 2. The death rate; ratio of number of deaths to a given population.

Multiphasic Screening: A battery of clinical tests to which a patient is subjected in order to evaluate his or her medical status.

Orthotic Device: A device for straightening or correcting a deformity or disability.

Osteoporosis: Increased porosity of bone, seen most often in the elderly.

Periorbital: Surrounding the socket of the eye.

Picture Archiving: The use of computers to digitize and store images.

Prosthetic Devices: Devices designed to replace missing parts (limbs, etc.)—artificial substitutes.

Rehabilitation Engineering: A subspecialty of biomedical engineering concerned with the development of devices to assist the disabled.

SA (Sino-Atrial) Node: Node at junction of superior vena cava and right cardiac atrium, regarded as the site of initiation of the heartbeat.

Scintillation: The photoeffect caused by collision of particles emitted by radioactive substances and a detector surface.

Streak Artifacts: Blurs which occur on computed tomographic (CT) images.

Sulfanilamide (Para-aminobenzenesulfonamide): White, slightly bitter, crystalline substance derived from coal tar, the parent of the azo family of dyes. Formerly widely used in the treatment of a number of infections, due to its toxic effects its use has been superceded by more effective and less toxic sulfonamides.

Tomography: Any of several noninvasive special techniques of roentgenography designed to show detailed images of structures in a selected plane of tissue by blurring images of structures in all other planes.

Thrombogenuity: Producing or tending to produce a clot.

Ultrasound: Inaudible sound in the frequency range of approximately 20 kHz to 10 GHz. Ultrasound waves have different velocities in tissues of different densities and elasticity. This property permits the use of ultrasound in outlining the shape of various tissues and organs in the body.

INTRODUCTION

Feelings of fear and dread are a typical initial reaction of most persons to the expression "radiation." Yet the expression simply means that energy is being transferred from one location to another. Often this transfer leads to useful applications that are highly beneficial to humans. Among applications of great benefit are the uses of radiation for the diagnosis and treatment of human disease and injury. This article examines these uses, and explores future possibilities that may add to the beneficial applications of radiation in medicine.

1. OVERVIEW

1.1 Radiation as a Diagnostic Probe

The detection and diagnosis of disease and injury has always been a significant challenge to physicians. Before the end of the past century, this challenge frequently was insurmountable, because the physician was confined primarily to interpreting external signs for evidence of anatomic, physiologic and metabolic difficulties within the patient. Vague indicators such as temperature, pulse and respiratory rates, and visual and muscular reflexes were often all the physician had available to determine what may be troubling the patient. Exploratory surgery to identify the cause of a patient's suffering was a common but risky procedure. On other occasions sympathetic understanding and emotional support were all the physician could offer as the patient struggled to recover from a malady.

The discovery of x rays in 1895 by Wilhelm Röntgen, a physicist at the University of Wurzburg, provided the first opportunity to examine the interior of the body in a noninvasive manner. Unlike lower-energy forms of electromagnetic radiation such as visible and ultraviolet light, x rays (and gamma rays emitted by radioactive nuclei) have the ability to penetrate biological tissues. As a beam of x rays traverses the body, it is absorbed to varying degrees depending on the anatomic structures in the path of the beam. The x-ray beam

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

exiting from the body varies in intensity from one location to another, depending on the structures through which each part has passed. By directing the x-ray beam onto a fluorescent screen or x-ray film, the varying x-ray intensity can be transformed into a pattern of differing light intensity or optical density. This pattern forms a two-dimensional image of the three-dimensional structures in the body through which the x-ray beam has passed. One of the first x-ray images captured on film is shown in Fig. 1.

Today x-ray imaging, referred to as radiography when the image is captured on film or digital storage device, and fluoroscopy when the image is displayed dynamically on a fluorescent screen, is widely employed in medicine. Over the years it has been joined by several other techniques to display images of internal anatomy and physiology. The creation of cross-sectional images of patient anatomy from x-ray projections obtained at different orientations and processed by computer is referred to as computed tomography. In nuclear medicine (*q.v.*), images depict the distribution of radioactive materials inside the patient's body after they have been administered orally, intravenously or by breathing a radioactive gas. Ultrasonography employs beams of ultrasound to reveal the internal anatomy of patients and the flow of blood within arteries and veins (see BIOLOGICAL EFFECTS OF SOUND AND ULTRASOUND). Magnetic resonance imaging (*q.v.*) produces images from weak radiofrequency signals elicited from patients by placing them in an intense magnetic field. All of these imaging technologies are invaluable aids in the detection and diagnosis of disease. Each has contributed in a substantial way to the dramatic improvements in the health and well-being of people that have occurred over this century.

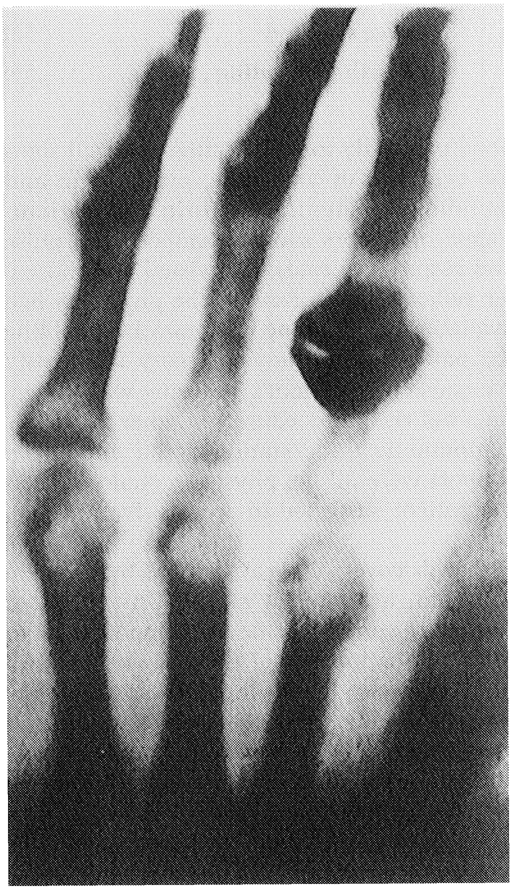

FIG. 1. Early radiograph of the hand taken by Röntgen with his wife as the subject. The enlargement on one finger is a ring. (Courtesy of Deutches Röntgen-Museum, Remschied-Lennep, West Germany.)

1.2 Radiation as a Therapeutic Agent

As a beam of x or gamma rays traverses the body, it gradually loses intensity by transferring energy from the beam to the atoms comprising the tissues along the path of the radiation. Beams of particles such as electrons and protons exhibit a similar behavior. This dissipation of energy causes the ejection of electrons from the atoms, resulting in a concentration of ions along the path of the radiation. Hence, the radiation is categorized as ionizing radiation.

An ionizing event can injure or kill a cell if it occurs in an atom contained within a critical molecule of the cell. This effect, termed the "direct effect of radiation," is responsible for some of the biological effects of radiation. More often, however, the ionizing event occurs in an atom that is not an integral part of an essential cellular structure. Cell injury or death can still occur, however, because the event may create reactive products called free radicals that in turn attack cellular structures. This mechanism of radiation action on cells is referred to as the "indirect effect of radiation." The direct and indirect mechanisms of radiation action on cells are responsible for the damaging consequences of exposure to radiation, including the induction of cancer (carcinogenicity), development of abnormalities in persons exposed before birth (teratogenicity), and production of genetic effects in offspring of exposed individuals (mutagenicity) [Hendee, in press (A)] (see BIOLOGICAL EFFECTS OF ELECTROMAGNETIC AND PARTICLE RADIATIONS).

Cancer is a disease in which certain cells have been transformed so that they are growing and multiplying at a much faster rate than normal. If these cells can be destroyed, the patient often has a good chance of recovering from the cancer. If the cells are disseminated throughout the body, perhaps because the cancer has spread (metastasized) from its initial (primary) site, the preferred treatment usually is to try to kill the cells with a cellular poison. This approach is referred to as chemotherapy, and the specialists who employ it are called medical oncologists. If the cells are confined to a specific region of the body, often they can be removed surgically, or destroyed by concentrating radiation in the region. The latter technique is referred to as radiation therapy, and the physicians who utilize it are called radiation oncologists. A frequent approach to cancer treatment is to employ radiation to destroy the primary site of the cancer (sometimes after most of the cancer has been removed surgically), followed by chemotherapy in an effort to kill cancer cells that have spread to distant sites.

In the early years following the discovery of x rays, radiation was used to treat a wide spectrum of conditions, including arthritis, muscular aches and pains, tuberculosis, and cancer. Over the years, most of these conditions have succumbed to better methods of treatment. However, radiation continues to be used for treatment of cancer, with excellent results for many forms of cancer when the disease is confined to a primary site, or when distant metastases can be treated with cellular poisons.

2. PROPERTIES OF X AND GAMMA RADIATION

2.1 Production

X rays and gamma rays are electromagnetic radiations with energies greater than those possessed by other components of the electromagnetic spectrum (Fig. 2). X rays are produced as a result of electron transitions within atoms, whereas gamma rays are released as atomic nuclei undergo transitions from higher to lower energy states. In medicine, x rays are produced in x-ray tubes in which electrons that have been accelerated to high energy bombard a metal target where they interact with target atoms to produce x rays. The x rays are both characteristic x rays emitted during interactions of the incident electrons with electrons of the target atoms, and *bremsstrahlung* released during interactions of the incident electrons with target nuclei. Each of these types of interactions is discussed below. Medically useful gamma rays are released from radioactive atoms selected to yield radiations of desired energies.

As electrons accelerated through a potential difference of several thousand volts impinge on the metal target of an x-ray tube, they interact with the electrons and nuclei of the target atoms. Interactions with electrons cause the electrons to be ejected from the target atoms, including some from the electron shells nearest the nucleus. As the vacancies left by these ejected inner electrons are filled by other electrons cascading down from higher levels, x rays are released. These x rays are called characteristic x rays because their energies are characteristic of the electron energy levels of the particular metal used for the target. In a typical x-ray beam used for medical diagnosis, 10% or so of the x-ray intensity

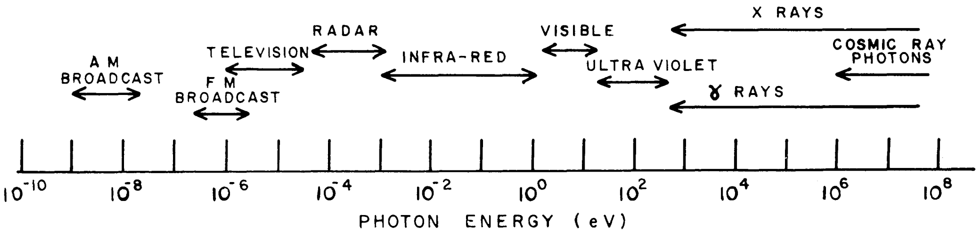

FIG. 2. The electromagnetic spectrum.

is contributed by characteristic x rays (Hendee, 1979).

High-energy electrons impinging on a target also interact with the nuclei of the target atoms. These interactions result in a slowing of the electrons and a release of energy in the form of x rays. This radiation is termed "braking radiation" or *bremsstrahlung*. In a diagnostic x-ray beam, over 90% of the x-ray intensity is due to bremsstrahlung (Hendee, 1979). In the higher-energy x-ray beams used for therapy, the x-ray intensity is almost entirely due to bremsstrahlung.

For the x-ray beams used for diagnosis, a relatively simple x-ray tube can be used to produce x rays. The device consists of a filament that is heated to high temperature to release electrons by thermionic emission, and a voltage of several thousand volts to accelerate the released electrons toward a metal target. X rays are produced as the electrons are absorbed in the target. However, less than 1% of the electron energy is released as x rays, and over 99% is dissipated as heat (Curry, Dowdey, and Murry, 1990). Often the metal target is embedded in a rotating anode so that the intense heat can be dissipated over a larger volume of material. The filament and anode are enclosed within an evacuated glass envelope to prevent molecules of air from scattering the electrons on their way to the target.

X rays used for radiation therapy are much more energetic than those employed in radiologic diagnosis. To prevent their emission in undesired directions, heavy shielding is required around the x-ray source. Also, the electrons that produce them must be accelerated to very high energies, on the order of several million electron volts. (An electron volt is the kinetic energy acquired by an electron accelerated through a potential difference of one volt.) Electrons accelerated to such high energies produce x rays more efficiently compared with those accelerated to several thousand electron volts in diagnostic x-ray tubes. Hence, stationary targets, sometimes embedded in a large mass of copper and cooled by a circulating fluid, are used in radiation therapy.

For x-ray beams of several million electron volts, it is not feasible to provide acceleration all at once by subjecting the electrons to a single voltage difference between electrodes. Instead, the acceleration is provided in a continuous fashion in an accelerating tube known as a waveguide that is part of a linear accelerator (see ACCELERATORS, LINEAR). In a traveling-wave linear accelerator, electrons are accelerated by riding the crest of an electrical field that sweeps down the entire length of the waveguide. At the end of the waveguide the electrons are either extracted as a high-energy electron beam, or directed onto a metal target to produce x rays. In a standing-wave linear accelerator, electrons are accelerated by injecting them into a waveguide in which the electrical field is present in a standing-wave pattern. Most linear accelerators used today in radiation therapy are the standing-wave type (Hendee, 1981).

2.2 Interactions

X and gamma rays are electromagnetic radiations, termed photons, that carry no electronic charge and hence do not interact through charged particle (Coulombic) interactions with matter. Instead, they are absorbed by various mechanisms, of which three are especially important for the range of photon energies employed in diagnostic imaging and radiation therapy. These three types of interactions are the photoelectric effect, Compton interaction, and pair production.

Photoelectric interactions occur primarily with relatively low-energy x and gamma rays such as those used for medical diagnosis. In these interactions, the photon interacts usually with an inner electron of an atom by transferring its entire energy to the electron. In this manner the x or gamma ray disappears, and in its place is a high-speed electron that has escaped from the atom as a consequence of receiving the photon energy. The kinetic energy E_k of the electron is

$$E_k = h\nu - E_B,$$

where $h\nu$ is the energy of the x or gamma ray, and E_B is the binding energy of the electron, defined as the energy required to remove the electron from the attractive influence of the nucleus. In general, the likelihood of a photoelectric interaction increases rapidly with increasing atomic number of the absorbing material, and decreases rapidly with increasing energy of the x or gamma ray. These trends are depicted in the attenuation curves shown in Fig. 3, which also reveal discontinuities

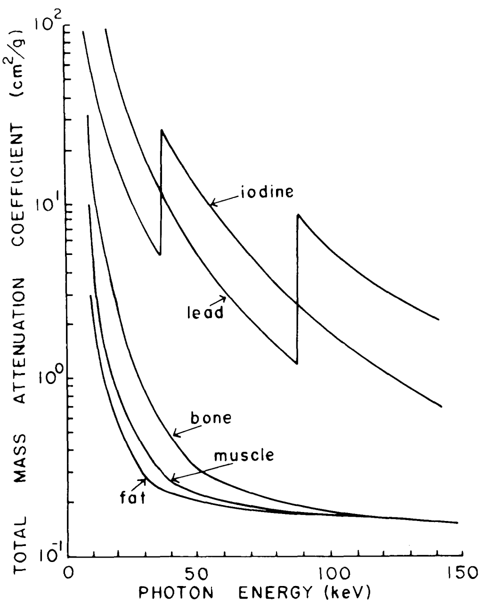

FIG. 3. The attenuation coefficient of x rays in lead and iodine, plotted as a function of x-ray energy.

where the absorption curves for iodine and lead rise rapidly at the specific energy of 33 keV for iodine and 88 keV for lead. This "resonance energy," termed an absorption edge, occurs at an energy where the photon has just enough energy to eject an electron from the innermost electron energy level (the *K* shell) of the absorbing atom.

Higher-energy x rays in diagnostic radiology, and almost all x rays employed in radiation therapy, tend to interact with matter by a process known as the Compton interaction. In this process, the x ray transfers part of its energy to an outer electron of an atom, with the x ray scattering in a new direction with reduced energy. The electron is ejected from the atom with a kinetic energy essentially equal to that received from the photon, because the binding energy of the outer electron is negligible. The probability of a Compton interaction decreases gradually with increasing energy, and does not depend on the atomic number of the absorbing material. It does, however, depend on the electron density (number of electrons per gram) of the absorber. Hydrogen is a particularly efficient absorber of x rays by the Compton process because it contains no neutrons and hence has almost twice as many electrons per unit mass as do other elements. Compton interactions produce scattered radiation that interferes with the portrayal of fine detail in diagnostic images unless it is removed by use of a mechanical grid in diagnostic radiology or a pulse-height analyzer in nuclear medicine. Compton interactions are preferred in radiation therapy because they do not produce excessive absorption of energy in tissue components (e.g., bone) of high atomic number.

For photons of energy greater than about 1 MeV, a third type of interaction, pair production, can occur. This process involves an interaction of an x or gamma ray in the presence of a nucleus of the absorbing material. The photon disappears, and a pair of electrons, one negative and one positive, is created. The kinetic energy of the negatron-positron pair equals the energy of the photon, less 1.02 MeV of energy which is expressed as the mass of the pair of particles. The positron exists only until its kinetic energy has been expended, at which time it interacts with an electron. The interaction causes the particles to be annihilated, with their mass expressed as two "annihilation photons" of 0.51 MeV each that emerge in opposite directions from the interaction site. The likelihood of pair production increases with increasing photon energy, and it is a common interaction for x and gamma rays of several MeV.

2.3 Detection

Energetic radiations such as x and gamma rays, and charged particles such as electrons and protons, can induce cellular damage in tissues that ultimately may affect the well-being of exposed individuals. In spite of this damaging effect, ionizing radiations are not detectable by any of the human senses. Consequently, the presence of radiation can be measured only through indirect methods that take advantage of some property of the radiation that affects materials in a manner that is detectable by humans. In most cases this property is the ability of radiation to ionize and excite atoms in an absorbing medium.

The first detector of x rays was the fluorescent material in Röntgen's laboratory that glowed during his experiments of electrical conduction through gases. Studies of this fluorescence caused Röntgen to speculate that a new form of radiation, which he called "x rays," was generated by his experiments. As the x rays interacted by depositing energy in the fluorescent material, electrons were raised to higher energy levels. As these electrons returned to more stable levels, visible light was emitted which could be seen as fluorescence.

The property of x-ray-induced fluorescence was used by Edison to construct fluorescent screens to provide x-ray images of human anatomy, and to enhance the sensitivity of techniques to record x-ray images on photographic film. For several decades, fluorescent screens of materials such as (Zn,Cd)S were employed in medicine to display dynamic x-ray images. These images were very dim and could be viewed reliably only in a darkened room. The ability to see fine detail in the images was compromised by these requirements, because the persons viewing the images had to be dark-adapted, and hence were forced to use rod vision rather than the cone vision available under conditions of brighter illumination. Also the method was time-consuming and tedious.

In the 1950s efforts were directed to developing a way to increase the brightness of the fluoroscopic x-ray image so that dark-adaptation could be eliminated and the visibility of detail improved. The product of these efforts was the x-ray image intensifier. This device amplified image brightness by converting the x-ray induced light image to a pattern of electrons that could be accelerated and then converted back into a light image. The image intensifier is illustrated in Fig. 4. X rays from the patient impinge on a fluorescent screen where they are converted into light. The light is projected onto a photoelectric surface that emits electrons in response to the intensity of incident light. The electrons are accelerated through a potential difference of several thousand volts onto a second, smaller fluorescent screen. Emerging from this screen is a light image that is much brighter than the original light pattern from the input fluorescent screen. The ratio of the brightness of the two screens, known as the brightness gain of the intensifier, is a product of two factors: the minification gain accomplished by decreasing the size of the image, and the electronic gain achieved by accelerating the electrons to high energy before the output image is produced. Brightness gains of 3000–4000 are typical of modern image intensifiers, and they alleviate the need for dark-adaptation and the use of rod vision.

For several years, the input screen of the image intensifier was composed of materials identical to those used in fluorescent screens. In the 1960s, however, CsI replaced (Zn,Cd)S as the most common fluorescent material. Today almost all fluoroscopy is performed with image intensifiers employing CsI screens. The output image can be viewed directly through an optical system that collects the light and projects it into an orientation convenient for observation. More commonly, most fluoroscopic systems employ a television camera coupled to the output screen so that the image can be viewed on one or more television monitors.

Fluoroscopic images are very useful for examining rapidly changing anatomic pro-

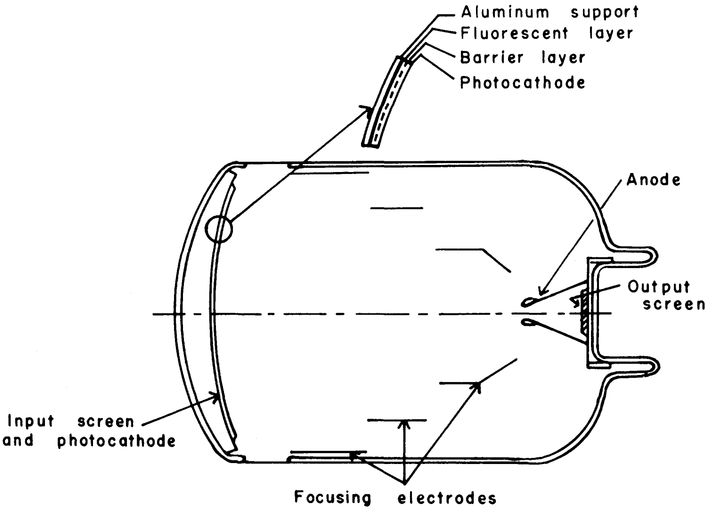

FIG. 4. An x-ray image intensifier.

cesses. However, they do not provide permanent images. To obtain a permanent record of an x-ray examination, images must be captured on photographic film or some type of electronic storage medium. In some examinations, the x-ray pattern emerging from the patient is imposed directly on a film. In most cases, however, the film is exposed primarily by light released during interactions of x rays with fluorescent screens positioned on both sides of the photographic film. These intensifying screens greatly enhance the sensitivity of the recording process and yield acceptable images in much shorter examination times that require less exposure of the patient to radiation. For many decades $CaWO_4$ was the fluorescent material most commonly employed in intensifying screens. In the 1970s rare-earth fluors were introduced as a replacement for $CaWO_4$. Rare-earth intensifying screens are more efficient absorbers of x rays, and today most intensifying screens employ these materials in place of $CaWO_4$ (Mackay, 1984).

Fluorescent screens and photographic film are excellent methods for recording images of the pattern of x rays emerging from a patient during an x-ray examination. They are not entirely satisfactory, however, for routine quantitative measurements of the amount of radiation present at some location near a source of radiation. For these measurements, two other types of detectors have been developed. These types of detectors, referred to as gas-filled detectors and solid detectors, are discussed in detail in companion articles on DETECTORS, RADIATION; DETECTORS, SEMICONDUCTOR; and DETECTORS, SCINTILLATION. Hence, only an overview of gas-filled and solid detectors is provided here.

2.3.1 Gas-Filled Detectors. Radiations such as x and gamma rays are termed "ionizing radiations" because they ionize any material through which they pass. If the material is a gas, the ejected electrons and residual positive ions can be collected by charged electrodes to yield a signal that depicts the passage of radiation through the gas. In some cases, the signal can be interpreted not only that radiation was present, but also how much radiation was present.

Conceptually, the simplest type of gas-filled detector is the ionization chamber. This device consists of two electrodes operated at a potential difference of a few hundred volts. The electrodes are suspended in a gas, often air, inside a detector whose walls are similar in atomic composition (but not physical density) to the gas. As radiation interacts with the walls of the chamber, electrons are released that traverse and ionize the gas inside the chamber. The resulting electrons constitute a tiny electrical signal signifying that radiation has interacted with the detector.

With an air-filled ionization chamber, measurements usually are expressed in units of coulombs/kilogram to signify the amount of charge collected per unit mass of air inside the chamber. This unit specifies the "radiation exposure" present at the location of the chamber. In past years, a different unit, the roentgen (R) was used to describe the "exposure" of the chamber to radiation. A person exposed to the radiation source at the location of the chamber for the same length of time was described as receiving a certain "exposure" to radiation expressed in roentgens. With adoption of the International System (SI) of Units, the roentgen has fallen into disfavor. Today the unit coulombs/kilogram, rather than roentgen, is preferred for descriptions of radiation exposure.

The ionization chamber is a useful device for measuring relatively intense beams of radiation. For small amounts of radiation, however, the ionization chamber is less useful because the current or voltage drop is extremely weak. For these measurements, a device that amplifies the signal electronically in the detector is more useful. This approach is used in a number of devices, including portable proportional and Geiger–Mueller (GM) survey meters, to provide a relatively simple and inexpensive way to detect the presence of radiation.

2.3.2 Solid Detectors. Gas-filled detectors are useful in a variety of applications to detect and measure the amount of radiation present at a particular location at some moment in time. For x and gamma rays, however, these detectors are relatively inefficient because not many of the photons are stopped by the detectors. Absorption of x and gamma rays could be improved substantially by using solid detectors of greater physical density. However, the solid material must be carefully chosen so that a signal is generated only when radiation interacts with the detector.

Certain semiconducting solids have this property, and detectors that employ them are known as semiconductor radiation detectors.

A semiconductor is a material with properties intermediate between those of an insulator and a conductor. Under normal circumstances the most energetic electrons in a semiconductor are confined to the energy level known as the "valence" band, and the material functions as an insulator. However, the valence band is separated from the higher-level "conduction" band by only a few electron volts of energy. Hence electrons can be moved from the valence band into the conduction band by absorption of small amounts of energy such as those delivered during exposure of the semiconductor to radiation. During exposure, the number of electrons moved into the conduction band can be measured by placing a potential difference across the material and collecting the resulting current. In this manner, the semiconductor serves as a radiation detector. Semiconducting materials frequently employed as radiation detectors include germanium and silicon. These materials are usually "doped" with a small amount of lithium to improve their detection characteristics, and are known as Ge(Li) and Si(Li) detectors.

Scintillation detectors present an alternative approach to the design of solid detectors of radiation. In these devices, a solid insulating material such as sodium iodide is used in which a few electrons are raised to a higher energy band during exposure to radiation. By adding a small amount of impurity (usually thallium) to the NaI crystal, some of the electrons return to the lower energy band through an intermediate energy state. This return path results in the release of visible light that can be measured with one or more photomultiplier tubes. Combinations of NaI(Tl) crystals and photomultiplier tubes are known as scintillation detectors. These detectors are widely used for imaging in nuclear medicine (Fig. 5).

Another type of scintillation detector is useful for measuring the amount of radiation delivered in radiation therapy. This type of detector, known as a thermoluminescent detector (TLD), can be exposed to radiation, and later heated to release an amount of light proportional to the energy absorbed in the detector. The most common TLDs are $Li_2B_4O_7$ and LiF. These materials have a composition that resembles soft tissue, so the signal depicts the approximate energy that would have been absorbed in tissue at the location of the detector. In this manner, the detector is said to measure the "dose" of radiation absorbed in soft tissue, where absorbed dose is expressed in grays (Gy), with 1 gray = 1 joule of energy absorbed per kilogram of absorbing material. An earlier unit of absorbed dose, the rad, is still frequently encountered in the radiologic literature. An absorbed dose of 1 rad equals 0.01 joule of energy absorbed per kg of absorbing material. That is, 1 rad = 0.01 Gy.

3. X-RAY IMAGING

An x-ray beam emerging from an x-ray tube presents a relative uniform intensity of x rays across its area. This uniform intensity is

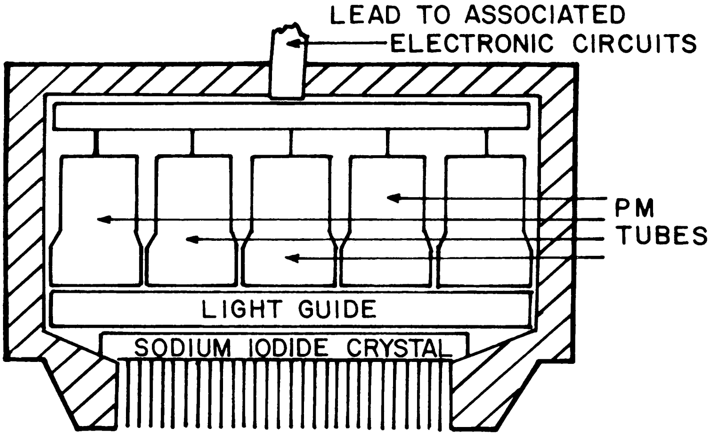

FIG. 5. A scintillation detector used for nuclear imaging.

modulated by the types of tissues encountered as the x-ray beam traverses the patient. X rays that traverse bone are attenuated to a greater extent than those that pass only through soft tissue, because bone has a higher atomic number and a greater physical density than soft tissue. Fat transmits slightly more x rays than muscle because its atomic number and physical density are lower. X rays are transmitted readily through air-filled structures such as lung because the physical density is very low. At times highly attenuating substances known as contrast agents are added to the patient to enhance the absorption of x rays. For example, barium-containing substances are frequently administered orally [barium swallows for upper gastrointestinal (GI) studies] or rectally (barium enemas) to improve the visualization of the esophagus, stomach, small and large intestine and rectum. Contrast agents also can be administered intra-arterially and intravenously to improve visualization of the circulatory system, a specialty of diagnostic imaging known as angiography. Contrast agents also are useful in visualizing the kidneys and urinary tract (pyelography), spinal column (myelography), and a number of other anatomic structures.

Because of its differential attenuation in various tissues, the x-ray beam emerging from the patient is no longer uniform in intensity. Instead, it possesses an intensity pattern that conveys information about the composition of the body through which the x-ray beam has passed. As discussed earlier (and in the companion articles on IMAGING TECHNIQUES, BIOMEDICAL and X-RAY IMAGING: RADIOGRAPHY AND TOMOGRAPHY), this information can be captured as a dynamic image on a fluoroscopic screen (fluoroscopy), or as a permanent image on film (radiography).

3.1 Fluoroscopy

In fluoroscopy, the image is captured on a fluoroscopic screen and viewed as a dynamic display of anatomy. This technique is especially useful for studies where the anatomy is constantly in motion, such as those of the gastrointestinal tract and heart. However, even in fluoroscopic studies of rapidly-changing anatomy, images must be recorded to permit later review and consultation and provide a permanent record of the examination. Permanent images may be captured in a variety of ways. For example, inserting a cassette containing intensifying screens and film momentarily into the x-ray beam between the patient and the image intensifier provides a "spot film" of patient anatomy at a particular moment. Alternatively, the light image from the output screen of the intensifier may be deflected momentarily into a 100-mm "photospot" camera positioned near the output screen. High image frame rates required for studies of the heart can be achieved by taking a motion picture of the fluoroscopic image with a 35-mm camera coupled to the intensifier output screen. This technique is known as cineradiography or cineangiography. Most fluoroscopic systems in use today employ a television camera and monitor to view the image. In these systems, the image may be captured on video tape or disk for later playback and analysis. If the television signal is converted from analog into digital form, the resulting images can be stored on computer disk or tape for subsequent retrieval and display.

3.2 Radiography

Virtually everyone has had radiographs made to assess a possible fracture or to evaluate the lungs and chest. Each year many people have a radiographic examination to identify a possibly fractured vertebra, or to characterize problems in the urinary or GI tract. Women are encouraged to have periodic x-ray examinations (mammography) of the breast to rule out the presence of breast cancer. Radiography is a very common diagnostic technique, and medical diagnosis would be severely handicapped if it were not available.

Until recently, radiographs were obtained by exposing film directly to x rays or indirectly to light emitted from intensifying screens exposed to x rays. Today, radiography is in transition from a film-based diagnostic specialty to one that will eventually depend, at least in part, on the use of electronic detectors. Electronic detectors are important for radiology because electronic signals can be easily digitized for processing and display by computer. The movement of radiography from an analog to a digital mode of operation is of great interest because it addresses a major problem facing medical institutions today.

In most institutions the x-ray film fileroom is regarded as a major weak link in the chain of services provided for patients. Films are easily lost, misplaced and borrowed, and not infrequently are unavailable when needed for medical diagnosis and follow-up. Improving this situation by maintaining a computer file of all diagnostic images would be a major improvement over retaining images in analog form. However, a digital process for capturing or translating radiographic images is a precondition for a computerized information file.

With the exception of radiography and fluoroscopy, diagnostic imaging techniques used today in medicine are largely digitally based. Adding digital radiography to this array of digital devices permits consideration of a digital imaging network (DIN), often described as a picture archiving and communications system (PACS). In the PACS approach, digital images can be acquired, stored, retrieved, transmitted, and displayed at great convenience throughout an institution. A few institutions have made a firm commitment to evolution of a PACS approach to diagnostic imaging. Many problems remain to be solved, however, not the least of which are the cost of transition and the challenge of converting existing films to digital form [Hendee, in press (B)].

3.3 Angiography

One of the most important applications of x-ray imaging is for the study of the circulatory system. From studies of the heart and great vessels to analyses of the circulation in the brain and extremities, x-ray imaging is relied upon for the depiction of normal anatomy and the identification of abnormal conditions, including circulatory malformations, dysfunctional heart valves, coronary artery disease, the presence of atherosclerotic plaques and blood clots, abnormal circulation caused by injuries and diseases such as cancer, and a wide spectrum of other conditions. Under most circumstances, blood-containing vessels are not distinguishable from muscle and other soft tissues displayed in x-ray images. To help the vessels stand out in an x-ray image, they must be filled with a contrast agent. The agent must have the same physical density and osmolarity as blood; however, it can contain a substance of high atomic number to increase the absorption of x rays. Iodine-containing materials are the preferred substances for studies of the circulatory system, primarily because the absorption edge of 33 keV for iodine (Fig. 3) is about equal to the average energy of x rays in a typical diagnostic x-ray beam. X-ray studies of arteries and veins with iodine-containing contrast agents is referred to as angiography.

3.4 Computed Tomography

For the first seven decades of this century, the medical applications of x rays improved slowly but steadily. In the early 1970s, however, a revolutionary approach to x-ray imaging was introduced. This approach was x-ray transmission computed tomography (CT).

One of the major disadvantages of conventional x-ray imaging is that a three-dimensional volume of tissue is represented as a two-dimensional image. The person viewing the image is forced to interpret the third dimension of depth by knowing the anatomy and noticing which structures seem to lie in the shadows of others. Computed tomography reduces this difficulty by presenting images of thin slices of tissue with little overlapping information. Consequently, the visibility of structures of similar composition is improved, and the images are easier to interpret. Visualization of low-contrast information is improved also because only a thin slice of tissue is exposed to x rays, and scattered radiation is reduced.

The first CT scanners commercially introduced employed a tightly collimated, pencil-like x-ray beam that scanned across the patient (Fig. 6). Moving in synchrony on the opposite side of the patient was a scintillation detector that measured the intensity of x rays transmitted through the patient. Measurements of x-ray transmission were made at mm increments along each of several scan paths oriented at slightly different angles with respect to the patient. After several thousand measurements had been obtained, the data were subjected to a reconstruction algorithm that computed a cross-sectional distribution of x-ray attenuation coefficients for the anatomic section of interest. These coefficients could be sorted into numerical ranges, with each range assigned a shade of gray for display as a cross-sectional image. Coefficients in contiguous sections could be interpreted in

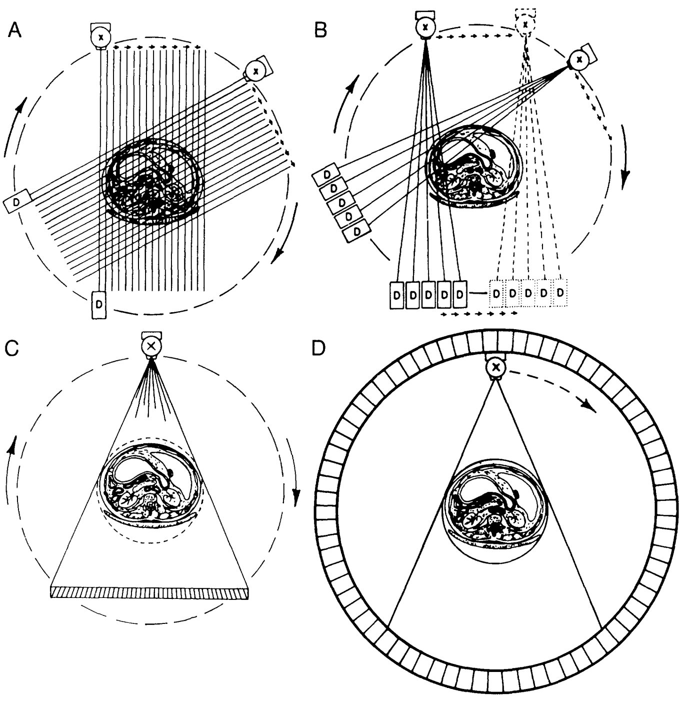

FIG. 6. Different geometries used for data acquisition in x-ray computed tomography. (A) First generation; (B) second generation; (C) third generation; and (D) fourth generation.

similar fashion to yield coronal and sagittal images. Representative CT images are shown in Fig. 7.

The major difficulty with early CT scanners was that several minutes were required to obtain the transmission data from which images were reconstructed. Within a few months imaging times were reduced to several seconds by employing a fan-shaped x-ray beam and a bank of detectors on the opposite side of the patient to record the transmission data. This second-generation CT scanner also quickly became outdated as a third generation scanner was developed that employed purely rotational motion of the x-ray tube and bank of detectors. With this approach, imaging times as short as 1–2 s could be achieved. An alternate approach, known as a fourth

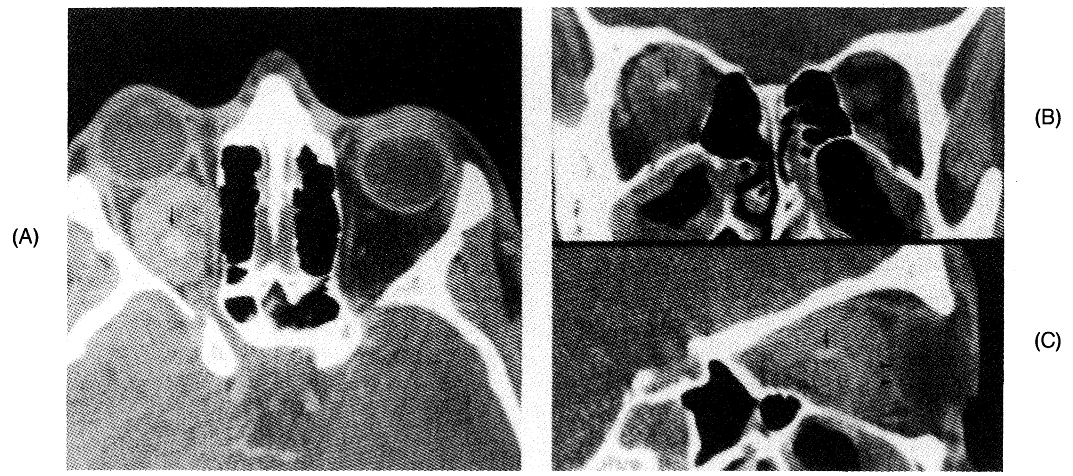

FIG. 7. (A) Cross-sectional (transverse), (B) coronal, and (C) sagittal CT images of an optic nerve glioma (astrocytoma). The cancer cannot be discriminated from the optic nerve and exhibits calcifications (arrows) and compression of the globe (arrowheads). [From Zonneveld (1988).]

generation scanner that was competitive with third generation scanners, employed a circular array of stationary detectors and an x-ray tube that rotated around the patient inside the detector array (Fig. 6). Some third and fourth generation scanners employ fast scintillation detectors, usually bismuth germanate crystals, while others use ionization chambers filled with a high atomic number gas such as xenon.

Computed tomography revolutionized the field of diagnostic imaging and opened the discipline to the development of similar techniques employing other types of radiations, including gamma rays (SPECT and PET imaging) and magnetic resonance imaging (*q.v.*) (MRI) (Hendee, 1983). Today CT is a well-established and mature technology that is found in almost every hospital and outpatient imaging center of modest or greater size. Computed tomography has been of particular benefit to neurology and neurosurgery, and it is difficult to remember some of the diagnostic difficulties encountered frequently by these specialties before CT became available.

4. NUCLEAR IMAGING

Many atomic nuclei are unstable because they contain unusual configurations of neutrons and protons, or because they possess more energy than required to exist in the state of least energy. In the latter case, the nucleus can gain stability by releasing its excess energy. The most common mechanism for releasing excess energy is by its emission as one or more gamma rays, electromagnetic radiations that resemble x rays except that they originate from nuclear rather than electronic transitions. Gamma-ray emission is one of the modes of radioactive decay available to unstable atoms. Because gamma rays can penetrate tissue in a manner similar to x rays, they can be detected outside the body after their emission from radioactive materials present inside the body. The procedure of administering a radioactive substance to a patient, and then using radiation detectors to measure the gamma rays emitted from the patient, is known as the medical specialty of nuclear medicine.

Nuclear medicine originated in the 1920s and 1930s during studies of the behavior of certain radiopharmaceuticals (chemical compounds containing radioactive atoms) in specific organs such as the thyroid and kidneys. A major impetus to nuclear medicine occurred after World War II when nuclear reactors became available for the wide-scale production of radioactive atoms (radionuclides) that were potentially useful in diagnostic medicine. Two developments in the early 1960s, the scintillation camera and the technetium-99m generator, further advanced nuclear medicine as a diagnostic specialty. In the 1970s the computer was incorporated into nuclear imaging to permit studies of dynamic physiologic processes with radiopharmaceuticals. These studies were enhanced in the 1980s by application of computed tomographic techniques to analyses of the distribution of radiopharmaceuticals in the body. As nuclear medicine moves into the 1990s, the technology of positron emission tomography promises to be another milestone in the evolution of nuclear medicine. Today nuclear medicine is one of the most sophisticated of the imaging technologies, and is essential to the detection and diagnosis of a variety of diseases and injuries.

4.1 Radiopharmaceuticals

The key to success in nuclear imaging is the availability of radiopharmaceuticals that distribute in the body in ways that reveal the static and dynamic features of certain organs and regions. Desirable characteristics of a radiopharmaceutical are that it should

1. be relatively inexpensive and easy to prepare,
2. remain intact chemically after administration,
3. concentrate rapidly in the organ of interest,
4. emit gamma rays of easily measurable energy,
5. emit little particulate radiation,
6. be eliminated rapidly from the organ after analysis, and
7. have a relatively short half life for radioactive decay.

Several radiopharmaceuticals satisfy these criteria for the study of specific organs and tissues in the body (Sorenson and Phelps, 1987).

The nuclide employed most frequently for nuclear imaging is a radioactive isotope of the element technetium known as technetium-99*m* (${}^{99}\mathrm{Tc}^{m}$), where 99 defines the isotopic form of technetium, and "m" depicts a metastable energy state (i.e., a higher-energy state with a lifetime significantly longer than the typical nuclear time scale of 10^{-13} s). This nuclide emits gamma rays of 140 keV, an almost ideal energy for measurement with a scintillation camera. Little particulate radiation is emitted with the gamma rays. The half life of technetium-99*m* (the time required for half of the atoms in a sample to decay) is 6 h, long enough to conveniently synthesize a radiopharmaceutical containing ${}^{99}\mathrm{Tc}^{m}$, and short enough to limit the absorbed dose delivered to tissue containing the nuclide. It can be readily incorporated into a variety of compounds with desirable physiologic properties. A major advantage of technetium is its production by decay of molybdenum-99 (${}^{99}\mathrm{Mo}$), an easily produced radioactive nuclide with a half life of 66 h. The molybdenum-99 can be placed on an ion-exchange column, and the ${}^{99}\mathrm{Tc}^{m}$ removed periodically in the laboratory by washing the column with a saline solution. Many nuclear medicine laboratories receive one or more of these "technetium generators" each week from a commercial supplier. Often a generator is referred to as a "technetium cow," and removal of the technetium, usually twice a day, is referred to as "milking the cow." An image of the liver obtained following intravenous administration of a colloidal suspension of technetium sulfide labeled with technetium-99*m*, is shown in Fig. 8.

At least 85% of all nuclear medicine studies are performed with technetium-99*m* incorporated into various chemical compounds for analysis of lung physiology, cardiac dynamics, liver integrity, kidney function, the presence of cancer metastases in bone and various organs, and a number of other conditions. Other radioactive nuclides used in specific applications include iodine-123 and iodine-131 for studies of the thyroid, and thallium-204 for detection of impaired heart muscle. The use of radiopharmaceuticals for medical diagnosis and evaluation is essential to the care of millions of patients each year, and the quality of their health care would be severely compromised if radiopharmaceuticals were not available.

4.2 Scintillation Camera

Almost all nuclear medicine images are obtained with a scintillation camera. This device includes a radiation detector consisting of a large-diameter (up to 20 inches) but very thin ($\frac{1}{4}$–$\frac{1}{2}$ in.) scintillation crystal of sodium iodide that is optically coupled to several (up to 70 or so) photomultiplier tubes. When a gamma ray emerging from the patient's body interacts with the crystal, light is emitted which is captured by the photomultiplier tubes. This process induces a signal in each tube that varies with the total amount of light emitted (and therefore the energy of the gamma ray), and with the distance of the tube from the interaction site in the crystal. By analyzing the signals from the photomultiplier tubes, the site of interaction in the crystal can be determined, as well as whether the interaction represents absorption of a primary gamma ray or one scattered into the crystal during a Compton interaction in the patient. By using a pulse-height analyzer to reject signals induced by scattered gamma rays, the anatomic detail presented in the image can be preserved.

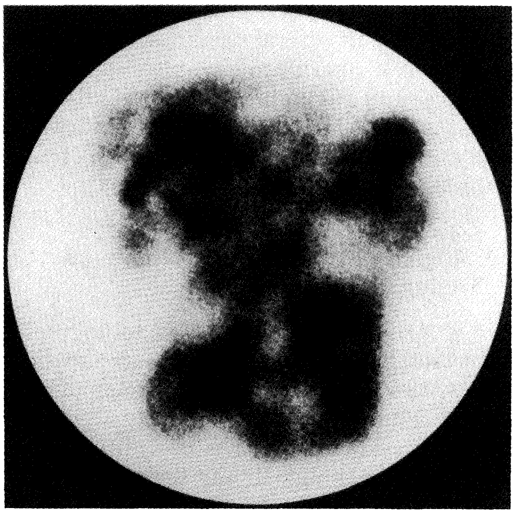

FIG. 8. A TcS liver image revealing areas of reduced uptake indicative of cancer metastases. [From Phillips and Bernardino (1988).]

Knowing where the gamma-ray interactions occur in the crystal is useful only if the interaction sites can be correlated with the origin of the gamma rays in the patient. This correlation is achieved by placing a mechanical collimator on the patient side of the scintillation crystal. The type of collimator most often used is the parallel multihole collimator. With this collimator, a gamma-ray interaction in the crystal can be correlated with the origin of the gamma ray directly below the interaction site. In this manner the distribution of interactions across the crystal reflects the distribution of radioactivity in a region of the patient directly below the crystal. Other types of collimators that are useful in limited applications include the pin-hole collimator (particularly helpful in thyroid imaging) and the converging collimator (used primarily for cardiac studies).

Nuclear images reveal the static distribution of radioactivity in a particular organ or region of the body, or the transient passage of radioactivity through the organ or region. Nuclear images are captured on film as a permanent record, often in a multiformat camera that places several sequential images on one large sheet of photographic film. Data processing by computer is an integral feature of nuclear imaging, and permits quantitative measurement and display of the distribution of radioactivity in selected regions of interest over time. Production of radioactive pharmaceuticals, and acquisition and interpretation of nuclear images requires the involvement of specialists in several disciplines, including chemistry or pharmacology, physics or engineering, and medicine. Consequently, nuclear medicine is a true multidisciplinary specialty that represents the leading edge of high technology in medicine (Saha, 1984).

4.3 Single Photon Emission Computed Tomography

The principles of computed tomography have been applied to nuclear imaging to yield the useful imaging technique of single photon emission computed tomography (SPECT). The expression "single photon" is included in the title to distinguish the technique from Positron Emission Tomography (PET) in which images are produced by collecting annihilation photons emitted and collected in pairs. In the SPECT approach, images of the distribution of radioactivity in the patient are obtained from several orientations, usually with a rotating camera that acquires data from several angles during the examination. These projection data are combined by computer to yield cross-sectional images of the distribution of radioactivity. Application of the SPECT approach to nuclear imaging is particularly useful in studies of the heart where cross-sectional displays of radioactivity in the myocardium reveal damage to the heart muscle caused by diminished blood flow in the coronary arteries. Another application of growing importance is the use of SPECT to study the distribution of radioactivity in the brain, and how the distribution is affected by conditions such as Alzheimer's dementia, epilepsy, and stroke. Additional applications are under development, and SPECT is today an important part of the services offered by any nuclear imaging facility.

4.4 Positron Emission Tomography

Atomic nuclei with a ratio of neutrons to protons that is too low for stability tend to decay by the emission of positively charged electrons. These electrons are referred to as positrons. In the immediate vicinity of their origin, positrons unite with electrons to produce annihilation photons, electromagnetic radiations of 0.51 MeV that leave the annihilation site in opposite directions. If a positron-emitting pharmaceutical is administered to a patient, the annihilation photons can be detected with scintillation detectors positioned on opposite sides of the patient. By operating the detectors in coincidence (i.e., an interaction is recorded only if it occurs in both detectors simultaneously), the origin of the photons can be localized to the cylinder of tissue between the two detectors. If the patient were examined with coincidence detectors operated at different angles, the origin of the photons could be localized to a small volume of tissue within the patient.

In a positron emission tomographic (PET) imaging device, the patient is surrounded by a ring of detectors, with each detector operated in coincidence with a few detectors on the opposite side of the patient. Annihilation photons are detected by this network of coincidence detectors to yield a tomographic image of the distribution of the positron-emitting pharmaceutical across a slice of tissue through the patient. The usefulness of PET imaging is being explored for a number of applications, including the detection of cancer and the study of heart disease. But the application generating the greatest interest is the use of PET for studying the physiology of the brain.

Several investigators are studying the usefulness of PET for fundamental investigations of mental activity in response to various internal and external stimuli, and for evaluation of a number of mental disorders ranging from dementia and depression to schizophrenia and sociopathic behavior (Wong, 1990). In addition, PET is being used to examine conditions such as autism and dyslexia. In these studies, images of the rate of utilization of positron-labeled glucose derivatives, or of the concentration of other positron-containing agents, are examined to determine how well they delineate the condition under investigation. Examples of PET images of the utilization of deoxyglucose labeled with the positron emitter carbon-11 are shown in Plate 1 for an individual subjected to various external stimuli.

5. RADIATION THERAPY

Radiologic diagnosis is accomplished by exposing the body to radiation delivered by a distant source (x-ray imaging), or by measuring radiation from a source of radiation present inside the body (nuclear imaging). Similarly, radiation therapy of cancer is conducted by exposing the body to an external source of radiation (teletherapy, where "tele" is from the Greek for *distant*), or by placing one or more radiation sources inside the body (brachytherapy, where "brachy" is from the Greek for *short*). Although most applications of radiation therapy employ x or gamma rays, beams of energetic electrons sometimes are used, and other types of particles are being explored experimentally.

Before WWII, teletherapy was performed almost entirely with x rays of intermediate energy (between 100 and 400 keV). These x rays were not very penetrating, and high doses were required to superficial tissues in order to deliver enough radiation to the cancer. The highest doses often were administered to the skin, and inflammation and burning of this sensitive tissue often occurred during treatment. In fact, skin reddening (erythema) was used as an indicator of the effectiveness of the treatment and the ability of the patient to withstand it.

5.1 High-Energy Teletherapy

At the close of WWII, nuclear reactors became available for the production of radioactive nuclides that might be useful in medicine. One of the first nuclides to be explored was cobalt-60 (^{60}Co) for use in radiation therapy. Each decay of a ^{60}Co nucleus releases two gamma rays that are high enough in energy (1.17 and 1.33 MeV) to deliver the maximum dose a few millimeters below the skin rather than on the skin surface. This "skin-sparing effect" of ^{60}Co greatly reduced the problems of inflammation and burning encountered with x rays of lower energy. For this reason, and because the gamma rays are more penetrating than conventional x rays, ^{60}Co teletherapy units were widely adopted for radiation therapy in the 1950s and 1960s. However, the skin-sparing effect also removed a familiar landmark with which the radiation oncologist monitored the patient's treatment. In place of this landmark, indirect methods of dose estimation became very important to the delivery of radiation treatments. These methods required more elaborate dosimetry and treatment planning, and many physicists became involved in clinical radiation therapy. Although a few physicists had worked in radiation therapy in earlier years, the advent of high-energy therapy with ^{60}Co required many more, and gave rise to the specialty of medical physics.

Although ^{60}Co units were a major advance in treating cancer with radiation, they had some disadvantages as well. Unlike an x-ray tube, a ^{60}Co source could not be "turned off," since it is always radioactive. Hence, elaborate means were required to shield the source when not in use, and to move it automatically into position during treatment so that a beam of unshielded radiation could be directed towards the patient. This massive shielding made ^{60}Co units bulky and difficult to maneuver into desired positions around the patient. Also, the ^{60}Co source was relatively large, and the edges of the radiation beam were not as well-defined as needed for precise separation of treated and untreated tissues. Cobalt-60 decays with a half life of 5.3 yrs, and the high-activity sources used for teletherapy had to be replaced every few years, a precarious operation for all involved. Finally, the intensity of radiation delivered by a ^{60}Co source was limited by the activity of the source, and was never as high as might be desired for the treatment of some types of cancer. These limitations resulted finally in replacement of most ^{60}Co units with linear accelerators in the late 1960s and 1970s.

Linear accelerators provide a versatile and dependable method for delivering high-energy x rays (a few MeV) in a sharply defined beam to cancers deep within the body. The x-ray beam can be directed towards the cancer from several directions so that the absorbed dose is concentrated in the cancer, while the dose to overlying tissues is spread over several entrance pathways. The technique of using x-ray beams at several orientations is referred to as a multiple-field treatment, and permits delivery of higher doses to the cancer without major complications caused by the irradiation of normal tissues. In addition, tissues such as the spinal cord, esophagus and rectum that are particularly sensitive to radiation often can be spared from direct exposure to radiation (Withers and Peters, 1988). Many linear accelerators also permit extraction of the electron beam for treatment of certain cancers by electrons rather than by x rays.

5.2 Treatment Planning

The delivery of high doses of radiation to cancers deep within the body is a challenging problem. Enough radiation must be delivered to kill all (or nearly all) of the cancer cells in patients for whom there is a reasonable prospect of cure. In some patients this prospect is remote at best, possibly because the cancer has already spread to one or more essential organs, or perhaps because the cancer is present in a critical organ and has already done so much damage that the patient cannot survive. Radiation plays a vital role in the treatment of these patients as well, because it can prevent further spread of the cancer, and often shrink its volume, thereby preventing or alleviating some of the agony that often accompanies cancer. This use of radiation is called palliative therapy. In a typical radiation therapy facility, about half of the patients are seeking a cure, and the others are undergoing palliative therapy.

With all radiation therapy patients, enough radiation must be delivered to the cancer to accomplish the objective of treatment. At the same time, great care must be taken to not expose normal tissues, especially those particularly sensitive to radiation, to an amount of radiation that will initiate severe consequences. Achieving this balance is the challenge of radiation therapy, and it is why the high-energy x rays, sharply defined beams, and versatile orientations provided by the linear accelerator are major advantages. It is also why a full course of radiation treatment requires several weeks. Normal tissues can tolerate more radiation if it is delivered gradually rather than all at once. This challenge is also why careful and precise planning of radiation treatments is essential.

Radiation treatments are planned in a series of steps that require the work of physicians, physicists, and technologists. First the patient is examined by the radiation oncologist, who may request additional imaging studies to complement those in the patient's file. The oncologist provides information about the patient's anatomy, including the location of the cancer and diagnostic images relevant to the case, to the medical physicist who enters the information into a computer. The physicist's responsibility is to generate a treatment plan, usually in consultation with the oncologist, that delivers an adequate amount of radiation to the cancer and preserves normal tissues to the maximum extent possible. The treatment plan is constructed on a computer in which the physical characteristics of a variety of radiation beams are simulated from data obtained by direct measurements on the treatment unit. These simulated data are positioned in the computer at the orientations proposed for the treatment beams, and composite curves are constructed to display the summation of radiation doses at each location in the patient. Analysis of the composite curves allows the oncologist and physicist to judge whether the proposed treatment plan is satisfactory.

Often a number of treatment plans are constructed for a patient before one is identified that satisfies the criteria for a satisfactory plan. The accepted plan is then implemented on a treatment-planning simulator that resembles the radiation therapy unit except that

the patient is exposed to diagnostic x rays rather than to the high-energy x rays used for treatment. Images obtained with the simulator are used to verify the acceptability of the treatment plan and to refine it where necessary. Once a plan judged acceptable by the oncologist and physicist has been constructed by iteration between the computer and simulator, treatment of the patient can begin. A computer-generated treatment plan for a radiation therapy patient is shown in Fig. 9.

5.3 Brachytherapy

For a small source of radiation, the intensity of radiation decreases as the square of the distance from the source, a property known as the "inverse square law." By placing small sources of gamma rays within tissue to be treated, large doses can be delivered to cancer cells in the immediate vicinity, with much smaller doses administered to tissues farther away. Of course, the tissue to be treated must be accessible for implantation of the sources. Regions of the body where gamma-ray sources can be implanted include the skin, oral cavity, vagina, uterus, and prostate. By far the most common application of the technique of "short-distance" or brachytherapy is its use for treatment of cancer of the uterus and vagina.

For many years radium was almost the only radioactive nuclide employed for brachytherapy, and the technique still is sometimes referred to as radium therapy. However, radium is almost never used today, because cesium-137 sources in the form of capsules and needles are safer to use and store. Also used occasionally are small seeds of iodine-125 for treatment of prostate cancer. These seeds are permanently implanted with a pistol-like impeller, where they deliver radiation as they decay with a half life of 60 days.

Careful dosimetry and treatment planning is as important for brachytherapy as it is for teletherapy. In treatment of cancer of the uterus, for example, a high dose of radiation is delivered over a period of a few days with a source applicator that is removed from the patient after the desired dose has been reached. The preferred time for removal is

determined from computer-generated computations of the dose distribution estimated from images obtained with the applicator in place in the patient. After removal of the applicator, most patients are subjected to additional radiation from an external beam to treat cancer cells that may have spread to surrounding lymph nodes. This radiation is then added by computer to the dose delivered by the applicator to yield a composite dose distribution for the entire course of therapy.

5.4. Particle Therapy

Electron beams from a linear accelerator are particularly useful for treating relatively superficial cancers. These beams deliver a relatively uniform dose of radiation over a depth of a few centimeters corresponding to the range (penetration) of the electrons in tissue. The range of the electrons varies directly with the energy of the electrons, which can be varied within limits with most accelerators. Beyond the electron range, the radiation dose decreases very rapidly, and tissues beyond the treated region receive very little radiation. The dosimetry of electron beams is more complex than that for x and gamma rays and represents a continuing challenge to medical physicists.

Neutrons also are being studied for their possible use in radiation therapy. For example, neutron beams from cyclotrons are under investigation in a few institutions around the world for their effectiveness in treating a wide variety of cancers (Cohen and Awschalom, 1982). One potential advantage of neutrons is that they are more effective than x rays in killing poorly oxygenated cells that may be present in the central region of cancers. It is the survival of these cells that may be responsible for the occasional recurrence of cancers after their treatment with radiation. Preliminary results from the clinical trials of neutrons are promising, but definitive data have not yet been collected for most cancer sites.

Heavy charged particles (charged particles with a mass greater than that of an electron) also have been investigated for their possible uses in radiation oncology. These particles offer excellent treatment characteristics because of the manner in which they deliver energy to tissue. As a beam of heavy charged particles enters a patient, it produces only light ionization along its path, and the surrounding tissue receives a relatively low dose of radiation. Near the end of the trajectory of the charged particles, however, the rate of energy deposition increases markedly, creating a concentration of radiation dose at depth in a region known as the Bragg peak. The depth of the peak can be altered by varying the particle energy, and the width of the peak region can be changed by inserting a "range modulator" that continuously varies the amount of external absorber in the path of the charged particle beam. In this manner, the Bragg peak can be shaped to encompass cancer cells located at a specific depth and occupying a particular space in a patient. Beyond the Bragg peak, the dose from the charged particle beam rapidly falls to near zero. The characteristics of charged particles are illustrated in Fig. 10, in which the dose-delivery properties of helium ions are compared with those of 24 million volt x rays.

Heavy charged particles are described as high LET (linear energy transfer) radiations, because they produce dense ionization and deliver high radiation doses in the region of the Bragg peak. High LET radiation is especially effective in killing cells in the center of a cancer that are deprived of oxygen (so-called hypoxic cells) and that are relatively resistant to destruction by x and gamma rays. The oxygen enhancement ratio (OER) is the quotient of the radiation dose needed to produce a given effect (e.g., cell killing) in the absence of oxygen, divided by the dose required to produce the same effect in the presence of oxygen. Beams of charged particles have OERs near unity, whereas x and gamma rays

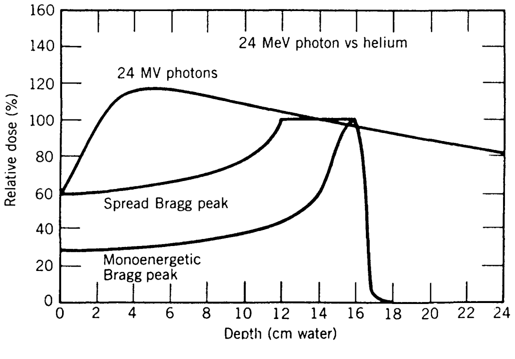

FIG. 10. Comparison of depth dose distributions for 24-MV x rays, monoenergetic, and spread Bragg peak helium beam. [From Chen (1988).]

exhibit OERs usually in the range of 2–3. Hence, only $\frac{1}{2}$–$\frac{1}{3}$ as much dose may be required from charged particles compared with x and gamma rays to reduce the fraction of surviving cells to a prescribed level. Many investigators believe that the biological advantages of heavy charged particles are even more important than their physical characteristics with respect to the application of charged particles to radiation oncology.

Heavy charged particles that offer potential advantages for radiation oncology include protons, helium ions, and accelerated nuclei of carbon, neon, silicon and argon. The earliest exploration of heavy charged particles for radiation oncology was the pioneering work of scientists at Berkeley (Tobias, Anger, and Lawrence, 1952). Since 1975, several hundred cancer patients have been entered into clinical trials with heavy charged particles at the Lawrence Berkeley Laboratory, and explorations of charged particles are currently underway in several other institutions, including Harvard University, University of Uppsala, United Kingdom Atomic Energy Authority, and the Institute of Clinical and Experimental Oncology in Moscow (Raju, 1980). Cancers being treated include malignant tumors of the brain, advanced cancers of the head and neck region, esophagus, stomach and pancreas, sarcomata arising in bone, choroidal melanomas of the eye, and juxtaspinal tumors (Chen, 1988). In addition, several nonmalignant diseases have been treated, including benign tumors of the pituitary and arteriovenous malformations (Verhey and Munzenrider, 1982).

6. FUTURE PROSPECTS

The use of ionizing radiation as a diagnostic probe to reveal abnormal conditions within the patient is an invaluable tool in medicine. In recent years it has been supplemented by important diagnostic advances such as ultrasonography and magnetic resonance imaging. Additional nonradiation technologies such as magnetic source imaging and electrical impedance tomography offer promise for the future. Although these advances complement the use of radiation for the production of diagnostic images, they are unlikely to replace more traditional imaging techniques such as radiography, fluoroscopy, and nuclear medicine. The most probable scenario for the near future is an increased digitization of traditional imaging techniques, and a gradual but continual movement towards integrated diagnostic imaging services networked through picture archiving and communications systems.

For decades self-professed clairvoyants have predicted the replacement of conventional radiation therapy by the use of cellular poisons, monoclonal antibodies labeled with radioactivity, and other "magic bullets" that will target cancer cells selectively for destruction while producing little damage to normal cells. These predictions have yet to be realized, principally because substances have not been developed that select only cancer cells with adequate sensitivity and specificity. Furthermore, many cancers are discovered only after they have grown and spread to such an extent that they produce clinical symptoms in the patient. These patients are less desirable candidates for the "magic bullet" approach to treatment, even if one were available. It seems safe to assume that radiation therapy will continue as an effective approach to cancer therapy for several years to come.

GLOSSARY

Absorber: Any material that absorbs or lessens the intensity of ionizing radiation.

Absorption: The process by which the number of particles or photons entering a body of matter is reduced or attenuated by interaction with the matter.

Alpha Particle: A positively charged particle ejected spontaneously from the nuclei of some radioactive elements. It is identical to a helium nucleus that has a mass number of 4 and an electrostatic charge of $+2$. It has low penetrating power and short range.

Attenuation: The process by which a beam of radiation is reduced in intensity when passing through some material. It is the combination of absorption and scattering processes.

Beta Particle: A charged particle emitted from a nucleus during radioactive decay, with a mass equal to $\frac{1}{1837}$ that of a proton. A negatively charged beta particle is identical to an electron. A positively charged beta particle is called a positron.

Decay, Radioactive: The decrease in the amount of any radioactive material with the passage of time, due to the spontaneous emission from the atomic nuclei of either alpha or beta particles, often accompanied by gamma radiation.

Detector: A material or device that is sensitive to radiation and can produce a response signal suitable for measurement or analysis. A radiation detection instrument.

Electromagnetic Radiation: A traveling wave motion resulting from changing electric or magnetic fields. Familiar electromagnetic radiations range from x rays (and gamma rays) of short wavelength, through the ultraviolet, visible, and infrared regions, to radar and radio waves of relatively long wavelength. All electromagnetic radiations travel in a vacuum with the velocity of light.

Gamma Ray: High-energy, short-wavelength electromagnetic radiation (a gamma packet of energy) emitted from the nucleus. Gamma radiation frequently accompanies alpha and beta emissions.

Geiger-Mueller Counter: A radiation detection and measuring instrument. It consists of a gas-filled tube containing electrodes, between which there is an electrical voltage but no current flowing. When ionizing radiation passes through the tube, a short, intense pulse of current passes from the negative electrode to the positive electrode and is measured or counted. The number of pulses per second measures the intensity of radiation.

Gray: A unit of absorbed dose in the International System of Units (SI), equal to 1 joule per kilogram.

Ionization: The process of adding one or more electrons to, or removing one or more electrons from, atoms or molecules, thereby creating ions. High temperatures, electrical discharges, or nuclear radiations can cause ionization.

Ionization Chamber: An instrument that detects and measures ionizing radiation by measuring the electrical current that flows when radiation ionizes gas in a chamber, making the gas a conductor of electricity.

Ionizing Radiation: Any radiation capable of displacing electrons from atoms or molecules, thereby producing ions. Examples: alpha, beta, gamma, and x rays, neutrons, and ultraviolet light. High doses of ionizing radiation may produce severe skin or tissue damage.

Photon: A quantum (or packet) of energy emitted in the form of electromagnetic radiation. Gamma and x rays are examples of photons.

Positron: Particle equal in mass, but opposite in charge, to the electron; a positive electron.

Rad: Acronym for radiation absorbed dose. A basic unit of absorbed dose of radiation.

Radiation: Particles (alpha, beta, and neutrons) or photons (gamma) emitted from the nucleus of an unstable (radioactive) atom as a result of radioactive decay.

Radioactivity: The spontaneous emission of radiation, generally alpha or beta particles, often accompanied by gamma rays, from the nucleus of an unstable isotope.

Radioisotope: An unstable isotope of an element that decays or disintegrates spontaneously, emitting radiation. Approximately 5000 natural and artificial radioisotopes have been identified.

Roentgen: A unit of exposure to ionizing radiation.

Scintillation Detector or Counter: The combination of phosphor, photomultiplier tube, and associated electronic circuits for counting light emissions produced in the phosphor by ionizing radiation.

Sievert: A unit, in the International System of Units (SI), of dose equivalent which is equal to 1 joule per kilogram.

Survey Meter: Any portable radiation detection instrument especially adapted for inspecting an area to establish the existence and amount of radioactive material present.

X Rays: Penetrating electromagnetic radiation (photon) having a wavelength that is much shorter than that of visible light.

INTRODUCTION

Biophysics is the synthesis of chemistry, physics, and biology. Biophysicists elucidate the chemical and physical processes of biological molecules and systems through the application of physical techniques. Since biophysics is a diverse and broad field spanning the extremes of science, often what one considers biophysics is related to one's point of

digital Encyclopedia of Applied Physics

view. For example, a physicist may apply the principles of chaos to the cardiac cycle, whereas a chemist's interests may be along the lines of understanding how a small molecule such as oxygen binds to hemoglobin.

Biological molecules and systems are inherently complex. The quote by P. W. Anderson, "more is different" (Anderson, 1982), underscores the idea that new physics and new phenomena will emerge from the study of complicated molecules and systems that would go undiscovered by the study of simple systems alone. It is precisely this complexity that provides the intellectual challenge in biophysics.

Key questions in biophysics concern the way that biological information is encoded, processed, stored, and used, as well as the structure and function of biological molecules. The goal is to understand how biology implements, e.g., assembly, recognition, energy transduction, transport, distributed information coding, sensing, and perception. Biological information is stored and processed at several different levels, ranging from "simple" biological molecules such as DNA and strings of amino acids, to complicated organs such as the brain. Given the complexity of biophysics and the enormous range of science that it encompasses, an introductory article on biophysics cannot possibly cover all aspects of the field. Recognizing this dilemma, we have chosen to introduce the reader first to the building blocks of biology, then to the physical techniques used to study them, and finally to a detailed example of the application of biophysics to the visual system.

In this article, the building blocks are presented according to their biological hierarchy, beginning with the simplest molecules of life, the nucleic acids and the amino acids, and following their assembly into DNA (deoxyribonucleic acid) and proteins. These larger molecules do not function in isolation, but rather are incorporated into membranes and organelles such as the nucleus or the mitochondria. These organelles are the functional elements of cells, which are themselves assembled into organs. Each organ carries out its specific function in the organism. Finally, the organisms themselves form systems, such as bacterial colonies. Biophysics embodies the study of each level in this hierarchy as well as the information transfer between levels.

Many physical techniques provide unique windows into the biological structure and function of these various levels of hierarchy. Recognizing that each of these physical techniques cannot be covered in reasonable depth in this article, we describe them only briefly and tabulate their typical applications.

We have chosen a single example, the visual system, to illustrate the scope of biophysics. We will follow this system, beginning with its molecular assembly, to the rods and cones, and finally up to visual perception and processing of visual information. The visual system will thus be used to highlight selected techniques of biophysics.

1. BUILDING BLOCKS OF BIOLOGICAL SYSTEMS AND THEIR HIERARCHICAL ASSEMBLY

1.1 Simple Building Blocks

Biological systems are built from relatively few basic molecular units. The many diverse functions of complete molecules, organelles, and organs result from the composition, order, and arrangement of these small building blocks. It is for this reason that a major focus in biophysics has been to elucidate the structure of biological molecules in order to determine how a given structure leads to a specific biological function. To appreciate the contributions biophysical studies have made in the past and can make in the future on the understanding of biological molecules and processes, it is necessary to be familiar with these fundamental molecules of biology and to know how they are combined and assembled into complex systems that carry out the functions that are necessary for the survival of the organism. We first describe the simple building blocks and how they are combined to form the basic molecules of biology. We then show how these molecules of biology are assembled into living structures. Many fine reference books are available where in-depth information on biomolecules may be obtained. See, e.g., Alberts *et al.* (1983) and Stryer (1988).

1.1.1 Nucleic Acids and the Central Dogma of Molecular Biology. The existence and continuity of life and its diversity depend on the order of four simple bases which are the functional elements of DNA. These four bases (nucleotides) are joined to form a polynucleotide by a polymeric sugar-phosphate (see Sec. 1.1.4) backbone. The entire assembly is called a biopolymer. Owing to this very simple structure, illustrated in Fig. 1, polynucleotides are the most highly ordered class of biological macromolecules. In DNA there are four nitrogenous bases: adenine (A) and guanine (G), which are purine derivatives, and cytosine (C) and thymine (T), which are pyrimidine derivatives. The structure of DNA is formed by attaching one of these bases to a deoxy ribose sugar through a glycosidic linkage. The deoxy ribose is connected to phosphate groups at its 3′ and 5′ positions forming a backbone for the macromolecule. Specific base pairing (A to T, G to C) (see Sec. 1.2, Fig. 5) through hydrogen bonding permits DNA to exist in a double helix of complementary polymeric strands, although many single-stranded forms of polynucleotides also exist. The order (primary structure) of the base pairs determines the end products of protein synthesis and the arrangement (secondary structure) determines the efficiency of the synthetic process. Ribonucleic acid (RNA) is closely related to DNA. The sugar of RNA differs from that of DNA by having a hydroxyl group at the 2′ position rather than a proton. The bases of RNA are adenine, guanine, cytosine, and uracil instead of the thymine which is present in DNA.

The process by which the genetic information which is stored in the DNA is translated into a protein sequence has been termed by

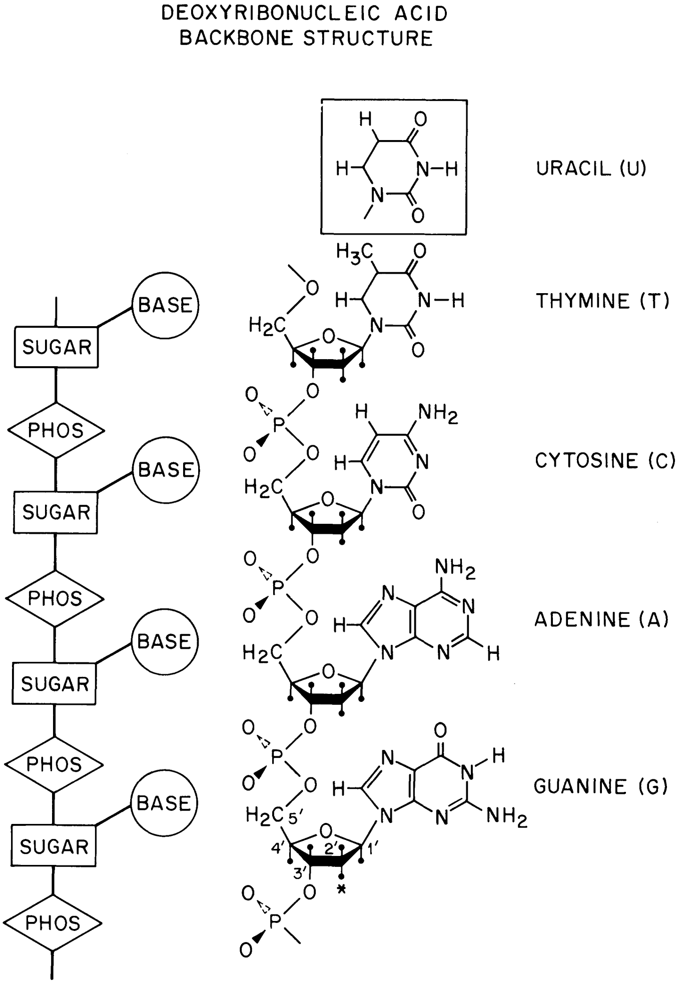

FIG. 1. Structure of polynucleotides. The black dots on the ribose (sugar) units of the molecular structure of deoxyribonucleic acid (DNA) represent hydrogen atoms. In ribonucleic acids (RNA) the 2′ position on each ribose, one of which is marked with an asterisk, has an OH group on it. Thymine, cytosine, adenine, and guanine are the bases in DNA and uracil replaces thymine in RNA.

Francis Crick as "the central dogma of molecular biology." It involves a series of steps known as replication, transcription, and translation (Watson, 1977). This process, illustrated in Fig. 2, involves the flow of information from DNA of the gene to a series of RNAs, to the formation of protein sequences in an organelle within the cell called a ribosome. In all eukaryotic species (all plants and animals other than bacteria and certain algae) the DNA of the gene is sequestered in a membrane-bound organelle (the nucleus) and is wrapped around a protein structure (a histone). It is the interaction between DNA and the histone that allows the very long strands of DNA, nearly 1 m long in the human genome, the full set of chromosomes, to fit into the very small nucleus. Biophysical studies using electron microscopy have played an essential role in identifying and determining the organization of the strands of DNA in the various organelles. Furthermore, the structure of DNA first reported by Watson and Crick (1953) was the triumph that ushered in the era of molecular biology. Biophysical studies have played a central role in determining the complex series of events which comprise the "central dogma." The techniques of x-ray crystallography and electron microscopy have been essential in determining the structures of DNA, the many RNAs that are part of the information transfer, and the protein-polynucleotide complexes which are crucial elements of the pathway.

The transcription process (Fig. 2) involves transcribing the genetic information in the DNA to RNA. In this process three different types of RNA are formed: messenger RNA (mRNA), which contains the genetic message, ribosomal RNA (rRNA), which is a component of the ribosomes, a set of oganelles in which protein synthesis takes place, and transfer RNA (tRNA), which transports amino acids to the ribosomes for incorporation into proteins. The "workbench" for protein synthesis is the ribosome where the mRNA translates its message into the protein sequence. Translation of genetic information into the protein sequence depends on the genetic code (i.e., a mapping from the sequence of bases in RNA to specific amino acid residues). The discovery of this code is one of the great achievements of molecular biology (it can be considered its Rosetta Stone). It was found that a sequence of three bases codes for a specific amino acid. For example, AUG codes for methionine and GCU, GCC, GCA, and GCG all code for alanine. Thus, the protein sequence information is completely stored in the primary structure of the polynucleotides. These sets of three bases that code for specific amino acids are known as "codons."

All the proteins needed by the organism are synthesized on the ribosomes. The mechanism by which a polypeptide, generated in the ribosome, folds into a biologically active protein is very complex and is currently a

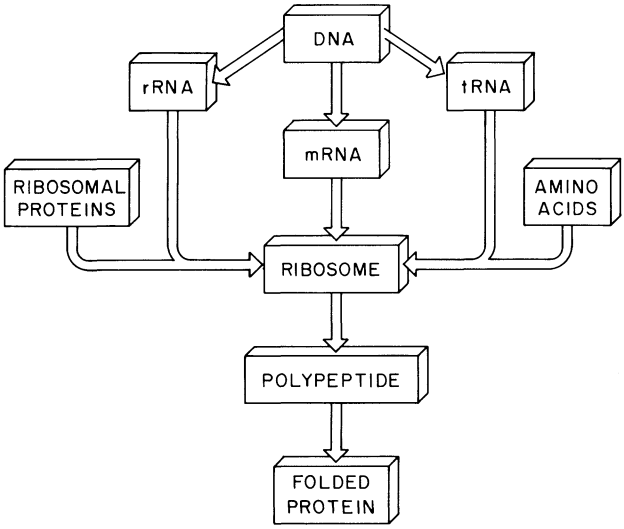

FIG. 2. The flow of genetic information from DNA to assembled proteins.

topic of intensive experimental and theoretical biophysical studies. Indeed, the protein folding problem, to be discussed in more detail below, has been termed the second half of the genetic code. Another area of extensive study involves the controlling mechanisms by which protein synthesis is initiated and terminated.

1.1.2 Proteins. Proteins, the product of genetic translation, form the foundation, structure, and machinery of life. In order for proteins to carry out their diverse functions they have structures that are far more complex than the polynucleotides. Furthermore, whereas the polynucleotides have only 4 bases, proteins are comprised of 20 amino acids, each with different characteristics. Proteins with vastly different properties may be generated, depending upon how the amino acids are combined in a polypeptide chain. Many proteins function as enzymes, i.e., they catalyze a specific chemical reaction. There is an enormous number of chemical reactions that are constantly occurring in any living system. In the absence of the catalytic properties of enzymes the progress of these reactions would be so slow that life could not exist. Enzymes speed up these reactions by 1000-fold or more. To have the specificity needed to function in only selected chemical reactions, both the diversity of the amino acid properties and the final three-dimensional structure are fully utilized. For example, some proteins are membrane-bound (see Sec. 1.1.3). These proteins have hydrophobic amino acid residues on their exterior that allow them to interact with the lipids of the membrane. Enzymes exhibit high specificity, since they possess very specific active sites each of which will react with only a single type of molecular group. This function is achieved by forming a structure, called an active site, that contains a specific set of amino acids according to their size, charge, and hydrophobicity. Certain proteins also incorporate special ligands or chromophores within their structures, such as the retinal group of rhodopsin or the heme group of hemoglobin.

Proteins display several levels of structural organization. The first level is the primary structure, which is the sequence of the amino acid residues comprising the protein (see Fig. 3). The amino acid residues are joined by peptide bonds between the amine group of one amino acid and the carboxylic acid group of another. The secondary structure involves local interactions between the adjacent amino acids of the chain. The most frequently found secondary structures are alpha helices (Fig. 3) and beta sheets (so named because the α helix was the first structure identified and the β sheet was the second). As their names imply, in the alpha-helical structure the polypeptide chain is coiled into a helix, whereas in the beta-sheet configuration the polypeptide chains are arranged into a pleated sheet-like configuration. The configuration that a given amino acid sequence adopts is determined by both the amino acid sequence of that segment and its overall environment. The tertiary structure of a protein involves the long-distance interactions in the protein and the spatial arrangement of the helices and sheets with respect to each other. Many forces are involved in determining the tertiary structure, including hydrogen bonding, van der Waals interactions, and electrostatic forces. The complexity and long-range nature of these forces makes prediction of the tertiary structure of a protein from its amino acid sequence extremely difficult. This is currently a very active area of biophysics research. Its full understanding will lead to a knowledge of the interactions that hold proteins together as well as a tool for predicting structures and thereby tailoring proteins for specific needs. The final level of organization of proteins lies in the quaternary structure. This is the relationship between independent polypeptide chains in proteins which have multiple subunits, such as hemoglobin. In the case of hemoglobin small changes in the relationship of the subunits can significantly affect the functioning of the local active site of the protein. The way long-range structure can influence local functional properties is another area of intense biophysical research.

In the past, inferences concerning the influence of particular amino acids on protein function could not be tested readily. However, since the development of recombinant DNA technology, site-directed mutagenesis has allowed the replacement of one amino acid by another, almost at will. Thus, the influence of specific amino acids can be tested directly. This development has significantly changed the field of biophysics by allowing many qualitative inferences to be tested spe-

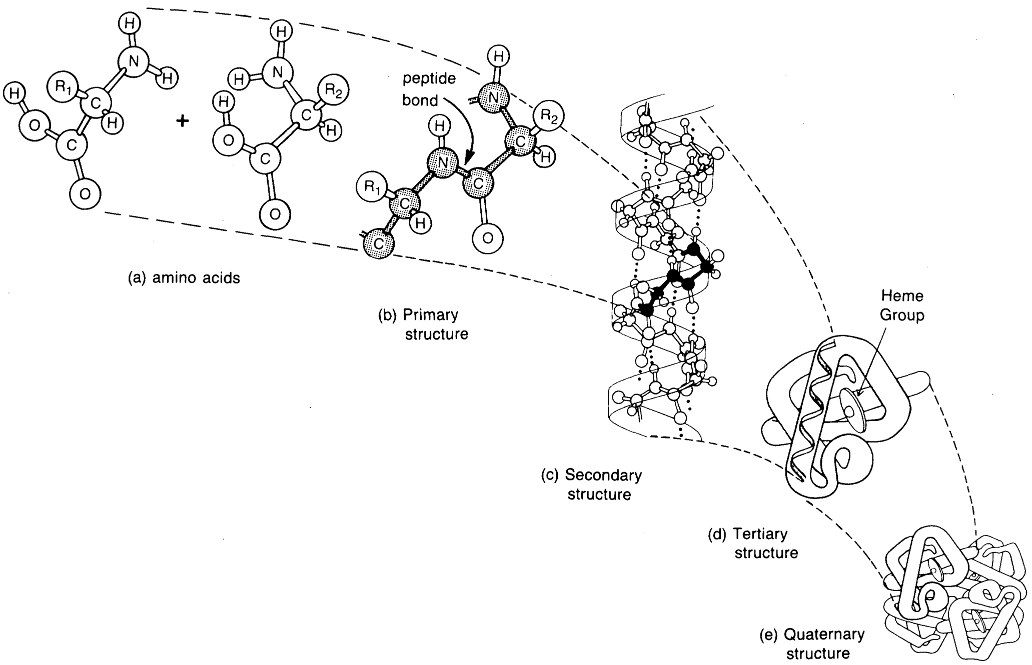

FIG. 3. The levels of protein structure. Amino acids (a) form a peptide bond (b) through the condensation of an amine group with a carboxylic acid. The order of the amino acids in the chain constitutes its primary sequence. The secondary structure (c) pertains to the formation of specific ordered but local structures such as helices, β sheets, or loops. The tertiary structure (d) is the three-dimensional relationship between amino acids, helices, and sheets that are far from each other in the sequence. For those proteins which have more than one subunit, the arrangement of the subunits is referred to as the quaternary structure (e). The illustration in the figure refers to hemoglobin in which there is a heme group in each of the four subunits. The assembled tetramer comprises the hemoglobin molecule. [Adapted from Becker (1986), p. 86.]

cifically and often quantitatively (e.g., see Nagai *et al.*, 1987).

1.1.3 Lipids and Biological Membranes. A unique feature of living systems is that they are always operating out of equilibrium. This aspect of living systems is necessary so that the many ionic and molecular gradients that are used to generate chemical energy are maintained. The gradients are maintained by lipid bilayer membranes that encapsulate cells and organelles. These membranes are loaded with proteins that shuttle various ions and molecules across the membrane to maintain the needed gradients. These proteins may passively transport specific ions and molecules across the membrane by opening and allowing them to pass in the direction of the concentration gradient, or the proteins may actively translocate ions or molecules across the membrane by utilizing energy to transport ions against a gradient. The understanding of how such proteins function is currently a topic of extensive theoretical and experimental research.

Lipids are the structural elements of membranes. Most lipids are rod-like molecules, one end of which is hydrophobic and the other end of which is hydrophilic (see Fig. 4). Consequently, it is energetically favorable for lipids to assemble into a bilayer structure. In this bilayer all of the hydrophilic sections of the lipid are on the outside and the hydrophobic tails are on the inside, thereby forming a membrane which is about 75 Å thick. The spontaneous permeability of molecules and ions through the layered membrane barrier is very small. Such membranes enclose cells (plasma membranes) and enclose organelles within eukaryotic cells.

The most prevalent biological lipids are phospholipids. The structure of a typical phospholipid, phosphatidylcholine, is shown in Fig. 4. It consists of fatty acid hydrocarbon tails and a polar "head group" made up of

glycerol, phosphate, and an alcohol. Different alcohols are present in various lipids. Although the structural element of the membrane is the lipid molecule, biological membranes contain high levels of protein. Even myelin, which is an insulator around nerve cells, contains about 20% protein. Other membranes such as the inner mitochondrial membrane contain 75% protein. These proteins carry out extensive biological functions.

Whereas membranes serve as the structural elements, the proteins associated with them carry out many important biological functions. Proteins in membranes serve as channels, pumps, gates, receptors, structural anchors, identity markers, and enzymes. For example, in the mitochondrial inner membrane the chemical energy resulting from the burning of fuels, such as carbohydrates, is used to generate ATP (adenosine triphosphate), the energy currency molecule. ATP supplies the energy for chemical reactions, protein synthesis, and the generation and maintenance of molecular and ionic gradients throughout the organism. Diffusional properties are key features of the membrane, and are necessary for the proper function of many proteins. Within the plane of the membrane, lipid diffusion is very fluid. This is termed lateral diffusion and has been studied extensively by biophysical techniques, especially fluorescence. The rate of lateral diffusion of lipids in membranes is in the range of 2 μm/s. Some proteins have diffusion rates in membranes that are similar to that of lipids whereas others have much slower rates. For example, the diffusion rate of the photoreceptor protein molecules (rhodopsin) in the membrane is ~ 1 μm/s, very similar to that of lipids (Stryer, 1988). The flip-flop (transverse diffusion) of lipids or proteins from one side of the membrane to the other is very slow for lipids (rate about one per several hours) and has not been detected for proteins. This is an essential feature for the functional aspects of proteins in lipid membranes since many of the functions depend on the directionality of the protein in the membrane. This is true in energy generation, e.g., in which the production of ATP is driven by a proton gradient across a membrane.

1.1.4 Carbohydrates. The final class of biomolecules is that of the carbohydrates. Common carbohydrates include sugars, starches, and cellulose. Indeed, these biomolecules are so abundant that they make up most of the organic matter on earth. Carbohydrates, as the name implies, consist of carbon, hydrogen, and oxygen, with the hydrogen and oxygen in the atomic ratio 2:1, and serve many different roles. Sugar, stored as starch in plants and as glycogen in animals, is the fuel used in metabolism in the generation of energy. Cell walls of plants are composed of cellulose, another polymer of carbohydrates. Finally, as discussed above, the main structural element of nucleotides is a pentose unit, a five-carbon sugar. In nucleotides a base is attached to the pentose which is then attached to a phosphate. This forms the basic structural unit of all nucleic acids as well as a component of important coenzymes (e.g., NADH), metabolic regulators (e.g., GMP which will be discussed in a subsequent section), and energy storage molecules such as ADP and ATP.

1.2 Assemblies

DNA, proteins, and membranes self-assemble to form a hierarchy of structures, leading from the individual molecules to subcellular organelles, to cells, and finally to organs and the organism (see Fig. 5). Biophysics is concerned with both the individual and collective properties of these assemblies, as well as with the physical aspects of the assembly process. Biophysical studies have contributed greatly to our present understanding of the basic biology and function of these systems.

1.2.1 Molecule-Molecule Interactions and Assemblies

1.2.1.1 Protein-Substrate Interactions and Catalysis. Enzymes are proteins that carry out catalytic functions (see CHEMICAL REACTIONS; CATALYSIS). Generally they bind a substrate such as oxygen or a peptide, and chemically transform the substrate by oxidation, reduction, addition, or cleavage. Enzymes demonstrate highly selective recognition and binding as they carry out their catalytic functions. These reactions are in fact so selective that biocatalysis is used in some industrial processes, particularly involving the production of optically active materials. Understanding the recognition and binding events is an area of great research interest in biophysics.

The following example illustrates how genetic engineering and rate constant measurements can be used to uncover insights into protein-substrate recognition and binding events. Estell *et al.* (1986) studied the steric and hydrophobic effects involved when the enzyme subtilisin carries out its catalytic function of cleaving peptides. Using genetic engineering, they produced different mutant enzymes by replacing the conserved glycine of residue 166 with 12 different nonionic amino acids. They found that the catalytic efficiency toward small hydrophobic substrates was actually *increased* by as much as 16-fold over the nonmodified ("wild-type") enzyme when the glycine in position 166 was replaced with hydrophobic amino acids. Although the enzyme has evolved to be an efficient catalyst for a broad range of molecules, this result shows that the catalytic efficiency toward a *specific* molecule can be improved by genetic engineering. Protein engineering is being increasingly used to establish the basic biophysics of enzyme specificity (Carter and Wells, 1987).

The production and evaluation of bio-mimicking molecules is a completely different approach to understanding biological catalysis (Rebek, 1987; Cram, 1988). Here, the idea is to synthesize molecules that possess the minimum requirements for molecular recognition. Bio-mimicking molecules are often designed to test hypotheses based on our understanding of the biophysics of recognition and catalytic events.

function of organisms. For example, DNA that has been damaged by environmental chemicals, ultraviolet light, or ionizing radiation is continually being repaired by a series of enzymes that recognize the damaged DNA and repair it in a stepwise fashion. Furthermore, the binding of various proteins to DNA is thought to control the genetic expression of various gene products, ultimately turning on or turning off the gene. Some DNA-binding molecules are flat and they intercalate between the base pairs; others interact via hydrogen bonding, electrostatic, or van der Waals interactions (Dervan, 1986). Since the base-pair sequence controls the three-dimensional shape of DNA, including the helical twist, groove shape, and bending, the design and testing of sequence-specific DNA-binding molecules is an active area of biophysical research.

1.2.1.3 Protein-Protein Interactions. One of the most well-known examples of protein-protein interactions is how proteins recognize foreign substances. Antibodies are protein molecules, produced by the body's defense system, that recognize and bind specific target molecules. The target molecule, an antigen, can be either a foreign chemical substance or protein. The principles of antibody-antigen recognition are widely applied in diagnostic kits and in immunocytochemical staining of cells. Biophysical studies of antibody specificity have been advanced by x-ray crystallographic studies. One such study is of an antibody bound to its protein antigen, hen egg white lysozyme, a protein that cleaves the polysaccharides of bacterial cell walls. In this structure the two proteins, the antibody and lysozyme, interact at two almost completely flat surfaces with small indentations where amino acids from one protein penetrate the structure of the other (Marrack, 1987). For antigenic sites on another protein, myohemerythrin, x-ray crystallographic studies and work with small peptides suggest that the primary event, recognition of highly exposed side chains on myohemerythrin, is coupled to protein movements, thereby allowing the antibody to interact with otherwise buried side chains of the protein (Getzoff *et al.*, 1987). Thus, one proposed antibody-protein interaction mechanism involves recognition, induced fit, and binding, a mechanism which bears similarities to the induced-fit mechanisms suspected in enzyme-substrate and DNA-protein interactions.

Another well-known example of protein-protein interactions involves assembly of the structural protein, collagen. The type I collagen molecule is composed of two distinct types of chains: two $\alpha 1(\mathrm{I})$ chains and one $\alpha 2$ chain, that have the triplet amino acid repeat (gly-x-y), where x and y are often proline and hydroxyproline. (Here the α designator is purely historical and does not refer to the type of helix.) The presence of glycine as every third residue of the chains allows the chains to pack in a triple-helical structure [Fig. 6(a)]. Because of steric constraints, only the glycine residues occupy positions within the core of the molecule, where they participate in interchain hydrogen bonds that stabilize the helix. The side chains of other amino acids occupy positions on the surface of the molecules. The collagen molecule is approximately 3000 Å long and 15 Å in diameter. Its unusual rod-like shape makes it a favorite for biophysical light-scattering measurements.

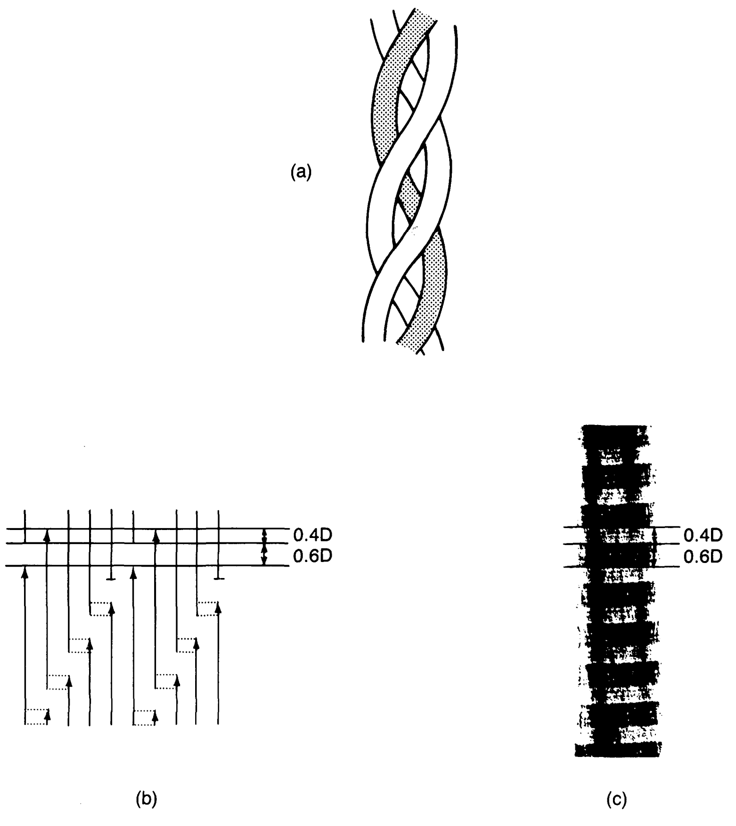

FIG. 6. An illustration of protein-protein assembly. (a) The type I collagen molecule is composed of two $\alpha 1(\mathrm{I})$ chains and one $\alpha 2$ chain (shaded) that form a triple-helical structure. (b) These triple helices pack so that the side chains (not shown) occupy the surfaces of the molecule. The molecules assemble in a highly regular fashion to form well-organized fibrils. They pack with a *D* stagger of 668 Å or 234 residues, forming gap and overlap regions. Probable intermolecular cross-link regions are indicated for some molecules by dotted lines. (c) An electron micrograph of reconstituted rat tail tendon collagen negatively stained with 2% sodium phosphotungstate. The dark areas correspond to the gap regions and the light areas to the overlap regions. [Adapted from Jelinski and Torchia (1980).]

The collagen molecules pack in a highly regular fashion, staggered by the D repeat of 668 Å, or 234 residues [Figs. 6(b) and 6(c)]. (The D repeat describes the side-by-side stagger between the heads of adjacent collagen molecules.) The biophysics underlying this highly regular protein-protein assembly was uncovered, in part, by analysis of the distributions of interacting residues along the axial projection of the molecule. Fourier analysis of the collagen $\alpha 1(\mathrm{I})$ and $\alpha 2$ chain sequences showed that the distribution of amino acids having charged or large hydrophobic side chains has regularities which are related to the D repeat. These regularities in the sequence explain various features of the three-dimensional packing of collagen molecules into fibrils (Piez and Trus, 1978).

1.2.1.4 Lipid-Protein Interactions. Although many proteins and enzymes reside inside cells in the cytosol, there are also integral membrane proteins. These proteins are actually part of the membrane and are specific to the function of the membrane. Because of lipid-protein interactions, integral membrane proteins have a very different structure than water soluble proteins. Instead of a hydrophilic exterior, they usually consist of a bundle of alpha helices with hydrophobic amino acid residues on the exterior. The protein structure is stablized by the interaction of these residues with the hydrophobic tails of the lipids on the interior of membranes. Membranes support a wide range of functions, including respiration, vision, photosynthesis, cell-cell recognition, and nerve impulse transmission. The middle inset in Fig. 5 shows a schematic representation of a membrane containing various membrane-bound proteins. Some of these proteins span the entire membrane while others face either side of the membrane. Since the lipid component is an electrical and chemical insulator, the proteins provide the main means for moving ions, molecules, or protons across the membrane. Although the protein content varies from membrane to membrane, it is generally very high.

Channels are membrane proteins that contain pores spanning the membrane. Channels have many purposes, including the regulation of gradients of ions such as Na^+, K^+, and Ca^{++}, maintaining intracellular pH, and transporting metabolites. Channel proteins are highly specific. For example, the acetylcholine channel, which functions in neural transmission, undergoes a conformational change and opens only after two molecules of the neurotransmitter, acetylcholine, have bound to the extracellular surface of the protein. Once open, it passes sodium and potassium ions.

Many theoretical and experimental biophysical studies are concerned with the diffusion of the lipid component in the presence of the protein obstructions; others are concerned with the motion of the proteins themselves. Nuclear magnetic resonance (NMR) spectroscopy has been particularly useful in probing the microscopic details of the dynamic structure of membrane lipids and proteins (Smith and Oldfield, 1984).

1.2.2 Organelles. Organelles are subcellular assemblies that carry out specified functions. Cells contain many different organelles (as shown in Fig. 5). Since it is beyond the scope of this article to describe all organelles, we will concentrate on two: the mitochondrion and the nucleus.

1.2.2.1 Pumps and Gradients: Bioenergetics in the Mitochondrion. Biological systems need energy to carry out their basic functions of protein synthesis, muscle contraction, and ion transport. They get this energy from hydrolysis of the molecule adenosine triphosphate, or ATP. ATP stores a large amount of free energy, which is liberated when its phosphate bonds are hydrolyzed to produce ADP (adenosine diphosphate) or AMP (adenosine monophosphate). This liberated energy is used to drive otherwise unfavorable reactions. Biological systems would "run down" once all of the ATP was utilized unless there were mechanisms to drive the "uphill" synthesis of new ATP molecules. *Bioenergetics* is concerned with how energy is transduced from the oxidation of substances or by the absorption of light to drive the synthesis of ATP.

Most energy transduction takes place in specialized energy-transducing membranes in organelles such as chloroplasts or mitochondria (Fig. 7) (Nicholls, 1982). The organelles within the cell also have membranes; e.g., the mitochondria have two membranes, an outer membrane that is very permeable, and an inner membrane, where respiration takes place. These membranes have many distinct protein assemblies including two which

[Adapted from Nicholls (1982), p. 6.] (c) A close-up view of the protein assemblies involved in respiration and electron transfer.

are involved in the generation of ATP. One is responsible for ATP synthesis, the "uphill" reaction. The other, the "downhill" reaction, uses respiration as its energy source. A proton gradient across the membrane, the proton electrochemical potential $\Delta\mu_{H^+}$, provides the link between these two protein assemblies. The coupling between these pumps is shown in Fig. 7(b). ATP synthesis is driven by the proton gradient (bottom part of figure). ATP is continuously removed into the cytosol to provide energy for cellular function, while the proton gradient is continuously replenished (top part of figure) by respiration. Consequently, the proton gradient is an interconvertible source of free energy.

The details of ATP synthesis and of mitochondrial respiration are far beyond the scope of this article. Figure 7(c) provides a glimpse into this complexity; it shows some of the different proteins in the membrane and the electron transfer events that comprise the proton pump. Electrons enter (on the left) via NADH (the reduced form of nicotinamide adenine dinucleotide, or NAD^+), one of the major electron carriers in the oxidation of metabolic fuels. Electrons are transferred from NADH (dark lines and arrows) as protons are pumped across the membrane. The electrons are transferred along this chain of proteins until they reach the final enzyme, cytochrome *c* oxidase, where the electrons are used to reduce oxygen to water, with the concomitant pumping of another H^+. The membrane potential thus produced is used to drive the synthesis of ATP.

1.2.2.2 The Nucleus. A eukaryotic cell, by definition, contains a nucleus (Fig. 5). The nucleus is surrounded by a membrane called the nuclear envelope and houses most of the cell's DNA. We have already seen (Sec. 1.1) that DNA winds around proteins called histones. The DNA-histone assembly is called a *nucleosome;* nucleosomes are the repeating units of chromatin. The structure of chromatin has been elucidated, in part, by electron microscopy and x-ray and neutron diffraction. The nucleolus is also a highly organized compartment of the nucleus, and is the part of the nucleus that is most readily apparent when a cell is observed under a light microscope. The nucleolus contains RNA and proteins and functions to synthesize and assemble ribosomal RNA.

1.2.3 Cells. Cells have an amazing diversity of function, size, and shape. Some organisms such as the bacterium *E. coli* and certain algae are comprised of single cells. Other cells have highly specialized functions. For example, red blood cells carry oxygen, muscle cells participate in locomotion, and nerve cells form the brain's complex electrical signalling system. Nerve cells differ somewhat from the "typical" eukaryotic cell that we have already examined. Figure 8 shows a typical neuronal cell with several of its synapses. The dendrites bring information toward the cell body and the axons carry it away. Although neuronal cells have all of the genetic material that other cells have, they do not divide. Information from other cells is communicated via chemicals that are released at the synapses (Stevens, 1979). Neurotransmitter molecules in the synaptic vesicles are released, they diffuse across the synaptic gap, and they bind to protein receptors of another cell, where they generally induce a channel opening or closing.

Biophysics is concerned with essentially every level of cellular function, including bioenergetics, photosynthesis, cellular division, differentiation, adhesion, electrophysiology, neural transmission, and chemotaxis.

1.2.4 Organs, Organisms, and Systems. Groups of cells form organs, the most complex organ being the brain. The brain is composed of about a billion neurons, and a single neuron can be connected to thousands of others (Nauta and Feirtag, 1979). Central issues in biophysics concern the ways that information is organized, stored, encoded, and utilized in the brain.

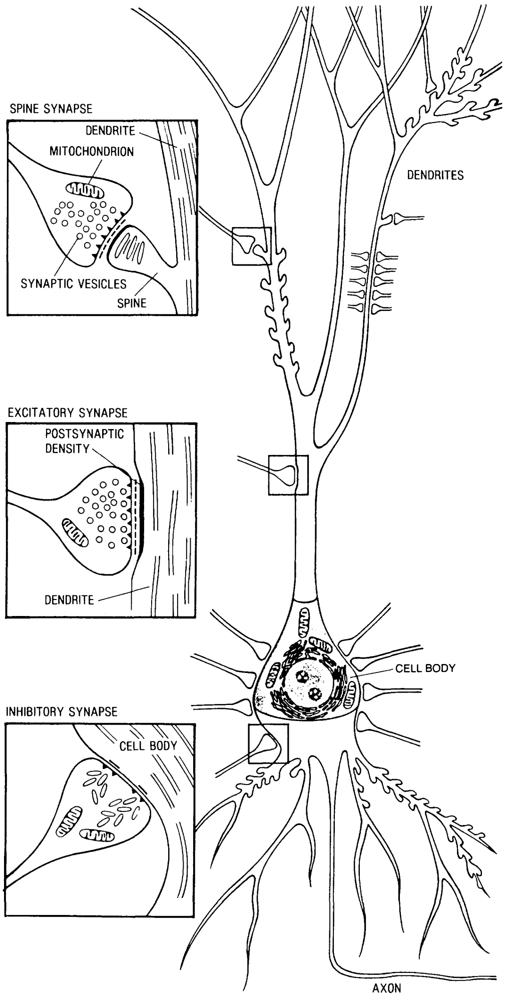

FIG. 8. Drawing of a typical neuron in the brain, showing three different types of synapses. [Iversen (1979).]

Organs in the body communicate with each other through a chemical signaling system mediated by hormones. The organism is of course comprised of organs; the human organism communicates with other organisms through its senses of hearing, feeling, seeing, tasting, and smelling. Biophysics of organisms and systems of organisms concerns areas such as perception, speech synthesis, and population behaviors. Here the tools generally are sophisticated measurement apparatus and statistical methodology. Certain insect colonies—honey bees, army ants, and fungus-growing termites—form superorganisms, where food, information, and aid pass freely among the members (Seeley, 1989). Such systems of organisms provide important models for mechanisms of genetic success.

2. TECHNIQUES OF BIOPHYSICS

2.1 Structural and Spectroscopic Techniques

Major advances in our understanding of biophysical phenomena have taken place as new techniques are developed. Typically, when a new technique is developed it is first applied to systems of interest to physicists, chemists, and physical chemists. Following its refinement it is then applied to more complex biological systems. This dependency on technique results primarily from the need to uncover structure to determine the molecular basis of the sought after function. In molecular biophysics it is the molecular structure that is determined, whereas in neurobiophysics it is the electrical impulse characteristics that lead to an understanding of the neural circuitry. Table 1 summarizes various spectroscopic techniques that are important in biophysical studies.

2.1.1 X-Ray Crystallography. X-ray crystallography ushered in the modern era of molecular biology. By x-ray diffraction the positions of the nuclei may be determined (see CRYSTALLOGRAPHY) and the structure of the macromolecule is thereby revealed from which inferences concerning the function of the molecule may be made. Comparison of two related structures will often reveal the structural basis for their differences in function. The early x-ray experiments on fibers of DNA by Franklin and Gosling (1953) and Wilkens and Randall (1953) allowed Watson and Crick (1953) to propose the molecular structure of nucleic acids. This work serves as the foundation of modern molecular biology. Later, the protein myoglobin was crystallized by Kendrew *et al.* (1960), giving the first glimpse of the three-dimensional structure of a protein. Even though the crystal structures of several hundred proteins have been determined, many proteins do not crystallize.

Macromolecular crystal structure determination, although very powerful, remains a very difficult task (Moffat, 1984). The prerequisite is a good quality crystal, which for some molecules cannot be obtained. When a suitable crystal is produced a set of x-ray scattering amplitude data is obtained. This is typically a set of many thousands of diffraction points. Next is the most difficult part of the determination, namely, solving the so-called phase problem. This problem results from the fact that each spot in the diffraction pattern is Fourier transformed, resulting in a wave with a given amplitude and phase. The amplitude is proportional to the number of electrons on each nucleus and the phase is the relationship of waves from different spots in the Fourier transform. The solution to the phase problem is to locate one position in the unit cell. The technique to do this is termed "isomorphous replacement" and involves replacement of one atom of the molecule by a heavy atom such as mercury. Once the phases have been determined the electron density map may be generated and the structure refined by various computer algorithms.

Table 1. Spectroscopic and structural techniques of molecular biophysics.

Technique	Excitation source	Typical wavelength (cm)	What is being probed	Typical information gained	Limitations
X-ray diffraction	X rays	10^{-8}	Diffraction from crystal lattice	Two- or three-dimensional arrangement of atoms of structural repeats such as helices	Molecules must form ordered structures or single crystals

Technique	Excitation source	Typical wavelength (cm)	What is being probed	Typical information gained	Limitations
Fluorescence	Ultraviolet and visible light	10^{-5}	Electronic transitions	Environment surrounding fluorophore, intramolecular distances via energy transfer molecular motion	Requires a fluorophore; not very specific if molecule contains more than one fluorophore; sensitive to quenching
STM	Electrons	10^{-5}	Work function of the surface	Surface landscape; atomic arrangement of atoms on surface, also information about band structure	Works best with conducting samples
AFM	Attractive and repulsive interatomic forces		Weak interatomic forces between surface atoms and tip	Topography of surface	Difficult data interpretation at present
TEM, SEM	Electrons	10^{-5}	Ultrastructure of metal-shadowed materials	Long- and short-range morphological features; organization of structures	Samples must be dried and fixed unless freeze-fracture techniques are used

The structures of many water-soluble proteins have been solved by the above techniques. However, to gain an understanding of proteins which play critical roles in cellular processes, crystallographers are now turning their attention to membrane-bound proteins. Since the structures of these proteins depend on interactions with lipids in membranes, in crystalline preparations the lipids are replaced by detergents. Great success has been achieved already with the photosynthetic reaction center from which a full crystallographic determination has been made (Deisenhofer *et al.*, 1985). Interestingly, many of the distances and relationships found in the crystallographic determination were in agreement with previous inferences made by other biophysical measurements.

A drawback of conventional crystallographic studies has been in the need to study only the static conformation of equilibrium forms of crystals. Other techniques, discussed below, permit the study of motional properties of molecules, properties which are known to be important for biological function. With the use of synchrotron radiation, in which high intensity pulses of x rays are generated, it is becoming possible to carry out time-resolved x-ray structural studies. This will allow the full set of changes in a molecule to be followed as it carries out its function. Another advantage that is being realized in the use of synchrotron radiation is that much smaller crystals may be used than in the past, thereby alleviating some of the difficulties presented by the need for large crystals when conventional instrumentation is employed.

2.1.2 Nuclear Magnetic Resonance (NMR).

Developed by Purcell and Bloch in 1946, NMR spectroscopy has been used extensively for biophysical problems (see NUCLEAR MAGNETIC RESONANCE). It is an exceptionally powerful technique and has been used, e.g., to establish motions in lipids, to determine protein structures, to follow *in vivo* metabolism, and to diagnose disease for medical applications (Jelinski, 1984).

2.1.2.1 Nuclear Interactions. The NMR phenomenon arises because most nuclei have a nuclear spin whose quantized energy levels become nondegenerate when placed in a magnetic field. The energy necessary to elicit transitions between these energy levels is in the radio-frequency regime. Thus, an NMR experiment consists of placing the sample in a highly homogeneous magnetic field and applying a radio-frequency pulse of exactly the correct resonant frequency. This excites the nuclei, which undergo a free-induction decay, providing a signal (voltage) as a function of time. This time-domain signal is amplified, digitized, and Fourier-transformed to produce a spectrum consisting of amplitude vs frequency.

NMR-active nuclei of biophysical interest include ^{1}H, ^{23}Na, ^{31}P, ^{39}K, ^{15}N, ^{13}C, and ^{17}O, although ^{2}H, ^{113}Cd, and ^{19}F, among others, can be used for labeling and tracer experiments. Although the interactions of these NMR-active nuclei with the main magnetic field produces the NMR phenomenon, most of the information content in an NMR spectrum arises from more subtle interactions, including the chemical shift, dipolar coupling, scalar, or *J* coupling, quadrupolar interactions, and relaxation effects.

The chemical shift reflects the electronic screening about the nucleus. For example, the four different types of protons in lactic acid [$CH_3CH(OH)COOH$] have slightly different chemical shifts because their electronic environments are not identical. The chemical shift tensor describes the direction and magnitude of the chemical shift with respect to the principal axis system of the molecule. If the molecule is tumbling isotropically in solution, the chemical shift tensor is averaged to its isotropic value. The isotropic chemical shifts of lactic acid can be used to identify its presence, to quantify the amount present, to monitor the *p*H of its environment, and perhaps to assess its interaction with other substances. Figure 9 shows how a ^{31}P NMR spectrum of the muscle of a living rat can provide information about the *p*H via the chemical shift of the inorganic phosphate peak and about energy metabolism via the intensities of the peaks from ATP (note that the α, β, and γ phosphorus peaks of ATP are well resolved).

The dipole-dipole interaction, a direct coupling effect, is also orientation dependent. Its strength is inversely proportional to the third power of the distance between the interacting nuclei, so that relaxation mechanisms based on the dipolar interaction are exceptionally useful for providing distance or structural information. Spectral broadening caused by the dipole-dipole interactions is theoretically averaged to zero for molecules that tumble isotropically in solution. Molecules which are unable to reorient freely give rise to broad features in the baseline of ^{31}P NMR spectra and are generally not observed.

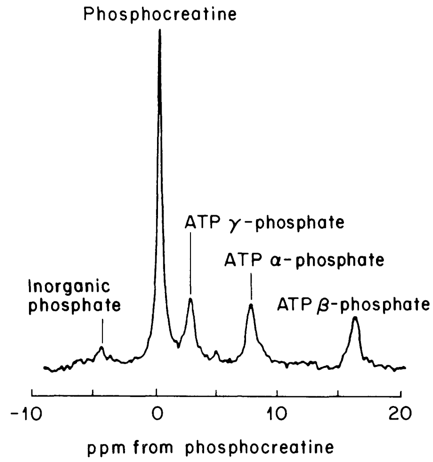

FIG. 9. ^{31}P NMR spectrum of the muscle of a live laboratory rat. Peaks corresponding to the major metabolites are labeled. [From Jelinski (1984).]

The scalar, or *J*, coupling is an indirect interaction mediated by the bonding electrons. Under high-resolution conditions, this produces a several-Hz splitting of the resonance lines. The multiplicity of the splitting is related to the spin of the nucleus and to the number of interacting spins. More importantly for biophysical studies, the magnitude of the splitting depends on the geometry of the molecule. For peptides and proteins, e.g., the relationship between dihedral angle and the size of the coupling constant between the N–H and the α-CH protons is well established and is used extensively to establish peptide geometries.

Quadrupolar interactions are usually dominant for nuclei with spin quantum number greater than $\frac{1}{2}$. For biophysical studies, these most commonly include ^{39}K, ^{23}Na, ^{17}O, and ^{2}H. As with the dipole-dipole interaction, quadrupolar broadening interactions for nuclei tumbling isotropically in solution are averaged to zero. For solids the quadrupolar interaction produces well-defined line shapes that can be analyzed to provide information about the rate and angular range of motion.

2.1.2.2 *Nuclear Relaxation.* There are two types of nuclear relaxation: spin-lattice and spin-spin. Spin-lattice relaxation pertains to relaxation induced by the lattice, or environment of the spin. For example, when a sample is placed in a magnetic field, a certain amount of time is required for the spins to align themselves either with or against the magnetic field. Although the population of spins in these energy states is determined by the Boltzmann distribution, the rate at which these populations are established is determined by the spin-lattice relaxation time T_1. Fluctuating local fields, most often dipolar or quadrupolar, provide a mechanism through which the spin can couple with its lattice. Spin-lattice relaxation can be used to uncover the details of molecular motion and molecular interactions.

Spin-spin relaxation, or T_2 relaxation, arises from fluctuating local fields set up by mutual spin flips. When motion is fast, the T_1 and T_2 are equal. They are unequal, however, in the regime of slow motions, where the T_2 provides valuable information on protein and DNA binding events.

The enhancement in intensity of a spin transition in one nucleus that occurs when a nearby nucleus is irradiated with a radio-frequency pulse at its resonant frequency is the nuclear Overhauser enhancement, or NOE. It arises from purely dipolar relaxation and has an inverse sixth-power dependence on distance. The NOE is widely used to establish tertiary structures of proteins and for exploring helices, bends, and interactions in DNA.

2.1.2.3 *Solid-State NMR.* Although the chemical shift anisotropy and the dipole-dipole interaction in solids produce substantial broadening, they are nevertheless valuable sources of orientation-dependent information, particularly if the molecule under study is involved in restricted molecular motions. It is possible, however, to eliminate these broadening mechanisms to produce high-resolution spectra of solids. These techniques involve magic-angle spinning, which reduces the chemical shift anisotropy pattern to its isotropic average, and dipolar decoupling, which removes the effects of dipolar broadening. (The "magic angle," or 54.7°, is the angle where the expression $3\cos^2\theta - 1$ is equal to zero. Both the chemical shift and the dipolar tensors have a $3\cos^2\theta - 1$ dependence.) High-resolution spectra of solids have been used in numerous studies of bones, teeth, and high-molecular-weight DNA, and in establishing the biophysics of the visual system (see Sec. 3).

Broad-line spectra of quadrupolar nuclei (obtained without magic-angle spinning and dipolar decoupling) have also been used with selective labeling techniques to study the visual system. Such experiments have also been applied to structural proteins such as collagen and elastin.

2.1.2.4 *Two- and Three-Dimensional NMR.* Two-dimensional (2D) NMR spectra can be obtained by adding an additional time period, the evolution time, to the standard pulse sequence used to obtain a one-dimensional spectrum. A number of spectra (perhaps 256) are acquired that differ from one another by the length of the evolution time. If subjected to a two-dimensional Fourier transform, a two-dimensional spectrum is obtained. Frequencies that were unchanged during the evolution period appear on the diagonal of the 2D data matrix, since $\omega_1 = \omega_2$. If two spins interacted with each other during the evolution time, perhaps by J coupling or by NOE, depending on the pulse sequence, $\omega_1 \neq \omega_2$, and off-diagonal elements appear.

Two-dimensional NMR spectra of proteins, DNA, and RNA have completely revolutionized structural analysis. Two-dimensional experiments are especially useful for structure determinations in proteins that do not crystallize, although at present they are limited to proteins that have less than about 140 amino acid residues. A 2D structure determination involves first assigning all of the resonances, a time-consuming and often difficult process made possible by an entire battery of 2D experiments. The structure is determined computationally using distance constraints imposed from 2D-NOE measurements. The structure of basic pancreatic trypsin inhibitor (BPTI), a 58–amino-acid protein, was the first to be analyzed in this manner. Since then, the structures of a number of proteins have been established. Much of what we know about DNA structure, including the way that bases are stacked one on top of the other, the sugar pucker (distortion of the five-membered sugar ring), and propeller twists (nonplanarity within pairs of hydrogen-bonded bases), have been established by 2D NMR experiments.

Two-dimensional NMR can be extended to 3D and 4D NMR by performing experiments with additional evolution times. When Fourier-transformed, these spectra produce a multidimensional data matrix where different planes correspond to correlations.

2.1.3 Electron Paramagnetic Resonance (EPR). The basic concepts for electron paramagnetic resonance (*q.v.*) (EPR; also called electron spin resonance, or ESR) are similar to those of NMR (Kosman, 1984). However, EPR is used to probe the environment around unpaired spins, whereas NMR is most useful for diamagnetic samples. When placed in a magnetic field, the electron spins exist in two energy states. The frequency corresponding to the difference in energy between these two states is in the microwave regime. Thus, the resonant condition is attained by microwave irradiation of the sample. One of the parameters of interest (analogous to the chemical shift in NMR) is the *g* factor. The *g* factor represents the ratio of the magnetic moment to the angular momentum and has a value of 2.002 319 for a free electron. The *g* value is sensitive to the chemical environment surrounding the unpaired spin. Furthermore, like the chemical shift anisotropy, it exhibits an anisotropy from which the extent of molecular motion can be derived.

Many insights into the environments at the active site of enzymes or in lipid bilayers have been obtained by a technique known as spin labeling. In this method, a small probe molecule containing a stable free-radical species (such as a nitroxyl) is attached to the biomolecule of interest. This probe molecule serves as a reporter of the environment and dynamics in its immediate vicinity.

2.1.4 Vibrational Spectroscopy (IR, Raman). Vibrational spectroscopy probes the frequencies of the molecular vibrations (see MOLECULAR SPECTROSCOPY). The energy of molecular vibrations is in the infrared region of the electromagnetic spectrum ($\sim$0.1 eV). Vibrational excitations may be measured by the direct absorption of light (infrared absorption spectrum) or by light scattering (Raman scattering). A serious difficulty in the infrared absorption technique results from the absorption by water which is a very intense absorber and overlaps with the vibrational modes of biological macromolecules. Because of this, extremely thin and highly concentrated samples must be used for infrared absorption measurements. In contrast, water is a very weak scatterer in the Raman spectrum and therefore does not present any difficulties. However, except for special conditions such as resonance enhancement, to be discussed below, the intensity in the Raman spectrum is quite weak and so high concentrations (at least 5–10 mM) are necessary. Crystalline or solution samples may be studied by either vibrational spectroscopic technique.

Vibrational spectroscopy may be used to study all classes of biomolecules (Rousseau and Ondrias, 1984; Alben and Fiamingo, 1984). In lipids, vibrational modes involving the head group (phosphate and C–N stretching modes) are present in Raman spectra, and several modes of the hydrophobic tail are also present. These modes have provided a great deal of information concerning the thermotropic transitions in lipid membranes. In proteins, amide modes of the polypeptide backbone are present in Raman scattering and infrared absorption spectra. Modes from some of the amino acid residues are also present. Many studies of proteins have been carried out and useful information has been obtained concerning protein secondary structure, residue exposure to solvent, and protein unfolding. Raman spectra of polynucleotides are also rich in information. Modes are present from the sugar phosphate backbone as well as from the individual bases. The spectra are sensitive to the degree of order of the polynucleotide, to the structure (*A*, *B*, or *Z*), and to the extent of base pairing.

To obtain a Raman spectrum the samples are exposed to incident laser light with wavelengths typically in the visible spectral region, and the spectrum of scattered light is recorded. The vibrational excitation is detected by the shift in wavelength of the scattered light. If the incident wavelength is in coincidence with a real electronic transition of the molecule being studied the intensity is enhanced and the effect is referred to as resonance Raman scattering. Two biological chromophores have been extensively studied by resonance Raman scattering: the heme macrocycle (Spiro, 1988) and retinal (Lugtenburg *et al.,* 1988), the visual pigment. The heme group consists of an iron atom coordinated to an aromatic porphyrin ring. Heme proteins are ubiquitous in the biological world and function in a variety of capacities ranging from multifunctional enzymes, to oxygen transport and storage proteins, to electron transfer proteins. A great deal of understanding of how the protein interacts with the heme group has been made by resonance Raman spectroscopy. Retinal is the biologically active center of the visual system. Resonance Raman studies of retinal-containing proteins have allowed for the identification of the various intermediates present in the visual system, as discussed in greater detail in Sec. 3 of this article. An important aspect of resonance Raman scattering as applied to these two chromophores (heme and retinal) is that it allows for the study of the biologically active site of the molecule without interference from the protein matrix which surrounds it. This selectivity makes this technique extremely powerful for the study of biological macromolecules containing chromophores.

When ultraviolet light sources are used, the advantages of resonance enhancement may be extended to aromatic amino acid residues and to polynucleotide bases (Asher, 1988). This is a growing field and although it has some difficulties, such as the need for high average laser power, it is very promising because information about specific amino acids and nucleotide bases can be obtained.

Many spectroscopic and crystallographic studies of biomolecules are carried out on molecules under equilibrium conditions. However, most biological reactions take place under nonequilibrium conditions. In addition there are often many different fleeting metastable intermediates which must be studied to determine a mechanism for a particular binding or catalytic process. For such studies it is necessary either to freeze trap a particular intermediate or do time-resolved spectroscopy. Both techniques have been widely applied to the study of biological reactions by vibrational spectroscopy. Most extensively studied have been the photoexcited intermediates in rhodopsin and bacteriorhodopsin (Lugtenburg *et al.,* 1988) and transient states following ligand photolysis in heme proteins (Rousseau and Friedman, 1988). Some of the results of the rhodopsin studies will be discussed in Sec. 3. Time-resolved vibrational studies have been carried out on heme proteins by using resonance Raman scattering from the picosecond time scale to the millisecond time scale. This work, along with freeze trap studies, has provided a determination of the relaxation pathway in hemoglobin and myoglobin following ligand photodissociation (Rousseau and Friedman, 1988).

2.1.5 Optical Techniques. In this section we consider several optical techniques that utilize visible and ultraviolet excitation. These include optical absorption, circular dichroism, and fluorescence. There are many excellent review articles which give in-depth descriptions of these techniques. In this section we present briefly some of the types of problems that are addressed by optical techniques.

2.1.5.1 Optical Absorption. The technique of optical absorption is one of the most widely used in biological research because it is a simple, inexpensive, and reliable probe of many macromolecules (Cantor and Schimmel, 1980). Indeed proteins, nucleic acids, and many small prosthetic groups have characteristic absorption spectra. Consequently, absorption spectroscopy is used at two levels. First, it is used as a way of characterizing and assaying a biological molecule or assembly. Second, it is used as a spectroscopic research tool.

In the optical absorption technique the incident light excites an electronic transition. These transitions are sensitive to molecular conformation and therefore, the absorption spectrum is a very rapid way of assessing the conformation of macromolecules. Spectra may be obtained from isolated molecules, organelles, organs, or intact animals. This broad range of applications makes it a powerful technique for characterizing materials. In addition, the light intensity used is generally weak so that no changes are induced in the system being studied. Finally, with the many different light sources that are available (e.g., lasers), time-resolution studies may be made as well. Such studies have been the basis for establishing the photocycle in rhodopsin, the visual pigment (Birge, 1981).

Proteins have two main optical absorptions: that of the polypeptide backbone and that of the amino acid residues. The π electrons of the peptide bond extend over three atoms: the nitrogen, the carbon, and the associated carbonyl oxygen. Two transitions involving these electrons are detected in the 190–220 nm region. The intensities and wavelengths of these transitions are sensitive to the secondary structure of the protein, displaying significant differences between alpha-helical, beta-sheet, or random coil structures. The aromatic amino acids phenylalanine, tyrosine, and tryptophan also have electronic transitions in the UV region. In the 230–300 nm region of the absorption spectrum these transitions are sensitive to changes in protein structure. For example, the electronic transitions are sensitive to whether an aromatic residue is in the interior of a protein in a hydrophobic environment or is exposed to the solvent and is thereby highly solvated. This sensitivity has been used to advantage in studies of hemoglobin in which its optical absorption spectrum has been used to monitor and characterize changes in the quaternary structure of the protein (Perutz, 1979). The optical transition in tyrosine is a sensitive reporter of *p*H, since the electrons on the oxygen of the -OH group affect the electronic structure of the ring through conjugation effects.

Prosthetic groups within proteins have been studied extensively by optical absorption techniques. The spectra of these groups are often sensitive to the protein environment in which they are embedded. The absorption spectrum of the heme group has played a very important role in characterizing this enormous class of proteins. Studies of heme proteins have ranged from investigating specific properties of isolated heme proteins, to observing the electronic structure when assembled in organelles, to characterizing metabolic states in the brain and monitoring the saturation of oxygen by blood in the tissues.

The absorption spectra of nucleic acids is dominated by the purine and pyrimidine bases. They produce a composite absorption band centered at about 260 nm. Although complicated by the overlap of the absorption band from each base, the intensity and the position of the absorption maximum is sensitive to *p*H and interactions between bases.

2.1.5.2 Circular Dichroism. Nearly all biological molecules are optically active. Optical activity results from the low symmetry of biological molecules and produces some measurable effects. Circular dichroism is the most widely used optical activity effect (Cantor and Schimmel, 1980; Maestre, 1984). In this technique a comparison is made between the absorption of left- and right-circularly polarized light. Because of optical activity the amount of absorption is different for these two polarizations.

Circular dichroism is used extensively to determine secondary structure in proteins. In the region from 190 to 250 nm, where the optical absorption is dominated by transitions from the polypeptide backbone, a strong CD spectrum is observed which is very sensitive to the secondary structure, as is evident in Fig. 10. By using various deconvolution techniques, the amount of secondary structure may be determined from the CD spectrum of a protein.

2.1.5.3 Fluorescence Spectroscopy. When a molecule absorbs light, the energy must eventually be reemitted in some form. Frequently this relaxation will take the form of fluorescence, a reemission which is shifted to somewhat lower energy than the excitation frequency. In biological molecules the wavelength, polarization, and lifetime of the fluorescence are each useful in characterizing the properties of the molecule (Stryer, 1978; Cantor and Schimmel, 1980; Schlessinger and Elson, 1982; Yguerabide and Yguerabide, 1984).

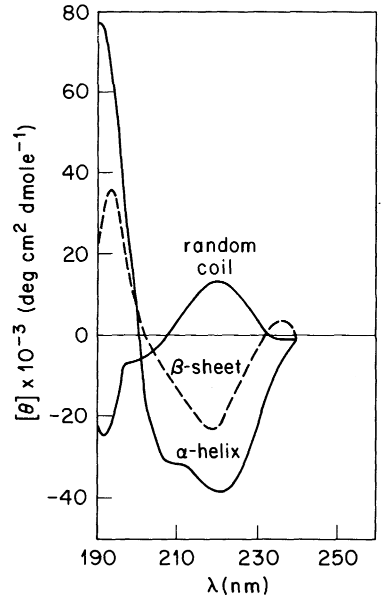

FIG. 10. CD curves showing characteristic patterns for random coil, β-sheet, and α-helix secondary structures. [Adapted from Cantor and Schimmel (1980), p. 427.]

In proteins, the tryptophan residue is the most common intrinsic chromophore studied by fluorescence. Excitation at about 280 nm leads to emission at about 350 nm. The wavelength of the fluorescence is sensitive to the environment surrounding the tryptophan, shifting significantly, e.g., when a tryptophan which is buried in the hydrophobic region of a protein becomes exposed to the solvent. The lifetime of the emission is also sensitive to solvent exposure and therefore can be used to separate the contributions from interior and exterior tryptophans.

Tumbling motions of molecules may be measured by polarization anisotropy. For a molecule that is fixed in space, the polarization of the fluorescence is a function of the angle between the absorbing and the emitting dipole. However, in a molecule that is tumbling on a time scale that is faster than the fluorescence emission time the anisotropy of the emitted polarization becomes zero. Thus, the polarization anisotropy can be used to measure the relationship between the two dipoles and it can be used to measure the tumbling frequency of molecules. Rotational and diffusional properties of membranes have been determined by following the time course of the anisotropy of the polarization of fluorescent probes placed in membranes.

Distances between two molecular sites may be determined by taking advantage of fluorescence excitation transfer. To carry out such measurements the fluorescence intensity and lifetime of a fluorophore are measured. These measurements are compared to those made when an acceptor molecule is placed at some nearby site. The energy transfer between the sites is proportional to $1/r^6$, where r is the distance between the sites. This theory for energy transfer involving the dipole-dipole interaction was developed by Förster. This technique has been used to measure distances in a wide variety of nucleic acids and proteins (Stryer, 1978).

2.1.6 Extended X-Ray Absorption Fine Structure (EXAFS). Atoms absorb light in the x-ray region by the photoionization of inner shell electrons. The absorption spectrum has a series of edges in it corresponding to each of the inner shell electronic orbitals. An absorption spectrum of the x rays reveals variations in intensity in the 50–100-eV region past the edge inflection. This fine structure in the absorption spectrum (EXAFS) results from elastic backscattering of the photoejected electrons with the electron density of nearby atoms. (For a good review see Scott, 1984.) As a result the EXAFS spectrum is sensitive to the distance and type of atom in the neighborhood of the atom producing the edge absorption. In biological applications absorption edges above 4000 eV are primarily studied to avoid the absorption by protein and water. The most commonly studied biological molecules are metalloproteins and metalloenzymes. EXAFS only became readily feasible for biological molecules since the development of synchrotron radiation which gives about two orders of magnitude more intensity than the conventional Cu K_α line.

EXAFS gives selective information around the metal center being studied. This turns out to be especially useful in biological applications because if there is a metal at the active center it can be probed without interference from other atoms in the molecule. The technique is especially powerful when the identity of atoms which are bound to a metal center is known and the distances must be determined. EXAFS measurements can be used to determine distances accurately in such cases and it also has the advantage that single crystals are not necessary as in x-ray crystallography. EXAFS measurements have been performed on nearly every type of metalloprotein and have been most successful on studies of iron-sulfur proteins, heme proteins, copper proteins, and molybdenum enzymes.

2.2 Electrophysiology

Much of what we know about neurobiology has come from electrophysiological measurements, which combine chemical and electrical information about cells. The neuron (Fig. 8) has a dual signalling system, since it uses both chemicals (neurotransmitters; see Sec. 1.2.1) and electrical impulses (action potentials) to transmit its information.

There is a voltage difference across the membranes of neuronal cells referred to as the membrane potential (Miles, 1969). This potential is a consequence of an ionic imbalance across the cell membrane. This imbalance is generated by two main features of the cell membrane: the sodium/potassium pump and the fact that the leakages of sodium and potassium ions back through the membrane are different. Consider a membrane with equal concentrations of Na^+ and K^+ ions on each side. The sodium/potassium pump transports three Na^+ ions out of the cell and two K^+ ions into the cell for each molecule of ATP hydrolyzed. This process creates a membrane potential. Moreover, the leakage permeabilities of these two ions back through the membrane are very different. K^+ ions go through the membrane much more easily than do Na^+ ions. Because of the permeability difference, the K^+ ions leak out and a significant membrane potential is developed.

In addition to the force of the concentration gradient, the ionic flow across the membrane is also dependent on the voltage gradient across the membrane. To understand the balance between these forces the concentration gradient is converted to a potential by the Nernst equation

$$V = (RT/FZ)\log(C_o/C_i).$$

In this expression R is the universal gas constant, F is the Faraday, Z is the valence of the ion, and C_o and C_i represent the concentration of some ionic species on the outside and on the inside of the membrane, respectively. Assuming that there is a channel for a given ion, the net flow of that ion through the membrane will be zero if the membrane potential is the same as the Nernst potential. The ion will flow out of the cell if its Nernst potential is less than the membrane potential and into the cell if it is greater than the membrane potential.

The resting potential of a cell membrane is the membrane potential when the net ionic flow is balanced. For typical nerve cells this potential is usually about -60 mV. When a nerve cell is excited, channels are opened or closed so that the flow of ions through the membrane changes and therefore the membrane potential changes. Signal propagation down a nerve cell is caused by the opening of Na^+ channels. When they are excited by an electrical pulse Na^+ ions flow into the cell (its Nernst potential is about $+50$ mV), causing the membrane potential to become depolarized, i.e., a positive shift in its potential. In some cases there are current flows in the other direction causing the cell to have a more negative membrane potential. This is referred to as hyperpolarization and will be seen in the example of the visual system as an essential feature in the visual information transduction process.

When a cell receives a depolarizing pulse it generates a wave, or action potential, which propagates along the axon of the cell until it synapses on the next cell in the circuit. The wave itself is very complicated, involving both sodium and potassium channels. At that point, information can be transmitted electrically to nearby cells or it can be transmitted chemically. In chemical transmission, the nerve terminal releases neurotransmitter into the synaptic gap. These neurotransmitter molecules diffuse across the gap and bind to receptor channel proteins on the surface of the next cell in the circuit. Once the molecules have bound, the channels open and ions flow, changing the intracellular potential. Thus, information is transmitted both by electrical and chemical means.

To characterize the properties of nerve cells the voltage across the cell or the current flow in or out of the cell is measured by placing electrodes in the cell. For example, by placing electrodes at several places along an axon the action potential may be followed as the voltage impulse passes down the cell. A common procedure used to study electrical and chemical properties of cells is to apply a voltage clamp. This is done by placing two electrodes in a cell: one measures the voltage and the other is used to inject current. By controlling the current which is passed into the cell the voltage may be fixed at predetermined values. The amount of current needed to hold the voltage at a certain value depends on the rate at which various ions can flow through the membrane. By changing the concentrations of each ion in the solution it becomes possible to determine which ions carry the transmembrane current.

Patch clamping is a method used to study the individual channels in the membrane. In this technique, a glass micropipette having a tip with a very narrow diameter (1–3 μm) is filled with a conducting salt solution. This micropipette is pressed onto the cell surface, where it forms a gigaohm seal with the membrane. The salt solution in the micropipette forms part of a circuit with the patch of membrane spanning the tip of the micropipette. Current flows through the single membrane channels, and the electrical potential across the membrane can be clamped at different voltages to provide information about the channel behavior. Different configurations possible for patch clamping are shown in Fig. 11. Whole-cell recording can be performed by applying enough suction to rupture the cell membrane or inside-out or outside-out patches can be formed. One can also obtain extracellular recordings by placing the electrode in a well-defined extracellular position. Information about the functioning of the cellular channels is obtained by applying known neurotransmitters, specific channel blockers, and solutions of known ionic concentration.

2.3 Imaging Techniques

Although they grew out of biophysical research, many imaging techniques have now found wide applicability in the medical community. Among these are positron emission tomography (PET), magnetoencephalography (MEG), computed tomography (CT), and nuclear magnetic resonance imaging (MRI). In addition to their medical utility, these imaging techniques continue to serve as valuable tools for biophysics research, particularly for studying *in vivo* function. Using these noninvasive techniques, it is possible to obtain images of pulsatile blood flow, to visualize the difference between normal and cancerous tissue, and to monitor activity patterns in the brain.

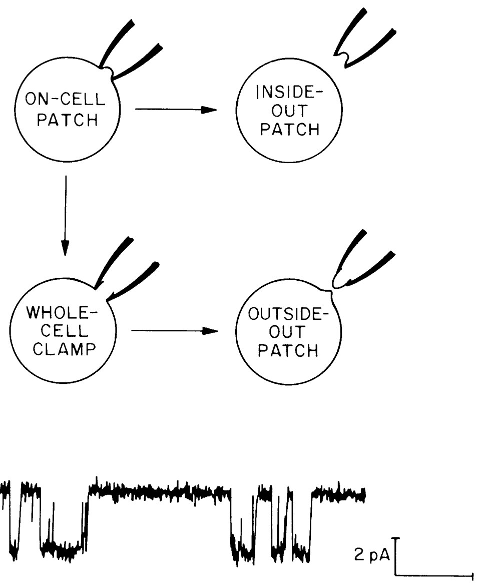

FIG. 11. Top: Various configurations for patch clamping. In the on-cell patch the electrode makes a tight seal with the outside of the intact cell. By pulling the electrode away from the cell, a patch of membrane remains on the electrode with its inside surface facing out. By applying suction to the on-cell patch the membrane is broken open and the voltage of the cell may then be clamped to a new value. By pulling the electrode away from the cell, in the latter case, the membrane reseals exposing the outside surface. Bottom: Patch recordings through a single protein channel, showing the open and closed states of the channel. [Adapted from Shepherd (1988), pp. 33 and 34.]

In contrast to these biomedical imaging techniques which produce macroscopic information, scanning tunneling microscopy (STM) and atomic force microscopy (AFM) produce atomic-scale information. Electron microscopy bridges the size gap, providing mainly supramolecular images.

2.3.1 Positron Emission Tomography (PET).

PET images provide information about oxygen utilization and metabolic disorders such as Alzheimer's disease, epilepsy, schizophrenia, Parkinson's disease, or stroke (Dagani, 1988).

In PET, the patient or animal is injected with radioisotopically labeled compounds such as glucose, ^{18}F-containing dopamine, or other labeled molecules. Because they are radioactive, these particular compounds emit positrons as they flow through the blood stream. When positrons collide with electrons, they annihilate and produce gamma rays that fly off from each other in opposite directions. PET scanners work by detecting these gamma rays with an array of detectors. The image is reconstructed by combining the information from the circular array of gamma ray detectors. Because the radiolabeled chemicals have very short half-lives, they must be prepared freshly in a nearby cyclotron.

2.3.2 Magnetoencephalography (MEG).

When neurons in the brain discharge, the tiny electrical currents produce magnetic fields which extend out beyond the skull (Rose *et al.*, 1987) (see BIOMAGNETISM, MEDICAL APPLICATIONS). These fields, 10^9 times weaker than Earth's magnetic field, can be measured with ultrasensitive detectors called SQUIDs (superconducting quantum interference devices). Multisensor SQUID systems can measure this magnetic field simultaneously at different locations around the head, thus mapping regions of neuronal activity in the brain. MEG has been used to show that a tone map exists across the human auditory cortex. It has also been used in cognitive studies and to locate the center of an epileptic discharge.

2.3.3 Computed Tomography (CT). Computed tomography uses x rays to make images. As in x-ray shadowgrams, the contrast in CT is dominated by the density of bones and tissues. Since these materials cast shadows in normal x-ray images, they obscure whatever is behind them. This problem is circumvented in CT by using an x-ray source that can rotate in a circle. This provides multiple pictures of the object from many different angles. All of these images are combined by the computer to produce an image of a slice of the body. These slices can also be used to construct three-dimensional images; these three-dimensional pictures are useful for finding the exact size, shape, and location of tumors, and for pinpointing the precise location for beaming radiation for radiation therapy. They can also be used in reconstructive surgery to define the shape and size of artificial joints.

2.3.4 Magnetic Resonance Imaging (MRI). Magnetic resonance imaging (*q.v.*) is an extension of NMR (see Sec. 2.1.2), wherein frequency information is encoded into spatial information (Jelinski *et al.*, 1989; Morris, 1986). The sample is placed in a homogeneous magnetic field and is subjected to radio-frequency pulses to achieve the resonance condition, as previously described for NMR spectroscopy. However, in MRI the frequency information is translated into spatial information by subjecting the sample also to field *gradients* in the x, y, and z directions. This produces images, or "slices" of the sample; one such slice through a plane of the brain containing the eyes is shown in Fig. 12.

Since MRI is a noninvasive technique that does not use ionizing radiation, it has found wide utility in clinical applications. Although MRI is routinely used for medical applications, much biophysical research is also being performed, particularly in the area of imaging of function.

MRI is most often used for imaging the protons in water, since water is ubiquitous in biological tissue. The contrast in an MRI image arises from several sources, and the contrast can be "tuned" for the desired effect by adjusting various experimental parameters. The amount of water present in the sample is responsible for only part of the contrast. The other aspects of contrast arise from the differences in relaxation times between water in various tissues. These relaxation times, called the spin-lattice (T_1) and spin-spin (T_2) relaxation times (see Sec. 2.1.2), are different for different tissues. These differences arise primarily from differences in the way that water interacts with the proteins and other macromolecules in the tissues. Thus, the molecular basis for relaxation time differences is an essential research area for MRI.

Although proton imaging of water is most widely used, other biologically important molecules such as lactate and nuclei such as sodium can also be imaged. MRI can also be used to provide information about blood flow. Some of the biophysical applications regarding the imaging of function require that a fourth dimension also be obtained. This fourth dimension is the chemical shift, wherein the chemistry occurring within a

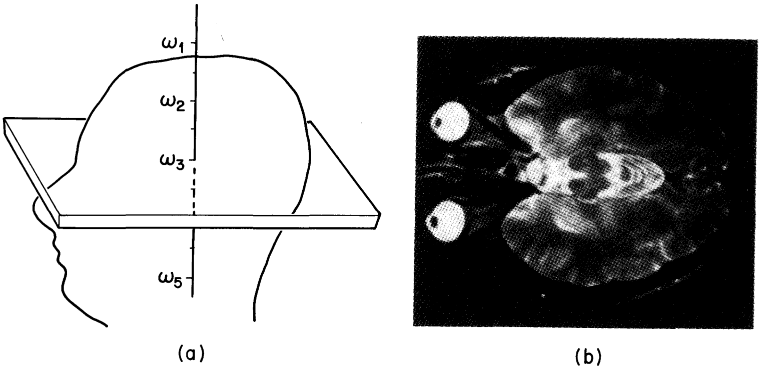

FIG. 12. Magnetic resonance image through a plane of a brain containing the eye. [Jelinski *et al.* (1989).]

particular volume element ("voxel") of the image is monitored.

2.3.5 Scanning Tunneling and Atomic Force Microscopy (STM and AFM). Binnig and Rohrer were awarded the Nobel Prize in physics for their invention of the scanning tunneling microscope (STM), which made it possible to obtain images with atomic-scale resolution of conducting surfaces (Hansma and Tersoff, 1987) (see SCANNING TUNNELING MICROSCOPY). Since its invention, STM and the related atomic force microscopy (AFM) have been applied to biological molecules such as leucine (Gould *et al.*, 1988), lipids (Zasadzinski *et al.*, 1988), and DNA (Amrein *et al.*, 1988), as well as to semiconductors and other inorganic and organic materials of nonbiological origin. The STM works in air and under water, as well as in vacuum. Figure 13 illustrates the basic operation of an STM instrument. The tip of the STM is made by etching a wire (usually tungsten) to produce a small radius of curvature. Tunneling occurs off the last atom or atoms on the surface of the tip. The tip is scanned across the sample by means of piezoelectric *x*, *y*, and *z* translators, which produce carefully controlled, atomic-scale steps. In the constant-current mode, the tunneling current is monitored as the sample is scanned, and a feedback circuit adjusts the height of the tip to maintain this current constant. The image is then read out as the movement of the tip. In the constant-height mode, the tip is kept at a constant height, and the image consists of the variations in the current as the tip passes over atomic features on the surface. Since the tunneling current varies exponentially with the distance between the tip and the sample, a small change in the distance translates into a very large change in the tunneling current, thus accounting for the sensitivity of this technique.

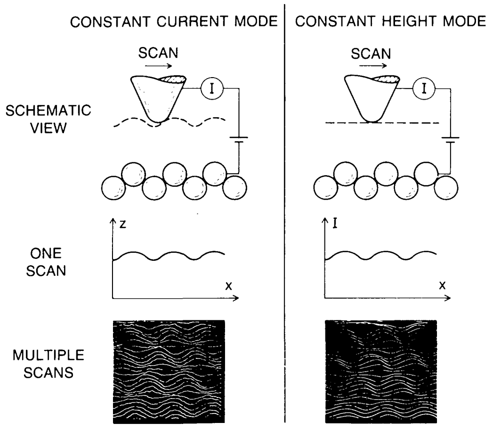

FIG. 13. Schematic view of the operation of a scanning tunneling microscope in the constant-current and constant-height modes. [Hansma and Tersoff (1987).]

The AFM works in a fashion similar to the STM (Binnig *et al.*, 1986), except here the sample need not be conductive or mounted on a conductive grid. The tip of the AFM is attached via a spring to a cantilever beam, and the deflection of the beam is monitored as the tip scans over the sample. Forces are generated by interatomic attractions and repulsions as the tip passes over various regions of the sample. The AFM can work in constant-force mode, where a feedback circuit adjusts the height of the tip from the sample to keep the force constant.

3. AN EXAMPLE: BIOPHYSICS OF THE VISUAL SYSTEM

In the last section of this article we focus on the visual system, which provides a specific example of how biophysical studies have uncovered some of the mysteries of nature. Information is received, converted into chemical information, and then into electrical information so that it may be transmitted, processed, and stored. This process of information transduction in vision is one of the most interesting and complex areas of biophysics. The machinery of this process spans nearly all areas of biophysics and essentially all biophysical techniques have been used to study the visual system.

3.1 Morphological Structure

Determination of the molecular and electrophysiological basis for the information transduction in the visual system has been made possible by understanding the physical map of the visual system from the many electron microscopic studies of the cells of the retina. Identification of these cells has allowed the pathway for the information flow to be determined. As may be seen in Fig. 14, light strikes the photoreceptor cells after first passing through the neurons which connect

the photoreceptors to the optic nerve. Identification of the photoreceptors from electron microscopy is very striking as is evident in Figs. 14 and 15 where the much larger rods and the smaller cones are clearly observed. Color sensitivity results from the cones. There are three types of cone cells with absorption maxima in the red, green, or blue. The same chromophore, retinal, is used in each of these, but its optical properties are modified by the protein which surrounds it, accounting for the differential color sensitivity.

The rods, which provide monochromatic detection of dim light, have been the most extensively studied photoreceptor cells. As shown in Fig. 15, the rods are complicated cells in which a section called the outer segment contains the photoreceptors, or disks (Figs. 15 and 16), and another section, called the inner segment, contains the cellular apparatus for generating energy and making molecules necessary for the functioning of the outer segment.

In addition, the inner segment contains a synaptic terminal which connects the rod to other cells of the nervous system. The electrical signals generated in the photoreceptor cells are processed by several layers of neurons (see Fig. 14) prior to passage through the optical nerve to the lateral geniculate nucleus, and finally to the visual region of the cerebral cortex (visual cortex).

3.2 The Primary Event in Visual Excitation

Within the disks (Fig. 16) of the outer segments of the rod cells is a membrane-bound protein called rhodopsin. It consists of a chro-

mophore, retinal, surrounded by a protein with several helical segments passing through the membrane wall of the disk. Retinal, one of the active elements of rhodopsin, is a polyene, an alternating chain of single and double bonds, attached to an ionene ring (Fig. 17). It is derived from all-*trans*-retinol (vitamin A). The delocalized electrons in the polyene chain give rise to a very strong optical absorption transition. Many experimental and theoretical studies of this transition have been made to understand how binding retinal to the protein (opsin) can shift the natural retinal transition from the near ultraviolet (380 nm) to the visible region (500 nm) for light absorption in the photoreceptor (Birge, 1981). This large shift of the optical transition of retinal is called the "opsin shift."

Recent solid-state NMR measurements showed differences in the ^{13}C chemical shift at positions 11, 12, and 13 in the comparison between the free retinal and the protein-bound form. These data confirm the point charge model for the opsin shift, i.e., the hypothesis that the shift is a consequence of a

negative charge located near positions 11, 12, and 13 (Lugtenburg *et al.*, 1988). Site-directed mutagenesis has established that this negative charge arises from glutamic acid residue 113 (Zhukovsky and Oprian, 1989). NMR data have also confirmed the orientation of the ring with respect to the polyene chain as being 6-*S*-*cis*.

Many different techniques have led to an understanding of the structure of rhodopsin and to the process which eventually leads to the production of free retinal. Our current picture of rhodopsin is summarized in Fig. 18 (Stryer, 1987). A number of biophysical studies contributed to the early understanding of the structural properties of the membrane-bound protein (Chabre, 1985). For example, neutron scattering studies demonstrated that 50% of the protein is embedded in the membrane bilayer (Saibil *et al.*, 1976). Similarly, small-angle scattering studies showed that rhodopsin consists of a hydrophobic region sandwiched between two hydrophilic ends (Osborne *et al.*, 1978). Infrared measurements of proton/deuteron exchange demonstrated that there are large regions of the protein that are not exchangeable, consistent with a hydrophobic region passing through a membrane (Osborne and Nabedryk-Viala, 1977). Circular dichroism measurements demonstrated that about 50% of the protein is alpha-helical in character (Shichi and Shelton, 1974). This latter finding, combined with other data, was taken as evidence that the alpha helices form part of the transmembrane structure. In summary, the biophysical measurements led to a view that rhodopsin is a transmembrane protein with alpha helices passing through the membrane and with hydrophilic sections on both sides of the membrane. These conclusions are supported by the amino acid sequence analysis in which seven hydrophobic sections were identified that would be expected to form alpha helices (Hargrave *et al.*, 1983). In addition, Henderson and Unwin (1975) built a three-dimensional structure of a related protein, bacteriorhodopsin, from high-resolution electron microscopic measurements of two-dimensional crystalline sheets. (Bacteriorhodopsin is a membrane-bound energy-transducing protein found in the purple membrane of *Halobacterium halobium.* Its active phototransduction element is also retinal.) The structural analysis done by Henderson and Unwin demonstrated that it, too, has seven transmembrane helical segments. Fluorescence energy-transfer measurements in-

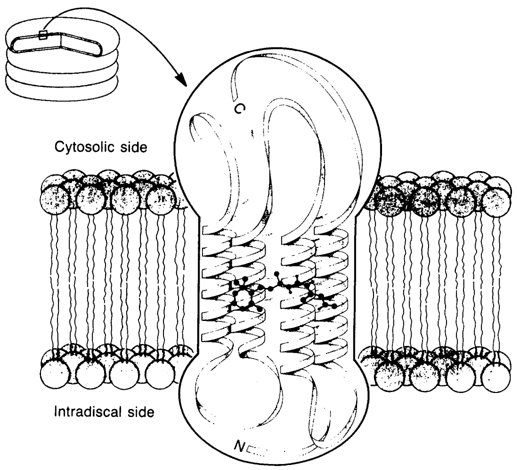

FIG. 18. Schematic drawing of a patch of membrane from a disk of a rod cell showing the proposed structure of rhodopsin. [From Stryer (1988).]

dicated that retinal lies in the center of the hydrophobic region of the protein (Stryer *et al.*, 1982).

The absorption of light by 11-*cis* retinal of rhodopsin brings about a structural change of the chromophore, causing it to isomerize to an all-*trans* form (Fig. 17). The large difference between the conformation of the all-*trans* retinal and that of the 11-*cis* retinal induces a series of conformational changes in the protein which surrounds it. There are several intermediate structures of the retinal associated with the evolving structure of the protein. Many physical techniques have been applied to study these intermediates to determine their photophysics, structure, and kinetics (Wald, 1968; Ebrey and Honig, 1975; Birge, 1981; Chabre, 1985). In the final step retinal is released by the protein and is only reconstituted with it after an enzyme converts the expended all-*trans* form back to the 11-*cis* isomer for reincorporation.

The process leading to the change in the rhodopsin structure and the associated release of the retinal have been very extensively studied. A molecular-level basis for these first steps in the information transduction process, known as the photocycle (Fig. 19), has been established. Information has been obtained both from direct studies of rhodopsin and from studies of bacteriorhodopsin, the analog of rhodopsin obtained from photosynthetic bacteria. Isomerization of the 11-*cis* retinal to the all-*trans* form has been confirmed by several studies. However, it was thought for some time that a *cis-trans* isomerization could not occur on the picosecond time scale. Molecular-dynamics calculations demonstrate that this isomerization can occur on the picosecond time scale (Birge, 1981). Furthermore, resonance Raman studies comparing model compounds and bathorhodopsin (the latter which forms on the picosecond time scale) indicate the presence of a strained all-*trans* isomer with a protonated Schiff base (Palings *et al.*, 1987). (A Schiff base is formed by the facile condensation of the aldehyde group of retinal with the amine terminus of a nearby lysine residue.) As expected for the very fast transition from rhodopsin to bathorhodopsin, changes in the protein are very small upon formation of bathorhodopsin. In contrast, infrared absorption studies have shown that there are larger changes in the protein in the next step, i.e., the conversion of bathorhodopsin to lumirhodopsin (Ganter *et al.*, 1988). The retinal remains a protonated Schiff-base all-*trans* isomer. However, the environment around the Schiff-base linkage changes, apparently in preparation for its deprotonation in metarhodopsin II. The change in the opsin shift presumably results from the changes in the electrostatic environment in this region of the retinal. Further relaxation to metarhodopsin I occurs on the 50- μs time scale. In this form, retinal in the protein has the structure of a fully relaxed, protonated Schiff-base all-*trans* isomer. Deprotonation occurs for the formation of the meta II intermediate at about 20 ms. This latter intermediate is referred to as R^*, the photoexcited state which is the enzymatically active form of the protein. This form is stable for about 1 min after which the Schiff base of the all-*trans* retinal is hydrolyzed and the retinal separates from the opsin. It is later reconstituted after enzymatic conversion to the 11-*cis* isomer.

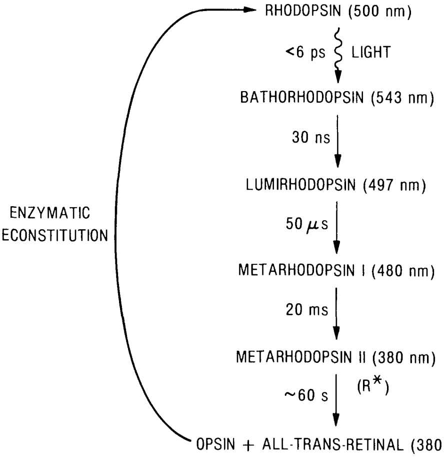

FIG. 19. Intermediate states in the thermal relaxation of rhodopsin following photoexcitation.

3.3 Electrical Response Induced by Molecular Conformation Changes

The primary event in the information transduction process discussed above results in a conformational transition in rhodopsin, i.e., the formation of R^*. Whereas this step was solved primarily by spectroscopic techniques, the next step, that of converting this structural information to an electrical impulse, was solved primarily by electrophysio-

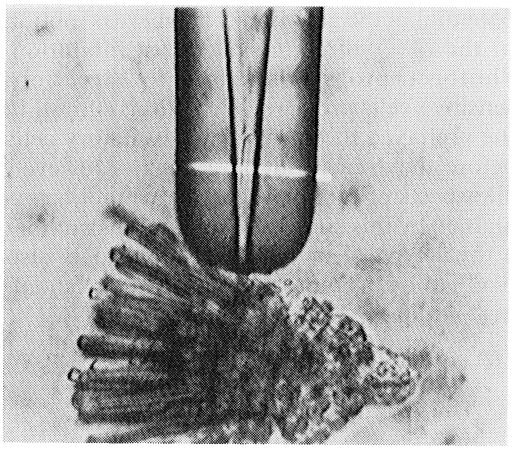

FIG. 20. Suction electrode method for measuring photoexcitation of a single rod cell. A seal between the electrode and the cell membrane allows for the removal of the remaining section of retina. Measurements of the single cell can then be made as a function of optical and chemical environment. [From Lewis and Del Priore (1988), from a photograph supplied by D. A. Baylor of Stanford University.]

logical measurements (Fig. 20) (Pugh and Cobbs, 1986; Stryer, 1987; Schnapf and Baylor, 1987). These were difficult experiments which in the end led to a very elegant model of how a structural change can be highly amplified so that single-photon events impinging on the retina can generate electrical signals which are processed by the brain.

Electrophysiological measurements showed that upon exposure to light the ionic permeability of the rod outer segment decreased. The conductance channels that are blocked by light absorption were found to be sodium channels. Normally, cyclic-GMP keeps the membrane sodium channels open. By blocking of these channels the sodium level in the photoreceptor cell decreases as there is also a sodium/potassium pump that is constantly pumping sodium out of the cell. The effect of this is a hyperpolarization, i.e., the potential inside the cell becomes more negative. This hyperpolarization, illustrated in Fig. 21 for several different light intensities, is transmitted to the synapse in the inner rod segment and the optical information is thereby passed to other cells for processing.

This mechanism of the energy transduction is so powerful that a detectable signal is generated by the absorption of a single photon by the photoreceptor. The amplification responsible for this sensitivity occurs during the chemical steps involved in the sodium channel closing. The first step in this process is the interaction of the light-modified rhodopsin (R^*) with a molecule called transducin, a signal-coupling protein. A subunit dissociation occurs in the transducin due to the conformational change in the rhodopsin. A single rhodopsin molecule can induce the subunit dissociation in 500 transducin molecules. These in turn activate an enzyme which hydrolyzes cyclic-GMP. No longer cyclic, GMP is thus unable to maintain the sodium channels in an open state, so the sodium influx stops and the cell hyperpolarizes. Each activated enzyme is capable of cleaving several thousand cyclic-GMP molecules. A single photon absorbed in the photoreceptor blocks the entry of a million sodium ions and results in a measurable nerve impulse!

3.4 Conversion of Electrical Signals into Visual Images: Motion and Color

Whereas the response of a rod cell to a single photon is large enough to be recorded, the response of a single cone cell is perhaps 100-fold lower and too small to be measured. However, the cone response is about four

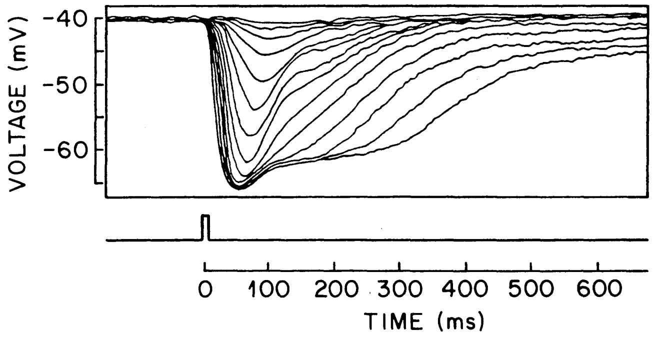

FIG. 21. Hyperpolarization of a photoreceptor cell as a function of the strength of the optical flash. Each flash is a factor of 2 more intense than the previous. [From Schnapf and Baylor (1987).]

times faster than the rod response. These different light-level and temporal sensitivities account for sensitive but monochrome night vision mediated by the rods as well as motion and color detection at high light levels by the cones (Schnapf and Baylor, 1987). There are three types of cone cells that have absorption maxima in the blue, green, and red regions of the visible spectrum. Color discrimination of light of a particular wavelength is computed by sensing the ratios of the responses of the three types of cone cells toward the light.

So far we have seen that the lens of the eye forms a pattern of light on the photoreceptors, and how the light impinging on these photoreceptors is first converted into molecular/chemical information, which is then transduced and amplified into an electrical signal. We examine how the nerve impulses, now encoding the amount of light received, are processed by the brain to interpret visual images, sensitive to form, movement, and color. The photoreceptors, oddly enough, are not on the surface of the retina; rather they line the back of the retina (see Fig. 14). The chemical and electrical signals generated by the photoreceptors are passed through several cell layers to the ganglion cells, which pass this information via the optic nerve to the brain.

The ganglion cells in certain species are capable of detecting the direction of motion. Certain cells respond to movement in only one direction. At its simplest level, motion in the preferred direction produces an action potential in the ganglion cell, whereas motion in the other direction produces inhibition. Photoreceptors connected to direction-sensitive cells are arranged so that stimuli in the preferred direction reach excitatory cells before they reach inhibitory cells. However, all aspects of motion detection cannot be explained by this simple model; it turns out that a third type of synaptic mechanism is also likely to be present, called "silent" or "shunting" inhibition (Poggio and Koch, 1987).

3.5 The Primary Visual Cortex

The primary visual cortex, also known as area 17, is located at the back of the brain in humans. It receives signals from the optic nerves after the signals have passed through the lateral geniculate nucleus (Fig. 22). The function of the lateral geniculate nucleus is to serve as a type of relay mechanism. Information from the left half of the retinas of both eyes passes through the left lateral geniculate nucleus, and then goes to the left-hand side of the brain. Thus, the left-hand side of the brain receives inputs from both eyes. The same is true for the right-hand side of the brain. However, within the lateral geniculate nucleus, cells in layers 1, 4, and 6 receive inputs from one eye, and the cells in layers 2, 3, and 5 receive inputs from the other eye. The segregation of left and right visual information is preserved as the signals pass into the visual cortex.

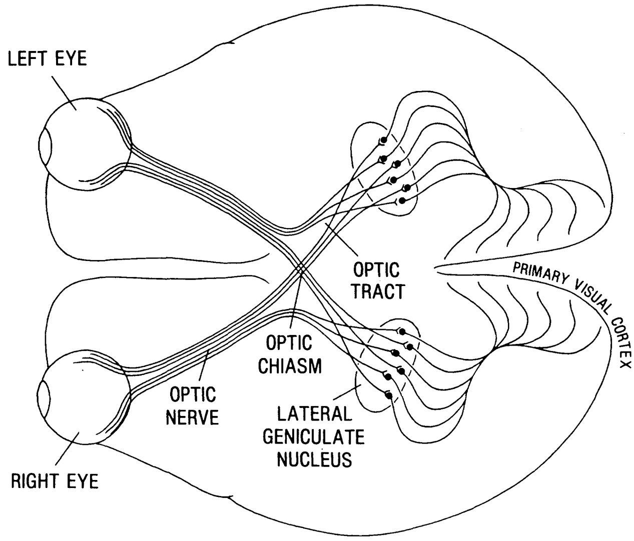

FIG. 22. Visual pathway is traced schematically in the human brain, seen here from below. The output from the retina is conveyed, by ganglion-cell axons bundled in the optic nerves, to the lateral geniculate nuclei; about half of the axons cross over to the opposite side of the brain, so that a representation of each half of the visual scene is projected on the geniculate of the opposite hemisphere. Neurons in the geniculates send their axons to the primary visual cortex. [From Hubel and Wiesel (1979).]

The primary visual cortex is a layered structure, wherein the six layers (layers I through VI) consist of dense and less-dense regions of cells. Early cell-staining work suggested that information coming into the cortex is processed in a very localized manner. That is, through synaptic connections, a signal can traverse the entire depth of the cortex in about four cells, whereas laterally, information is confined.

Basic experiments aimed at understanding the function of particular cells, whether in the cell layers of the eye, in the lateral geniculate nucleus, or in the cortex, consist of microelectrode recordings of single nerve fibers. Often carried out on monkeys, they are performed by presenting the animal with a visual stimulus, say a particular color, a dot, or a moving line. The responses to all these stimuli are recorded, and the cell is classified as to its function. Results from experiments of this sort showed that the receptive fields of the cells in the eye and in the lateral geniculate nucleus can be generally described as having "center-surround" behavior, i.e., a central circular excitatory field surrounded by an inhibitory one. They thus serve primarily to make comparisons between light levels in their receptive fields. Within the cortex the light-dark information is transformed into detection of line segments. Certain cells respond most strongly to lines or bars tilted at defined orientations. At this point the image is being operated on bit-by-bit, in a very localized fashion. At some point, the information must be analyzed to produce the perceived visual image.

The left and right visual information is combined within the cortex. This does not happen in the region that receives its input directly from the lateral geniculate nucleus, nor, in monkey, within the simple cells, which continue to preserve monocular information in what are called "ocular dominance" columns. The information from the two eyes is finally combined in subsequent projections.

Different regions of the primary visual cortex project into different regions of the brain. For example, the deepest layer, layer VI, projects back to the lateral geniculate nucleus, whereas layers II and III project to other regions of the cortex. Layer V projects to a visual center in the midbrain. It is likely that depth and color perception occur at these higher cortical areas. The study of these higher levels of perception and stereopsis rely heavily on psychophysics experiments and are somewhat out of the realm of biophysics.

The foregoing discussion has centered around the neural wiring of the visual system and the electrophysiological experiments that have established ocular dominance and sensitivity to motion and light intensity. Although genetic information dictates which neurons are initially wired together, these existing synapses are refined and new connections are made as the brain develops (Kalil, 1989). A series of very important biophysics experiments established many of the developmental aspects of the visual system. Torsten Wiesel and David Hubel in the 1960s sutured shut one of the eyes of newborn kittens and showed that activity of both eyes was necessary for the development of ocular dominance columns. Later work by Stryker and Harris (1986) showed through pharmacological blocking experiments that coincident nerve impulses, or action potentials, were essential for normal development. Work concerning the mechanism underlying these findings is of current research interest, and is presenlly focused on the protein molecules (receptors) and neurotransmitters involved in strengthening synaptic pathways (Kalil, 1989).

3.6 Summary

Experiments on the visual system have covered the full cycle, from the molecules responsible for the primary event in photoreception, to the membranes and organelles (rods and cones) which sense this information. Light absorption, converted to chemical information, is transmitted by electrical signals. These electrical signals convey information about form and motion to higher areas of organization in the brain, where perception takes place. Yet neural wiring in the brain is not a strict function of morphology and genetics; it is use-dependent. Hence, from the vantage point of this high level of organization, we are forced again to study the molecules, this time to uncover the mechanisms underlying synaptic strengthening.

This example of the visual system typifies the diversity and span of biophysics. Full understanding of this one aspect of biology— here the sense of vision— requires research at all levels of structure and function, including molecules, molecule-molecule interactions, assemblies, organelles, cells, and organs. Progress or a breakthrough in just one of these areas invariably opens up new lines of inquiry, which ripple through the entire fabric of the subject. Thus in biophysics, as in other areas of sciences, ideas and knowledge build upon an interplay between the results from various techniques and between the different levels of investigation.

GLOSSARY

Acetylcholine: A small molecule which is a neurotransmitter.

Action Potential: Transient electrical signal caused by alterations of the electrical properties of the membrane.

Adenine: A purine base found in nucleotides. Its one-letter code is A.

Adenosine Diphosphate (ADP): The product which results after one phosphate group has been hydrolyzed from ATP.

Adenosine Monophosphate (AMP): The product which results after two phosphate groups have been hydrolyzed from ATP.

Adenosine Triphosphate (ATP): A nucleotide containing three phosphate units. Hydrolysis of the phosphates provides energy for numerous biological functions.

***α* Helix:** A common structural motif found in proteins. It is stabilized by a hydrogen-bond network formed between the proton on the amino group of one amino acid and the carbonyl group of an amino acid three units away.

Amino Acids: Primary building blocks of proteins. They all contain a carboxyl group and an amino group, and one of 20 side chains. The amino acids condense through their carboxy and amino groups to form the polypeptide chains of proteins.

Antibody: A large protein molecule that recognizes a specific target molecule. Antibodies form the basis of the immune response.

Antigen: A foreign chemical substance or protein which is the target molecule recognized by an antibody.

Axon: The conduit which carries information from the neuron.

Bacteriorhodopsin: A membrane-bound, energy-transducing protein found in the purple membrane of *Halobacterium holobium.* Its active phototransduction element is retinal, the same chromophore present in the visual protein, rhodopsin.

Bases: The primary building blocks of DNA and RNA. These are nitrogen-containing ring compounds classed as either purines or pyrimidines. In DNA the purines are adenine and guanine; the pyrimidines are cytosine, and thymine. In RNA, thymine is replaced by uracil.

***β*-Pleated Sheet:** A common structural motif found in proteins. It usually contains an amino acid such as glycine or alanine which allows the polypeptide chains to be fully extended rather than coiled as in the *α* helix. Large stretches of this structure form a pleated sheet-like structure in which the polypeptide chains are either parallel or antiparallel to each other. Stabilization occurs by hydrogen bonding between an amino group on one chain and a carbonyl group on an adjacent chain.

Biophysics: An interdisciplinary field of science in which physical techniques and physical measurements are applied to biological problems. It combines physics, chemistry, and biology.

Cell: The simplest unit capable of reproduction in living organisms. It contains cytoplasm in which there are many different organelles and molecules and is surrounded by a membrane.

Channels: Proteins spanning a membrane and containing a pore, through which specific ions are allowed to pass.

Chemotaxis: Chemically directed movement of cells.

Chloroplast: An organelle found in plants which is responsible for photosynthesis.

Chromatin: The assembly of nuclear DNA and histones, which contains the complete genetic information for the cell.

Codon: The three-base code in DNA and RNA that specifies a particular amino acid.

Coenzymes: Small molecules associated with enzymes that are essential for enzymatic activity.

Cones: Photoreceptor cells largely responsible for color vision.

Cortex: The outer region of the brain, concerned with higher perceptual, cognitive, and motor functions.

Cytosine: A pyrimidine base that is found in nucleotides. Its one-letter code is C.

Cytosol: The intracellular fluid.

DNA—Deoxyribonucleic Acid: A biopolymer composed of a sugar (deoxyribose)- phosphate backbone which has bases (adenine, guanine, cytosine, and thymine) attached to it. DNA often forms a double helix and is the genetic material of all cells.

Dendrites: The fibers (processes) that carry information to the neurons.

Deoxyribose: A five-carbon sugar that occurs in DNA.

Depolarization: The process by which the cell's membrane potential becomes less negative.

Differentiation: The process during cell development, by which a cell acquires specialized characteristics.

Electrophysiology: The technique used to study the currents and electrical potentials associated with cells.

Enzyme: Proteins that catalyze specific biochemical reactions or transformations.

Eukaryotic: All plants and animals other than bacteria and certain algae. All of the cells in eukaryotes contain several organelles and have nuclei. The nuclei contain most of the cell's DNA.

Excitation: The neural process by which the electrical activity of a cell is increased.

Gene: A highly specific stretch of DNA along a chromosome that codes for a particular product.

Genetic Code: The mapping between the sequence of bases in DNA and specific amino acid residues.

Genome: Full set of chromosomes in a cell. The genome completely specifies the organism.

Glycosidic Linkage: A bond between a base and a sugar, found in nucleotides.

Guanine: A purine base that is found in nucleotides. Its one-letter code is G.

Guanosine Monophosphate (GMP): A nucleotide essential for the visual process.

Heme: An iron atom surrounded by a porphyrin macrocyclic ring, responsible for such diverse functions as oxygen storage and electron transfer.

Hemoglobin: A tetrameric heme-containing protein. It stores and transports oxygen.

Histone: A protein assembly inside the nucleus around which the DNA is wound.

Hyperpolarization: The process by which the cell's membrane potential becomes more negative.

Immunocytochemical: A technique in which cells are stained with antibodies which recognize specific chemicals in the cell.

Inhibition: The neural process by which the electrical activity of a cell is decreased.

Lateral Geniculate Nucleus: An electrical relay system which is part of the visual process.

Lipid: A molecule containing a hydrophobic tail and a hydrophilic head group. A fatty acid is a lipid.

Membrane Potential: The voltage difference across the cell's plasma membrane.

Membrane: A lipid bilayer which contains numerous proteins. It serves to isolate organelles or cells from their surroundings and also maintains chemical gradients and electrical potentials.

Messenger-RNA (*m*-RNA): The RNA which contains the genetic message, ultimately translated in the ribosome.

Mitochondrion (pl. Mitochondria): An organelle found in eukaryotic cells, responsible for ATP generation and respiration.

Neuron: A nerve cell. It receives, conducts, and transmits electrical signals.

Neurotransmitter: Small molecules that are released in the synapse and are responsible for chemical transmission of information in neurons.

Nucleic Acids: Linear polymers of nucleotides, linked by the phosphate of one unit and the sugar of the next. Examples are DNA and RNA.

Nucleolus: The part of the nucleus that contains RNA and proteins and functions to synthesize and assemble ribosomal RNA.

Nucleosome: A DNA-histone assembly.

Nucleotide: A basic building unit of nucleic acids. A nucleotide consists of a purine or pyrimidine base, a five-carbon sugar, and one or more phosphate groups.

Nucleus: The central organelle of eukaryotic cells. It contains a complete copy of the organism's DNA, and some of the machinery for genetic replication.

Ocular Dominance Columns: Regions of the visual cortex that are specifically associated with one eye or the other.

Organelles: Subcellular components that carry out highly specific functions. Examples include ribosomes, chloroplasts, and mitochondria.

Patch Clamping: Electrophysiological technique in which the electrode forms a high impedance "patch" with a portion of a membrane, enabling one to monitor channel activity.

Phospholipid: The most ubiquitous biological lipid consisting of a fatty acid hydrocarbon tail and a polar head group.

Photosynthesis: The biological transduction of light energy into chemical energy.

Photosynthetic Reaction Center: Membrane-bound assembly of several proteins responsible for photosynthesis. It is the first membrane-bound protein whose crystal structure was solved.

Polypeptide Chain: A linear polymer of amino acids.

Primary Structure: The linear sequence of monomer units that forms a nucleic acid or a polypeptide.

Procaryotes: Bacteria and certain algae whose cells contain simple internal structures.

Protein: A linear chain of amino acids, folded into a highly specific three-dimensional shape. Other than water, proteins are the most abundant molecules of the cell and take part in all aspects of cellular function and structure such as catalysis, transport, immune response, etc.

Pumps: Specific proteins responsible for maintaining ionic and *p*H gradients across the membrane.

Purine: A nitrogen-containing ring compound, derivatives of which form the bases adenine and guanine found in nucleotides.

Pyrimidine: A nitrogen-containing ring compound, derivatives of which form the bases thymine, cytosine, and uracil found in nucleotides.

Quaternary Structure: The relationship between subunits in multiple-subunit proteins, such as hemoglobin.

Random Coil: The random state of protein structure.

Receptors: Proteins that have specific binding sites for target molecules. Once the receptor has bound its target molecule, it undergoes a structural or chemical change, enabling it to control a specific biological function.

Replication: The process of forming identical copies of DNA from existing DNA.

Respiration: The biological oxidation of small molecules in which oxygen is the ultimate electron acceptor. Respiration generates the high-energy molecule ATP.

Resting Potential: The potential across the membrane of an electrically inactive (not spiking) cell.

Retinal: The chromophore of the visual system. Its structure is related to vitamin A and it undergoes a conformational change when it absorbs light.

Rhodopsin: A membrane-bound protein of the visual system. It contains retinal as its prosthetic group.

Ribose: A five-carbon sugar found in RNA.

Ribosome: An organelle in which protein synthesis takes place. The genetic message contained in RNA is converted into a specific string of amino acids on the ribosome.

RNA—Ribonucleic Acid: A biopolymer composed of a sugar (ribose)-phosphate backbone which has bases (adenine, guanine, cytosine, and uracil) attached to it.

Rod: A photoreceptor cell largely responsible for night vision.

Secondary Structure: In nucleic acids, the arrangement of bases which determines the efficiency of the replication process. In proteins, the secondary structure is generated by local interactions between adjacent amino acids of the polypeptide chain. The most frequently found protein secondary structures are α helices and β sheets.

Substrate: A molecule which is acted upon by an enzyme.

Synapse: The junction formed between neurons.

Tertiary Structure: The three-dimensional arrangement of helices and sheets with respect to each other. It involves both long- and short-range amino acid interactions.

Thymine: A pyrimidine base that is found in nucleotides. Its one-letter code is T.

Transcription: The process by which the genetic message in DNA is converted into various RNAs, including messenger-RNAs, transfer-RNAs, and ribosomal-RNAs.

Transfer-RNA (*t*-RNA): The RNA responsible for transporting specific amino acids to the ribosome for their ultimate incorporation into polypeptides.

Translation: The process in which the message contained in RNA is converted into the specified amino acid sequence.

Uracil: A pyrimidine base that is found in nucleotides. Its one-letter code is U.

Voltage Clamp: Electrophysiological technique in which the membrane potential is controlled by injecting current into the cell.

21.1
Introduction

The science of the deformation and flow of matter was termed *rheology* by E. C. Bingham on the occasion of the formation of the American Society of Rheology in 1929. During the First International Congress on Rheology, held in Holland in 1948, A. L. Copley suggested the term *biorheology* for the application of rheology to biological systems. Later on, further terms were introduced, such as *hemorheology* – also suggested by Copley – for the branch of biorheology that is, concerned with blood and blood vessels, or *electrorheology* – suggested by G. W. S. Blair. As in rheology, the fundamental problem in biorheology is the formulation of constitutive equations. The basis for the mathematical description of the rheological behavior of biological systems is a detailed knowledge of anatomical structures and organic functions. Against this background, close interdisciplinary cooperation is an essential prerequisite for the successful application of rheological methods to mechanical problems in biology.

This review of biorheology deals with several problems inherent in hemorheology, hemodynamics, and pneumodynamics. In the first section, an introduction to rheological concepts is given, which includes a description of pressure–flow relationships for steady and pulsatile flow. In the second section, the rheology of body fluids, in particular that of blood in macrovessels and microvessels, is outlined. The basic techniques for studying blood rheology are also presented. The third section deals with the rheological properties of the myocardium and arterial mechanics, in particular the viscoelastic properties of the arterial wall, the propagation of pulse waves within the arterial system, and the pressure–flow relationships within the venous system. Finally, in the fourth section, the rheological behavior of the lung–chest system and the problems inherent in the airway resistance are discussed.

21.2
Rheological Concepts

An important task in biorheology is to establish mathematical relationships between deformation or flow of biological material and those processes associated with changes in dimensions and time.

Handbook of Molecular Biophysics. Methods and Applications. Edited by Henrik G. Bohr.

21.2.1
Basic Constitutive Equations

Equations that define the relationships between stresses and dynamic variables, for example, strains, or, in the case of fluids, rates of strain, are called *constitutive equations.*

In the classical theory of elasticity, Hooke's law relates the stress σ applied to an elastic material to the change in extension, the strain ε:

$$\sigma = E\varepsilon \tag{1}$$

where the elastic modulus E is a proportionality constant that defines the elastic properties of the material. In the classical theory of hydrodynamics, Newton's law is a constitutive equation relating shear stress τ – which is the frictional force F over the area A – applied to a viscous fluid, to the shear rate γ – which is identical to the velocity gradient dv/dr within the fluid:

$$\tau = \eta\gamma \tag{2}$$

where the viscosity η is a proportionality constant that defines the viscous properties of the fluid, v is the velocity of the fluid, and r the radial coordinate.

In the case of infinitesimal changes in stress and strain, the behavior of many solids and fluids is well approximated by these laws. Marked deviations, however, can be observed when the changes are not infinitesimal, or when they apply to materials that combine elastic and viscous properties; solids and fluids exhibiting both elastic and viscous behavior are commonly termed viscoelastic.

21.2.2
Viscoelastic Models

Constitutive equations of viscoelastic solids and fluids are much more complicated than Eqs (1) and (2). Constitutive equations that permit a complete specification of the rheological behavior of biological material are still not available. A suitable way of describing the different types of behavior of materials, however, is to consider the analogy of the behavior of mechanical models. One approach to viscoelasticity is to describe elasticity and viscosity in terms of elastic springs and viscous dashpots, respectively, and to combine these elements to describe more or less complicated viscoelastic bodies.

The model most analogous to an ideal elastic material is the spring. The stress acting on a spring and the resulting strain are always in phase. Furthermore, the compressed spring can store energy, which can be used to do work when the spring is released. The mechanical model analogous to an ideal viscous fluid is the dashpot comprising a piston moving in oil. The dashpot is an energy-dissipating element. It cannot support any stress, which means that not the strain but the shear rate is directly proportional to the applied stress.

The simplest mechanical model of a viscoelastic solid is the parallel arrangement of a spring and a dashpot, known as the *Voigt (or Kelvin) model*, shown in Figure 21.1; it is a model of a solid, since the maximum extension of this model is limited by the elastic properties of the spring and the force applied. The simplest mechanical model of a viscoelastic fluid is a spring and a dashpot

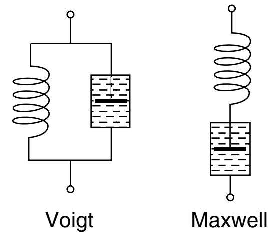

Fig. 21.1 Viscoelastic elements. Left: the Voigt element; right: the Maxwell element.

in series, known as the *Maxwell model* (Figure 21.1). This is a model of a fluid because any force applied leads to a continuous extension or flow of the model. More complex material that does not behave as an ideal viscoelastic solid or an ideal viscoelastic fluid can be described in terms of combinations of these basic two-element models.

21.2.2.1 **Transient Tests**

Fundamental rheological parameters can be measured using creep testing and by the use of the viscoelastic models. When a constant stress σ is applied to a Voigt solid, the spring cannot be extended instantaneously because of the viscous resistance of the dashpot arranged in parallel. As time proceeds, however, the strain gradually increases to a maximum value, which depends on the applied force and the elasticity of the spring (Figure 21.2a). When the stress is removed, the energy stored by the Voigt solid is also released and the system recovers its initial length. This behavior is termed *creep* and can be described by the following equation:

$$\varepsilon(t) = \sigma J(t) \tag{3}$$

where $\varepsilon(t)$ is the time-dependent strain, and $J(t)$ the creep compliance.

The quotient of the viscosity of the dashpot and the elasticity of the spring is a measure of the time required to extend the spring, which is retarded by the dashpot; this time is thus known as the *retardation time*.

When a Maxwell fluid is subjected to a constant strain ε, as shown in Figure 21.2b, there is an initial jump in the stress, reflecting the elastic extension of the spring. As time passes, the spring contracts and pulls the piston out of the

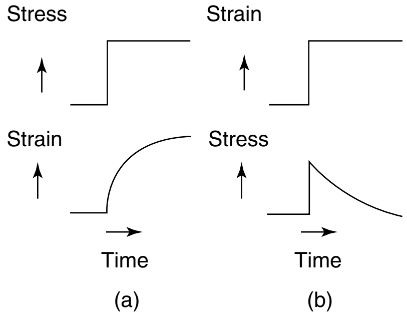

Fig. 21.2 Time dependence of stress and strain in (a) creep and (b) relaxation.

dashpot, so that the stress relaxes. When the spring reaches its initial length, the flow stops and the stress become zero. The relationship between the time-dependent stress and the constant strain is called *stress relaxation,* and is given by

$$\sigma(t) = \varepsilon G(t) \tag{4}$$

where $G(t)$ is the relaxation modulus.

In the case of the Maxwell model, the quotient of the viscosity of the dashpot and the elasticity of the spring is called the *relaxation time,* since it is a measure of the time required for stress relaxation.

21.2.2.2 **Oscillatory Tests**

In addition to these transient tests, dynamic tests are often used, during which the stress applied to material under investigation may be varied sinusoidally. If the material exhibits linear viscoelastic properties, the strain is also found to change sinusoidally, but there will be a phase shift between stress and strain. The relationship between stress and strain can be described by expressing the periodically varying stress and the relaxation modulus as complex quantities:

$$\sigma^*/\varepsilon = G^* = G' + jG'' \tag{5}$$

where σ^* is the complex stress, G^* the complex modulus, whose real part G' is the storage and whose imaginary part G'' the loss modulus, and $j = \sqrt{(-1)}$. For a description of the mechanical properties of viscoelastic solids, for example, blood vessels, the term elastic modulus is used instead of storage modulus. The loss modulus G'' is the product of the viscosity η and the angular frequency $\omega (= 2\pi f, f =$ frequency):

$$G'' = \omega\eta \tag{6}$$

G' is the in-phase relationship between stress and strain and is therefore associated with the elastic behavior and the energy storage and release of the material. G'' is the 90° out-of-phase relationship between stress and strain and is thus associated with the loss of energy in the form of heat due to the viscous resistance of the material.

When the storage and the loss moduli of a Maxwell model, and those of a Voigt model, are plotted against angular frequency, curves as shown in Figure 21.3 are obtained. In both models, G' increases with frequency, while G'' rises to a maximum at a frequency equal to the inverse of the relaxation and the retardation time, respectively. In most cases, biological materials deviate markedly from this simple behavior, so that the frequency dependence of the moduli is much more complicated.

Equations (1)–(6) are, strictly, valid only for linear viscoelastic materials. To overcome these restrictions, Frank (1920) introduced a differential definition of the elastic modulus E^*, relating an infinitesimal change in stress ($d\sigma$) to that in the corresponding strain ($d\varepsilon$):

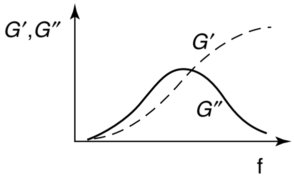

Fig. 21.3 Response of viscoelastic elements to sinusoidal stress. G': storage modulus; G'': loss modulus; and f: frequency.

$$E^* = \frac{d\sigma}{d\varepsilon} \tag{7}$$

This modulus, which is often referred to as *tangent elastic modulus*, permits a description of nonlinear viscoelastic solids when very small changes in stress are applied and the mean stress is varied over a wide range. This procedure is widely used for the examination of the mechanical properties of biological solids, for example, of the blood vessel wall (Section 21.4.2.2).

The elastic elements of the Maxwell and Voigt models are originally assumed to be Hookean and the viscous elements Newtonian. For the representation of nonlinear viscoelastic solids and liquids, these assumptions are no longer maintained, and merely the arrangement of the components of these models are termed Maxwell and Voigt.

21.2.3
Pressure–Volume Relationships

An alternative approach to the problem of characterizing the mechanical properties of structures, such as heart, lungs, or blood vessels, is the introduction of relationships between changes in pressure (dP) and changes in volume (dV) instead of those of stress and strain. Quantities that are frequently used are compliance C:

$$C = \frac{dV}{dP} \tag{8}$$

and the reciprocal of compliance, elastic stiffness E':

$$E' = \frac{1}{C} = \frac{dP}{dV} \tag{9}$$

Since compliance and elastic stiffness depend on the initial volume of the body, normalizations of C and E' are often employed, which are called *volume distensibility* C^*:

$$C^* = \frac{1}{V}\frac{dV}{dP} \tag{10}$$

and volume elasticity κ (the reciprocal of the volume distensibility):

$$\kappa = \frac{dP}{dV}V \tag{11}$$

21.2.4
Pressure–Flow Relationships

The flow rate i is defined as fluid volume dV flowing through the cross-sectional area A of a vessel in time dt:

$$i = \frac{dV}{dt} \tag{12}$$

As can be seen from a consideration of dimensional similitude, the flow rate can also be written as:

$$i = Av_m \tag{13}$$

where v_m is the mean velocity of the fluid in the vessel.

The flow rate in a vessel is proportional to the pressure difference ΔP over the length of the vessel, and may be written, in accordance with Ohm's law:

$$i = \frac{\Delta P}{W} \tag{14}$$

This is also known as *Darcy's law*. The proportionality constant W is the viscous or frictional resistance to flow.

21.2.4.1 Laminar Flow

When the flow of a Newtonian fluid in a very long, straight, rigid, cylindrical vessel is laminar, the frictional resistance can be calculated from the vessel dimensions and the viscosity of the fluid.

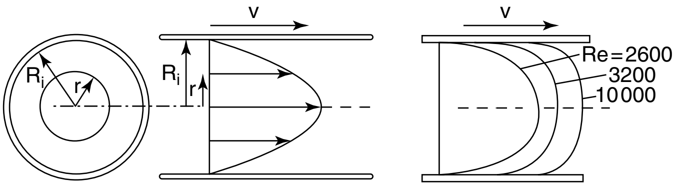

Fig. 21.4 Velocity profiles in a rigid, straight tube of a circular cross-section for steady (middle) and turbulent flow (right) with increasing Reynolds numbers (*Re*). R_i is the internal radius, r is the radial coordinate, and v is the velocity.

The fluid layers within the vessel are arranged in cylindrical form (Figure 21.4). The contact surface between two cylinders of radius r and length l is $2\pi rl$; thus, the viscous or frictional force F between these cylinders is, in accordance with Eq. (2), $F = 2\pi r\eta l dv/dr$. For the velocity v of the fluid to be steady, the frictional force has to be counterbalanced by the pressure difference ΔP over the length l acting on the cross-sectional area $r^2\pi$ of the cylinder:

$$\Delta Pr^2\pi = -2\pi r\eta l\frac{dv}{dr} \qquad (15)$$

Integrating and applying the boundary condition that the fluid rests on the vessel wall ($r = R_i$ = internal radius) gives the following expression:

$$v = \Delta P(R_i^2 - r^2)/(4\eta l) \qquad (16)$$

Thus, the velocity profile is parabolic, as shown in Figure 21.4, irrespective of the dimensions of the vessel and the properties of the fluid. With this type of flow, the velocity of the fluid is a maximum in the center of the vessel.

The flow rate i is obtained by integrating Eq. (16) once from $r = 0$ to $r = R_i$:

$$i = \Delta PR_i^4\pi/8\eta l \qquad (17)$$

This is known as *Hagen–Poiseuille's law.*

According to Eq. (14), the frictional resistance to flow is

$$W = 8\eta l/R_i^4\pi \qquad (18)$$

where W is proportional to the length of the vessel and to the viscosity of the fluid, and inversely proportional to the fourth power of the internal radius. It should be noted that this resistance to flow is always the smallest possible for given vessel dimensions and viscosity. The resistance to flow is far greater in all other types of flow than in the Hagen–Poiseuille type. To obtain a lower limit, Eq. (18) is often used for the estimation of resistances to flow in arteries, although none of the assumptions necessary for the evaluation of Eq. (17) is applicable to the circulation.

21.2.4.2 Turbulent Flow

In turbulent flow, the velocity components have random turbulent fluctuations superimposed on their mean values, so that it is not possible to characterize the motion of individual elements mathematically. The change from laminar to turbulent flow is determined by the entrance of the vessel, wall roughness, and Reynolds number *Re*; this number is defined by a dimensionless combination of the mean velocity v_m, the viscosity η, the density ρ of the fluid, and the internal diameter D_i of the vessel:

$$Re = D_i v_m \rho / \eta \tag{19}$$

The critical Reynolds number for the transition from laminar to turbulent flow is 2000–2200. However, if sources of disturbance such as roughness, vibration, or sharp corners are eliminated at the entrance of the vessel, transition can occur at Reynolds numbers as high as 40 000–50 000.

As shown in Figure 21.4, too, the velocity profile in turbulent flow is virtually uniform near the center of the vessel, with a very steep velocity gradient near the wall. Furthermore, the velocity profile depends on the Reynolds number; when Re increases, the velocity distribution becomes more and more uniform. The flow rate is no longer directly proportional to the pressure difference ΔP, but increases almost proportionally to the square root of ΔP over the vessel length. Hence,

$$\Delta P = K\, i^2 \tag{20}$$

where K is a proportionality constant.

The formation of eddies within a tube, for example, at branches, does not necessarily lead to true turbulence, since such disturbances may disappear again some distance downstream. This type of flow is called *transitional.*

21.2.4.3 **Oscillatory Flow**

The equations of motion for a viscous Newtonian fluid are the Navier–Stokes equations. In general vector form, these equations are

$$\frac{\partial \boldsymbol{v}}{\partial t} + (\boldsymbol{v} \cdot \nabla)\boldsymbol{v} = -\frac{1}{\rho}\mathrm{grad}P + \frac{\mathbf{F}}{\rho} + \frac{\eta}{\rho}\nabla^2 v \tag{21}$$

where ν is the fluid velocity, ρ and η are density and viscosity, P is the pressure of the fluid, $\mathbf{F}$ is an external force, for example, gravity, and ∇ is the nabla and ∇^2 the Laplace operator.

Exact solutions of the Navier–Stokes equations can only be obtained for the flow in situations permitting reduction of these equations to linear differential equations. A description of pulsatile flow in rigid vessels requires the application of various approximations.

1. The velocities must be small, so that the convective terms, $(\nu\cdot\nabla)\ \nu$, can be neglected.
2. All velocities except those in the axial direction are very small.
3. There is no pressure gradient in the radial direction.
4. The fluid velocity is independent of the axial position, that is, the total fluid mass within the vessel is accelerated and decelerated simultaneously.
5. Forces acting from the outside, such as gravity, can be neglected.

If these assumptions apply, the Navier–Stokes equations reduce to

$$\frac{\partial v_z}{\partial t} = \frac{1}{\rho}\frac{\partial P}{\partial z} + \frac{\eta}{\rho}\left(\frac{\partial v_z}{\partial r^2} + \frac{1}{r}\frac{\partial v_z}{\partial r}\right) \tag{22}$$

where v_z is the velocity in the axial direction, z the axial, and r the radial coordinate. Furthermore, assuming pulsatile flow under steady-state conditions, both the pressure gradient $\partial P/\partial z$ and the axial fluid velocity v_z can be written as components of Fourier series:

$$-\frac{\partial P}{\partial z} = P_z \exp(j\omega t) \quad \text{and}$$
$$v_z = V_z \exp(j\omega t) \tag{23}$$

P_z is the complex amplitude of the pressure gradient and V_z the complex amplitude of the velocity in the axial direction at vessel radius r. Under the boundary condition that the fluid does not slip on the wall ($v_z = 0$ at $r = R_i$), and using Eq. (23), Eq. (22) becomes

$$v_z = \frac{P}{j\omega\rho}\frac{J_0((r/R_i)\alpha_w\sqrt{-j})}{J_0(\alpha_w\sqrt{-j})}\exp(j\omega t) \tag{24}$$

As abbreviation, the dimensionless number $\alpha_w = R_i\sqrt{\omega\rho/\eta}$, which characterizes kinematic similarities in the oscillating fluid, is introduced. J_0 is a Bessel function of the first kind and zero order. Equation (24) gives the distribution of the fluid velocity in a rigid vessel as a function of the radius and angular frequency.

Using Eq. (24), the axial velocities of fluid layers and their distribution within the vessel can be calculated. For values of α_w below 1, all velocity profiles are virtually parabolic throughout pulse cycle. With increasing α_w, the velocity distributions become more and more uniform near the center, the velocity amplitudes decrease, and the velocity lags behind the pressure; this is shown in Figure 21.5 for three different α_w values. Furthermore, as shown in this figure, reversal of velocity begins in the layers near the wall, and the phases of the velocities near the center lag behind those of the marginal layers. At very high α_w values, the central layers oscillate like a solid body, so that the steepest velocity gradients are near the wall. An application of these computations for pulsatile flow in arteries is given in Section 21.4.3.3, Velocity Profiles in Arteries.

21.3
Rheology of Body Fluids

21.3.1
Viscosity of Non-Newtonian Fluids

Under conditions of unidirectional, laminar flow and constant temperature, Newton's law (Eq. (2)) can be used to define the viscosity η:

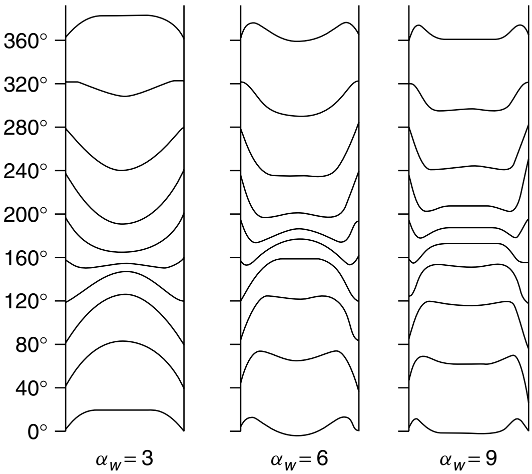

Fig. 21.5 Velocity profiles resulting from a sinusoidal pressure gradient in a rigid tube at three different values of α_w, as calculated with Eq. (24). Profiles are given at intervals of 40°. In each case, the zero value of velocity is indicated by a horizontal line in the left margin. The magnitudes of the velocities are multiplied (from left to right) by 1, 4, and 8, respectively.

$$\eta = \tau/\gamma \tag{25}$$

For homogeneous or Newtonian fluids, η is a constant of the fluid, which is independent of shear stress and shear rate and, thus also of the tube dimensions and the velocity of the fluid.

In the case of inhomogeneous fluids, the relationship between τ and γ is not the simple one proposed in Eq. (25); the viscosity of such fluids depends not only on temperature but also on shear rate and/or shear stress:

$$\eta = \eta(\tau, \gamma) \tag{26}$$

Fluids exhibiting variable viscosity are called *non-Newtonian*. In particular, suspensions of rigid particles in a homogeneous solution are numbered among the non-Newtonian fluids. The rheological behavior of a suspension is determined by the viscosity of the continuous phase and by the nonlinear viscoelastic properties of the suspended particles. Therefore, the Newtonian constitutive equation cannot represent the behavior of fluids exhibiting a variable η. If this fact is ignored and Eq. (25) is applied to a non-Newtonian fluid, the so-called *apparent viscosity* (η_{app}) is determined.

The particles impede the free movement of adjacent laminas of the streaming suspension. This gives rise to the formation of a central cell column with a thickness that is in the order of the dimension of the particles and results in an increase in apparent viscosity. The degree of obstruction of the laminar flow depends on the size, shape, number, and deformability of the suspended particles.

21.3.2
Instrumentation

When one investigates the rheology of biological fluids, specially designed equipment is required. The measurement of viscous or viscoelastic properties of liquids is carried out on viscometers that permit analysis of stress acting on a fluid for a given shear rate. The principle of such instruments is that of two parallel plates at a given distance y apart, with a fluid between them (Figure 21.6). A tangential force F acts on the top plate in such a way that this plate is moved relative to the resting bottom plate at a constant velocity v. The marginal fluid layer adhering to the top plate has the velocity v, while the velocity of the marginal fluid layer adhering to the bottom plate is zero. The velocities of the fluid layers between these two marginal layers increase linearly from the bottom to the top, so that a linear velocity gradient $-dv/dy$, referred to as *shear rate* γ, is developed. The force per unit area F/A is known as *shear stress* τ. According to Eq. (25), the plot of F/A vs $-dv/dy$ characterizes the viscosity of the fluid.

The parallel plate system is not a suitable viscometer, since the fluid cannot

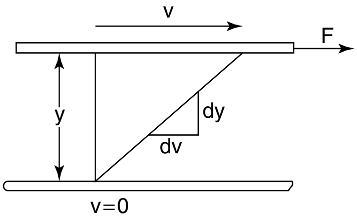

Fig. 21.6 Velocity distribution in a steady-state laminar flow between a fixed ($v = 0$) and moving plate (v).

be kept in place. Many instruments have been developed which overcome these difficulties. Viscometric devices designed for the measurement of the viscous properties of blood, blood plasma, and other body fluids, which are generally based on this two-plate principle and are capable of keeping the fluid in place, can be placed in one of three categories (Figure 21.7): cone and plate, cone in cone, and Couettetype (or narrow-gap concentric cylinder) viscometers. Within all such viscometers, the fluid under test is kept in the space between the cone and the plate, the cone and the cone, or the two cylinders. One unit is rotated and the drag transmitted by the fluid to the other unit is measured by the angular deflection of this unit or by the force required to return it to its original position.

A second type of viscometer is the capillary tube viscometer, which is often used in the measurement of macro- and microrheological properties of blood.

A third type, in which the resistance of a fluid to a body moving through it is measured, has also been employed in various forms of falling-sphere viscometers.

21.3.3
Rheology of Blood

Whole blood is a non-Newtonian fluid, since it is a suspension of formed elements – including red cells (erythrocytes), white cells (leucocytes), and platelets – in plasma. Plasma consists mainly of proteins, at an average concentration of 7% of the total volume, which are dissolved in a saline solution. In contrast to the results of earlier experiments, plasma is now described as a Newtonian fluid, so that it is a continuous suspension medium for the formed elements. Normally, at 37 °C the viscosity of plasma is 1.5–1.8 mPa s, that is, 1.5–1.8 times as great as that of water ($\eta_{\text{water}} = 1$ mPa s).

Apart from other parameters, the apparent viscosity of blood increases when the concentration of the formed elements increases. The ratio of blood cells to total blood volume is known as the *hematocrit*. For human blood, the hematocrit is normally about 45%, and the viscosity in large vessels at 37 °C is about 4–6 mPa s. The normal value of the hematocrit permits optimal oxygen transport within the vascular system. If the hematocrit increases – as in polycythemia – the potential advantage for increased oxygen transport capacity is offset by the increase in blood viscosity, thus reducing – at a given pressure – the flow to the tissues (Eq. (17)).

21.3.3.1 Macrorheology

The non-Newtonian behavior of blood is characterized by an increase in apparent viscosity when the shear stress (or the shear rate) decreases (Figure 21.8). The dependency of the apparent viscosity on shear stress is smaller when the hematocrit is lower. The high apparent viscosity under creep flow is due to cell aggregation, that is, the attraction of one erythrocyte for another, which under low

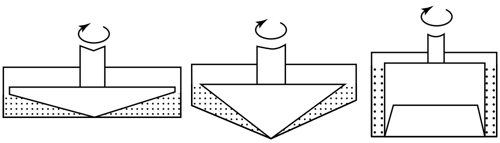

Fig. 21.7 Viscometers. Left: cone and plate; middle: cone in cone; right: Couette type.

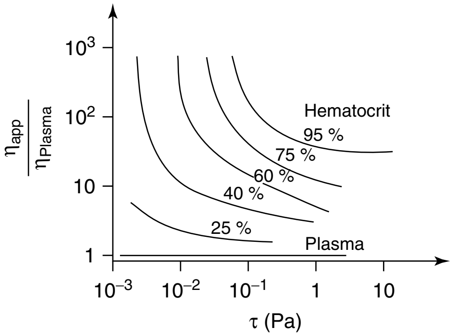

Fig. 21.8 Apparent viscosity (η_{app}) of human blood related to the viscosity of plasma (η_{plasma}) as a function of shear stress (τ). At each curve the hematocrit is given.

shear stress results in the formation of rolls of cells (rouleaux). When shear increases, the cells disaggregate, and the rouleaux disperse; this results in a decrease in apparent viscosity.

The aggregation of blood cells is accomplished under the influence of large proteins, for example, fibrinogen and α_2 globulins, the so-called agglomerines. These proteins support the aggregation of erythrocytes which impede their movement, thus the blood flow. At low shear rates, any increase in fibrinogen concentration leads to an increase in the apparent blood viscosity; the viscosity of a suspension of erythrocytes in serum, which is plasma lacking fibrinogen, is lower than that of a suspension of erythrocytes in plasma that has the same hematocrit.

21.3.3.2 **Microrheology**

In tubes with internal diameters greater than about 1 mm, whole blood behaves like a Newtonian fluid. Only in the microcirculation does the anomalous rheological behavior of blood become evident. In Figure 21.9 the relationship between the apparent viscosity and the hematocrit of red cell suspensions, streaming with relatively high velocities through tubes of various diameters, is shown. At tube diameters of 1 mm or more, the apparent viscosity increases markedly with increasing hematocrit of the suspension. This increase in viscosity is less pronounced for smaller tube diameters. In tubes with diameters of 11 µm, the apparent viscosity is almost independent of the hematocrit, and equals that of the solution.

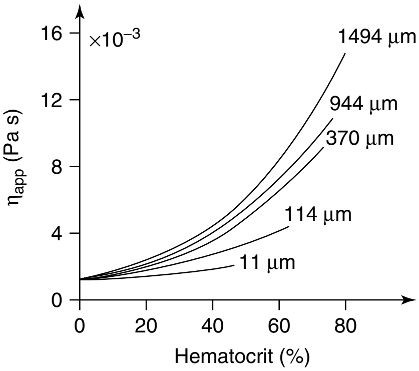

Fig. 21.9 Apparent viscosity (η_{app}) of suspensions of erythrocytes in physiological saline solution at 25 °C as a function of hematocrit. At each curve, the internal diameter of the perfused tube is given (Modified from Haynes, 1962).

For the same hematocrit, the apparent viscosity of the suspension decreases as the tube size becomes smaller. This rheological behavior of blood is due mainly to the deformability of the red cells, since these cells are the major formed elements in blood, occupying more than 95% of this volume. At rest, the shape of the erythrocytes is generally that of a biconcave discoid, the diameter of which is about 8 μm. Because of the fluid content of the erythrocytes and the high flexibility of their membrane, streaming blood behaves like an emulsion of liquid droplets rather than a suspension of rigid corpuscles. The shear stresses acting on the membranes cause rotation of the cells, which leads to deformation of the erythrocytes and to a sliding of the membrane relative to the viscous fluid within the cell. Thus, some force acting at right angles to the axis of the vessel is exerted on red cells near to the wall and carries the cells toward the axis. This radial migration results largely in the deformability of erythrocytes – as the deformability becomes less, so does the migration velocity – and the distribution of the shear rate in the fluid, which is high near the wall and low near the axis. Therefore, the radial migration velocity is greatest near the wall and decreases as the cells move toward the axis.

As a result of this migration, there is a higher concentration of blood cells near the axis than at the wall. The reduction in the number of red cells within the marginal fluid layers creates an almost cell-free zone of low viscosity, while in the middle of the vessel a central column is formed, in which the flexible erythrocytes are packed close together. Because of this process, the shear rate within the marginal zone further increases, while that in the vicinity of the axis is decreased, resulting in the formation of a nonsheared plug of cells, which moves at a relatively high velocity in a marginal zone of low viscosity. The narrower the tube, the greater the shearing force acting on the cell-free layers in the vessel diameter and the more pronounced the reduction in apparent viscosity. Therefore, the apparent viscosity of the blood is reduced. This decrease in apparent viscosity as the vessel diameter becomes smaller is referred to as the *Fåhraeus–Lindqvist effect* after the scientists who first reported it (Fåhraeus and Lindqvist, 1931). This effect starts at tube diameters of about 300 μm; the minimum value of apparent viscosity is reached at diameters of 8–9 μm. In these vessels, the apparent viscosity is only about 10–15% greater than the viscosity of plasma. In smaller vessels, the apparent viscosity increases again.

Dynamic Hematocrit The mean transit time of blood cells is reduced relative to the marginal plasma zone, since the central cell column streams faster through the blood vessel than the marginal layers. Therefore, the *dynamic* hematocrit in tubes exhibiting a marked cell-free marginal zone is smaller than the hematocrit in larger vessels (Fåhraeus effect; Fåhraeus, 1929). A proportion of the plasma leaks out of the capillary near the arterial end and returns in the distal zones. This extracapillary flow can help to explain the shorter residence time of blood cells in capillaries. The Fåhraeus effect is thought to be partly responsible for the reduction in the apparent viscosity in narrow tubes. It should be noted, however, that the relative volumes of blood cells and plasma moving through the microcirculation per unit time do not differ from the relative volumes defined by the *static* hematocrit.

Blood Flow in Capillaries It is not possible to give a uniform description of the systemic microcirculation, since there are considerable differences due to the specific vascular organization of each individual organ. Majno (1965) proposed a classification of capillaries on the basis of the continuity of endothelial cells into three main types: continuous, fenestrated, and discontinuous. Continuous capillaries are found in the skin, muscle, and central nervous system. The endothelial cells of capillaries in the intestine and endocrine glands and the glomeruli and the peritubular capillaries in the kidney manifest sievelike intracellular circular fenestrae having a diameter of 4 nm. Discontinuous capillaries with gross intercellular gaps exist in the sinusoids of the liver, spleen, and bone marrow. A further peculiarity that markedly influences shear stress and shear rate is seen in lung capillaries; blood is considered to flow around the alveoli in a space between two surfaces separated by posts having an irregular arrangement.

In spite of these substantial differences in detail, the passage of a suspension of relatively large particles at high concentrations is common to all capillaries. Therefore, capillary blood flow is generally discussed on the basis of typical capillary elements, namely continuous tubes ranging in diameter between 10 and 3 μm. At diameters down to about 8 μm, red blood cells can pass along a capillary without any distortion, but they have to flow in single file surrounded by a *zone* of plasma. In this case, the shape and deformability of the red cells do not noticeably influence capillary flow. Furthermore, at a diameter of about 10 μm, the apparent viscosity of blood is at its lowest and is independent of the hematocrit, since red cells can flow freely through this vessel, and an increase in the number of blood cells results only in a reduction in the distance between the cells within the single file, with no change in shear stress or shear rate.

In capillaries having a diameter of less than 8 μm, the erythrocytes must undergo deformation in order to pass through the lumen and normal red cells may adopt a variety of shapes, for example, parachute, drop, or arrow-head. Normal cells are capable of considerable distortion without any change in either surface area or volume. When the cells move along small capillaries, a lubricating layer of plasma is formed between the cell membranes and the vessel wall, which reduces the frictional forces between these surfaces. In order to keep the surfaces separate and to deform the cells adequately, high pressures must be generated locally. Therefore, shear stress increases at the same shear rate, so that, with decreasing tube diameter, apparent viscosity also increases. This is the reverse of the Fåhraeus–Lindqvist effect, which becomes apparent when the tube diameter is smaller than the diameter of the red cells.

Rheological Behavior of Pathological Blood Abnormal cells that are hardened or almost spherical cannot be deformed so easily, and therefore cannot pass undamaged through the smallest vessels. The deformability of erythrocytes further depends on the concentration of calcium ions in the plasma. When the blood contains less oxygen, calcium ions can enter the red cells in excess. This increase results in greater stiffness of the erythrocytes and, thus, in an increase in blood viscosity. In disorders such as sickle cell anemia, an increase in viscosity due to decreased deformability of red cells is also found. The spleen and kidneys of patients suffering from this type of disease are gradually destroyed by repeated blockage of the microcirculation.

21.3.4
Rheology of Viscoelastic Body Fluids

In contrast to blood or blood plasma, a large variety of biological fluids such as respiratory, gastric, and cervical mucus, sputum, and saliva are highly complex materials having a pronounced gel-like structure. Such fluids possess viscoelastic properties. With respect to both physiological and pathological processes, the rheological behavior of these biological materials is very important, since the viscoelastic properties of such fluids play a fundamental role in the clearance of both normal and pathological material.

For the investigation of sputum, saliva, and mucus, all types of viscometers have been widely used. In many cases, the viscoelastic model has been employed as a convenient starting point, and experimental results have been interpreted in terms of storage and loss modulus, as well as relaxation or retardation times (Section 21.2.2).

Sputum exhibits highly variable complex non-Newtonian rheological behavior. The characteristic relaxation time of sputum is in the order of several minutes; it is probably the most elastic of body fluids, to the extent that it may be termed *superelastic*. The viscoelastic properties already of normal sputum, however, are changed significantly by alterations in pH or concentration of substances. For instance, the values reported for viscosities of sputum range from 0.01 to 10^5 Pa s.

Saliva is viscoelastic, with similar properties to sputum; its storage modulus is strongly related to the mucin concentration.

The range of variation in the viscoelastic properties of normal mucus is also considerable, apparently with random variation in pH and concentration of substances being responsible.

Such wide variations point out the difficulty of comparing values obtained with different viscometers and different ways of collecting viscoelastic body fluids. These variations emphasize the need for rigid standardization of procedures to obtain representative data.

21.4
Hemodynamics

The circulatory system consists of two pumps – the cardiac ventricles – and a closed-loop system of vessels – the arteries, microvasculature, and veins – all filled with blood. The primary role of the cardiovascular system and the blood is to ensure the survival of all cells of the body, which at all times must be provided with materials rich in oxygen and metabolic substrates and have their metabolic wastes eliminated. The heart also permits the transport of hormones (which act as chemical signal transmitters), immunologically active substances, and heat between various regions of the body. The rate of flow of the blood is adapted to the conveyance of nutrients and wastes – which must be transported fastest – and the respiratory gases, oxygen and carbon dioxide.

A fundamental aim of hemodynamics is to describe the rheological behavior of both the heart and the blood vessels. To be able to do this, a detailed knowledge of the anatomical structures and functions of all parts of the circulatory system is essential.

21.4.1
Heart Mechanics

The weight of an average adult male heart varies between 280 and 340 g, that of the female heart between 230 and 280 g. With the exception of the valves and the fibrous "skeleton" separating the atria and ventricles and surrounding the tricuspid and mitral as well as the smaller aortic and pulmonary valve orifices, the heart consists mainly of muscle. There are two kinds of muscle fibers within the heart, specialized muscle cells arranged in the form of nodes and fibers, which mediate the rhythmic excitation of the heart, and the working muscle fibers of the atria and the ventricles, the myocardium.

By virtue of the rhythmic contraction of the heart and the function of the four heart valves, the blood is propelled in the mean unidirectionally through the blood vessels. As shown in Figure 21.10, the uniform direction of the blood in the various cavities of the heart and blood vessels is made possible by the atrioventricular valves between the atria and the ventricles, the mitral valve on the left and the tricuspid valve on the right of the heart, and the semilunar valves between the ventricles and the main arteries, the aortic and the pulmonary valves, which prevent the backflow of blood. From the left atrium the blood enters the left ventricle. The contraction of the left ventricle forces the blood into the aorta and the systemic arteries, which convey it to the organs of the body. From the peripheral tissues and organs, the blood returns through the systemic veins and the two venae cavae to the right atrium and ventricle. The contraction of the latter expels the blood through the pulmonary artery into the vessels of the lungs, from which it returns through the lung veins into the left

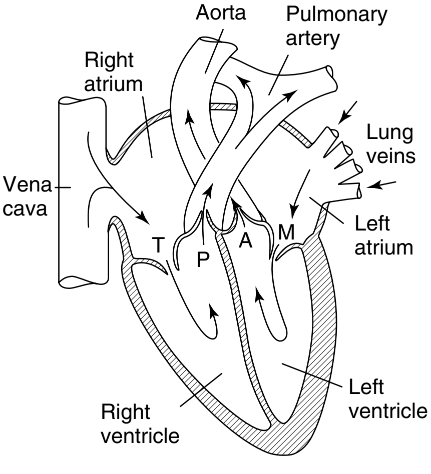

Fig. 21.10 Blood flow through the heart. Atrioventricular valves: *M*, mitral valve; *T*, tricuspid valve. Semilunar valves: *A*, aortic valve; *P*, pulmonary valve.

atrium and ventricle, thus completing the circulation.

21.4.1.1 Events of the Cardiac Cycle

Both atria are thin-walled muscular chambers while the ventricles have thick muscular walls – especially the left ventricle that has about twice the thickness and three times the mass of the right. Within one cardiac cycle, systole (contraction of the heart musculature) alternates rhythmically with diastole (relaxation of the ventricles).

Systole comprises two phases, the preejection period (PEP, line 1 in Figure 21.12) and the ejection period (EP, curve 2 in Figure 21.12). When the heart begins to contract, the ventricular pressure exceeds the pressure in the atria, which leads to the closing of the atrioventricular valves. During PEP, all four valves of the heart are closed, and the ventricular pressure increases rapidly, while the ventricular volume remains unchanged (isovolumetric contraction). When the ventricular pressures exceed the pressures in the roots of the aorta and the pulmonary artery, the semilunar valves open and the EP begins. The myocardial fibers shorten and about half of the blood volume contained in the ventricles is expelled into the aorta and pulmonary artery. The pressure within the ventricle reaches a maximum and then decreases. When the ventricular pressures become a little lower than the pressures in the aorta and the pulmonary artery, a very brief backflow of blood into the ventricles leads to closure of the semilunar valves, and diastole begins.

The diastole also comprises two phases: the isovolumetric relaxation (line 3 in Figure 21.12) and the ventricular filling phase (curve 4 in Figure 21.12). During the relaxation all valves are closed and the ventricular pressure falls rapidly. This phase ends when the ventricular pressure falls below the pressures in the atria. The atrioventricular valves now open, and the ventricular filling phase begins. Toward the end of the diastole, contraction of the atria helps to fill the ventricles. At the beginning of the next ventricular contraction, the atrioventricular valves are closed again, and the next cycle begins.

21.4.1.2 Rheological Properties of the Heart

For a description of the passive and the active properties of the heart, the following variables are available: ventricular pressure, ventricular volume and wall thickness, blood flow in the roots of aorta and pulmonary artery, and time. On the basis of these variables, the forces operative within the ventricular wall and the contraction velocities of the myocardium can be determined. The mechanical behavior of the intact heart is best described in terms of its stress–strain relation, rather than its force–length relation. With such parameters it is possible to make valid comparisons of the mechanical behavior of ventricles of different shapes and sizes.

Stress–Strain Relationships The ventricular wall must develop stress that counterbalances the ventricular pressure. Using simultaneous recordings of pressure and ventricular geometry, for example, by means of ultrasound echocardiography, computed tomography (CT), or magnetic resonance imaging (MRI) it is possible to quantify ventricular wall stress. The complex configuration of the ventricle, however, precludes an accurate determination of all the dimensions and stresses of the heart musculature without simplifying assumptions. For this purpose, the ventricles have usually been approximated by a sphere, and the myocardium is treated as an isotropic and homogeneous medium with linear elastic properties. If one assumes that the thickness of the ventricular wall h is uniform and small compared with the inner and outer radii, stress can be calculated by

$$\sigma = \frac{PR}{2h} \tag{27}$$

This equation is known as *Laplace's law*, and is widely used by many investigators for determining ventricular wall stress because of its simplicity and a lack of experimental evidence validating more sophisticated stress formulas (see Mirsky, 1979). Despite the fact that Laplace's law can lead to erroneous results if used in thick-walled left ventricles or in hypertrophic hearts – Laplace's law generally gives an overestimation of midwall stress – this simple equation reveals fundamental and important relationships, which are also true for the heart *in vivo*:

1. The greater the radius of the ventricle, the greater the ventricular wall stress at the same ventricular pressure. Therefore, dilation of the heart leads to an increase in wall stress, that is, in the load of the myocardial fibers.
2. The greater the wall thickness, the smaller the stress within the ventricular wall at the same ventricular pressure. Hypertrophy of the heart leads to a reduction in the stress within the ventricular wall.

The mechanical behavior of the heart muscle as a viscoelastic material which is rhythmically stretched and compressed can be described, according to Eq. (7), by the tangent elastic modulus. If the distribution of stress within the heart and all dimensions are known, the tangent elastic modulus at any point of the myocardium can be determined. Since our knowledge of ventricular stress is incomplete, the mechanical properties of the heart muscle are often represented in terms of the simplest possible analog models. In the late 1930s, Hill showed that the mechanical behavior of activated skeletal muscle could be described by means of a two-element model consisting of a contractile element (CE) representing the contractile processes, and an elastic element in series (series elastic element (SE)) representing the elastic properties of muscle fibers (Hill, 1938). In contrast to skeletal muscle, active myocardium develops a significant restoring force when stretched. Thus, in a model of the heart muscle, an additional elastic element (parallel elastic element (PE)) is needed, which can be arranged in parallel either to CE (Voigt model) or to the combination of CE and SE in series (Maxwell model), as shown in Figure 21.11. In both models, CE is responsible for generating force and shortening the myocardial fibers; during rest it is assumed that CE is freely extensible and exhibits no appreciable viscoelastic properties. SE and PE are assumed to behave as passive nonlinear springs whose lengths are determined by the forces.

Various mechanisms of the contraction of the heart have been proposed in terms of the Maxwell and Voigt models. The use of these models for the interpretation of the rheological properties of the

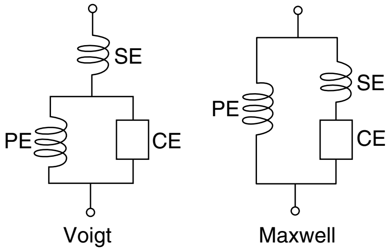

Fig. 21.11 Models of the heart muscle. Left: the Voigt model; right, the Maxwell model. PE: parallel elastic element; SE: series elastic element; and CE: contractile element.

heart muscle must, however, be treated with caution, since the stress–strain relationship of SE is time dependent, which implies that viscous elements may have to be included in these models. Furthermore, SE depends on the instantaneous state of contraction of the myocardium, which results in a nonsteady behavior of this element. The most appropriate model of the heart that represents actual performance best has not yet been established.

Pressure–Volume Relationships In general terms, the dependency of the time course of ventricular pressure $P(t)$ on ventricular volume V can be described as

$$P(t) = f(E', V) + g\left(W_v, \frac{dV}{dt}\right) + h\left(M', \frac{d^2V}{dt^2}\right) \quad (28)$$

where f, g, and h are symbols of functions. This equation shows that the pressure depends not only on the elastic stiffness (E', see Eq. (9)) and the volume of the heart, but also on the viscous resistance (W_v) of the ventricular wall, the rate of change of volume, the effective mass (M', see also Eq. (36)), and the acceleration of blood during ejection. The faster the filling of the ventricles and/or the ejection of blood, the greater the influence of the second and third terms on the ventricular pressure. Under normal conditions, however, the influence of these two terms is very small as compared with the first term.

Passive Properties of the Heart The passive behavior of the intact heart muscle can be determined only when the heart is at rest, that is, during diastole. For the nonactive heart, there is a progressive increase in pressure with increasing volume; this nonlinearity is due mainly to the increase in the tangent elastic modulus of the myocardial fibers with increasing wall tension.

The elastic stiffness of the ventricle determines the blood volume which can be stored within the ventricle during diastole. The stiffness depends on the thickness of the ventricular wall: thick, hypertrophic walls are stiffer than thinner walls; the left ventricle has a greater elastic stiffness than the right. Furthermore, the elastic stiffness of the heart depends on dimensions such that larger ventricles are stiffer than smaller ones at the same filling pressure; dilation of the ventricle increases its elastic stiffness.

Some actions do not markedly change the passive pressure–volume relationship of the left ventricle. For instance, the application of norepinephrine, which leads to an increase in the ability of the myocardium to contract and to develop force (which is sometimes referred to as *contractility*), or paralysis of the myocardium by means of potassium ions, has little influence on the passive mechanical behavior of the heart. However, during hypoxia, that is, decreased oxygen delivery to the heart muscle, elastic stiffness is increased due to incomplete relaxation of the muscle fibers. After myocardial infarction, the elastic stiffness of the myocardium is also increased, since fibrous tissue is incorporated into the heart musculature.

Active Properties of the Heart Suga, Kitabatake, and Sagawa (1979) found that for a given contractile state of the heart, instantaneous ventricular pressure is strongly correlated to instantaneous ventricular volume. On the basis of these findings, the authors proposed an equation for the instantaneous pressure–volume relationship of the active heart:

$$P(t) = E(t)[V(t) - V_0] \qquad (29)$$

where $E(t)$ is the quotient of the instantaneous pressure by the instantaneous ventricular volume, and V_0 an experimentally determined correction volume that corresponds approximately to the ventricular volume at zero pressure. The variation of $E(t)$ with time reflects the contraction of the myocardium (Figure 21.12). During the ejection period, $E(t)$ increases and reaches a maximum at the end of systole. It has been found that end-systolic (ES) maximum of $E(t)$ can be used for the characterization of the contraction state of the myocardium: ES increases with enhancement of the contractility of the heart. Generally speaking, this statement by the above-mentioned authors seems quite promising for the characterization of the mechanical properties of the active heart.

21.4.2
Rheological Approaches to Arteries

In common with all soft biological tissues, arteries are composed of highly distensible materials that exhibit nonlinear viscoelastic behavior. Under the conditions of cyclic loading and unloading, the combined effects of elasticity and viscosity result in hysteresis loops in the stress–strain diagram. In general, the cylindrical arterial walls show anisotropic behavior. Shear strains, however, are much smaller than the strains in the longitudinal, circumferential, and radial directions, which means that arteries are elastically symmetrical or orthotropic, and the three orthogonal strains are the

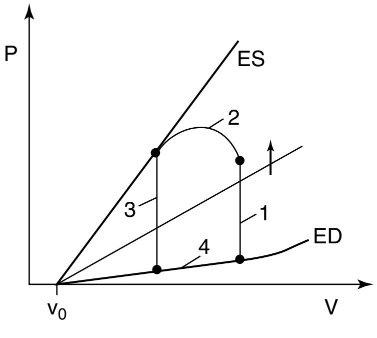

Fig. 21.12 Schematic representation of the ventricular pressure–volume (P–V) relationship. V_0, correction volume; ED, end-diastolic relation curve; and ES, end-systolic relation line. Lines 1–4 correspond to the four phases of the cardiac cycle.

only important ones. These orthogonal strains are interrelated, since the arterial wall is incompressible.

21.4.2.1 **Quasistatic Mechanical Properties of Arteries**

For the computation of elastic moduli of arteries, the differentially defined elastic modulus (Eq. (7)) must be used. For complete characterization of the arterial mechanics, the elastic moduli in the longitudinal, circumferential, and radial directions must be determined. Arteries *in situ*, however, are normally tethered in a prestretched state, so that the length of an arterial segment is independent of the pressure within the artery. The most important modulus for an analysis of pressure–volume relationships and the propagation of pressure and flow pulses within the arterial system is the circumferential elastic modulus, which is defined as the quotient of circumferential wall stress and circumferential strain.

The midwall circumferential wall stress (σ_c) of a cylindrical arterial segment is given by

$$\sigma_c = \frac{PR_i}{h} \tag{30}$$

where P is the pressure within the vessel minus the ambient pressure, known as the *transmural pressure*, R_i is the internal radius, and h is the wall thickness.

The circumferential strain ε_c is the ratio of the change in circumference of the segment ($=2dR_i\pi$) to the circumference of the segment ($=2R_i\pi$):

$$\varepsilon_c = \frac{dR_i}{R_i} \tag{31}$$

Simplifying $d\sigma_c = R_i dP/h$, the circumferential elastic modulus can be written as

$$E_c = \frac{dP}{dR_i}\frac{R_i^2}{h} \tag{32}$$

From this equation it can be seen that the wall thickness–radius relationship is one factor in determining the mechanical properties of blood vessels. Throughout the arterial system, the quotient of wall thickness and radius is virtually constant from the aorta down to the iliac artery, ranging between 0.12 and 0.14. In the peripheral arteries, this quotient increases, reaching a value of about 1.0 in the terminal arteries.

In addition to this geometrical factor, the mechanical behavior of an artery is determined by the viscoelasticity of its components, and their relative content within the wall. The histological structure of arterial walls may be divided into three layers: (from inside to outside) the intima, the media, and the adventitia. With respect to mechanical behavior, the media and the adventitia are of special interest since these layers contain the three components that above all determine the wall mechanics: the passive tissues elastin and collagen in the media and adventitia, and the vascular smooth muscle as the active component in the media. All three types of tissue show nonlinear viscoelastic behavior; the magnitudes of elasticity and viscosity, however, are very different. For low stresses, the elastic modulus of elastin is 0.3–0.6 MPa and that of collagen is 100 MPa, while the modulus of the vascular smooth muscle ranges between 10 and several hundred kPa. All three types of tissue are viscous; under pulsatile conditions, however, the viscosity of elastin and collagen exceeds that of the vascular smooth muscle.

There is a good correlation between the quasistatic elastic properties of arterial walls and the relative content of elastin and collagen within the wall. In the human ascending and thoracic aorta, the relation of collagen to elastin ranges from 0.5 to 0.7; in the middle abdominal aorta, this quotient increases abruptly in favor of collagen to about 1.5 and shows a further increase toward the periphery. Except for the coronary arteries, which have a collagen–elastin quotient of about 3 due to their small content of elastin, this quotient ranges from 1.5 to 2.5 for all larger arteries. According to this distribution, the ascending and thoracic aorta are very soft, while the quasistatic elastic modulus of the peripheral arteries increases with increasing distance from the heart.

On the basis of the distribution and the relative content of collagen, elastin, and vascular smooth muscle within the wall, it is not possible to give a reliable description of both the dependence of the elastic modulus on wall stress and the mechanical behavior of an artery under dynamic conditions, since these relationships are determined mainly by the functional arrangement of the various components within the vessel wall. In Figure 21.13, the pressure–radius relationship of a cylindrical arterial segment is shown. The volume changes applied to the artery were extremely slow (quasistatic conditions). According to Eq. (7), the elastic modulus of an artery corresponds to the slope of the stress–strain curve. The slope $d\sigma/d\varepsilon$ – which is equal to the slope of the pressure–radius curve – increases with increasing pressure; the nonlinearity of the viscoelastic properties of the artery can clearly be seen. The distensibility of the artery at very low stress is due to the high distensibility of the initially relaxed and then gradually stretched elastin tissue fibers, a behavior that is referred to as *recruitment*. In the physiological state of distension, the fibers of the collagen tissue are, because of their greater initial lengths, still unstretched and therefore exert no influence on the elastic modulus of the artery. Only at very high stress is the artery distended to such an extent that the very stiff collagen fibers act to protect the vessel against overstretching at high blood pressure.

The form of the curve during elongation and shortening results in the formation of a *hysteresis loop*. This hysteresis is more pronounced in the state of strong contraction induced by norepinephrine than in relaxation of the

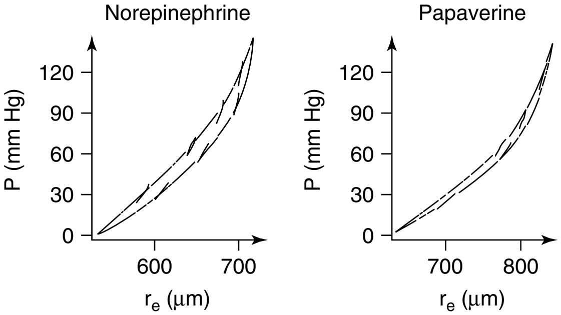

Fig. 21.13 Quasistatic pressure – external radius (P–r_e) curves of rat abdominal aorta under norepinephrine and papaverine. At different pressure levels, small sinusoidal pressure changes of 1 Hz were superimposed.

vascular smooth muscle induced by papaverine. In principle, the hysteresis can be explained by the combined effect of elasticity and viscosity of the vessel wall on the basis of the Voigt model (Section 21.2.2). To take into account the nonlinear behavior of the arterial wall, a specific strength of damping at each stress level and a spring with appropriately curved characteristics have to be taken into consideration.

21.4.2.2 Dynamic Mechanical Properties of Arteries

Since arteries *in vivo* are permanently subjected to periodic extensions of variable duration, an analysis of changes in stress and strain over a wide frequency range is of great importance in hemodynamics. Under dynamic conditions, the elastic modulus of the arterial wall increases. This is shown by Figure 21.13, in which small sinusoidal stress changes of 1 Hz were superimposed at different stress levels on the ascending and descending limbs of the quasistatic loops. The quotient of the dynamic and quasistatic elastic modulus depends on vascular smooth muscle tone and the content of muscle within the vessel wall. For larger arteries and relaxed smooth muscle, this quotient ranges from 1.3 to 2.0, while for muscular arteries and strong contraction of smooth musculature it can exceed a figure of 10. The transition between quasistatic and dynamic conditions takes place already at frequencies below 0.2 Hz.

To date, the mathematical description of the rheological behavior of blood vessels has been possible only under simplifying assumptions. For example, linear behavior of the arterial wall is usually assumed for small amplitudes of stress and strain. In this case, the equations given in Section 21.2.2.2 can be applied to the blood vessel wall. For sinusoidal oscillations of stress and strain, the elastic modulus can be defined as a complex modulus E^* (Section 21.2.2.2), the real part of which is represented by the dynamic modulus E_d and the imaginary part by the loss modulus $\omega\eta_w$:

$$E^* = E_d + j\omega\eta_w = E\cos\phi + jE\sin\phi \tag{33}$$

where ϕ is the phase angle between sinusoidal stress and strain changes. In accordance with Eq. (6), the loss modulus is the product of angular frequency ω and wall viscosity η_w.

An example of the interrelation between E_d, circumferential wall stress, and frequency of the stress changes under strong smooth-muscle contraction (induced by norepinephrine) and during smooth-muscle relaxation (induced by papaverine) is shown in Figure 21.14. From these diagrams, it can be seen that E_d increases markedly with increasing wall stress, while for a given wall stress, E_d is virtually independent of frequency. A comparison of the E_d values obtained for relaxed and strongly contracted smooth muscle shows that, for a given wall stress, E_d is virtually independent of the smooth-muscle tone.

The coefficient of wall viscosity increases with increasing wall stress – as does the dynamic modulus. Within a given wall stress range, the wall viscosity is not influenced significantly by the vascular smooth-muscle tone either. In contrast to the dynamic modulus, the wall viscosity decreases markedly with increasing frequency; the behavior of the wall viscosity is called – in the area of polymer rheology – *thixotropy* or *pseudoplasticity*.

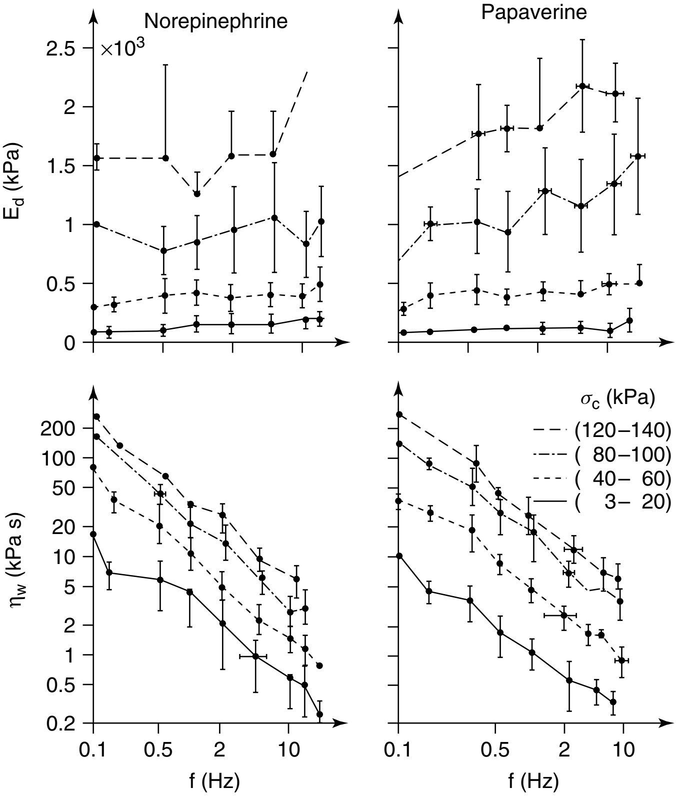

Fig. 21.14 Dependence of dynamic elastic modulus (E_d) and wall viscosity (η_w) of the rat abdominal aorta on frequency (f) for different ranges of circumferential wall stress (σ_c) under norepinephrine and papaverine. Symbols and bars represent means ± standard errors of the means (SEM).

The rheological behavior, as shown in Figure 21.14, is, in principle, common to all arteries. The values of E_d and $\omega\eta_w$, however, differ for large, medium-sized, and small arteries. The lowest values of both magnitudes are seen in the major arteries. The dynamic modulus of the thoracic aorta of a healthy young man, for example, is about 0.1 MPa at very low stress, and 0.4–0.5 MPa at a stress corresponding to the normal blood pressure range. The loss modulus of this artery is about 10–15% of the dynamic modulus. Medium-sized and small arteries show both greater dynamic and greater loss moduli. In the muscular arteries, however, the loss moduli increase more than the dynamic moduli. In general, vessels having a larger smooth-muscle component exhibit higher values of wall viscosity.

21.4.3
Pressure and Flow in the Vascular System

Pressure and flow in arteries fluctuate, since ejection of blood from the ventricles into the aorta and the pulmonary artery is intermittent. In addition to these fluctuations, the description of the relationship between pressure and flow within the arterial system is greatly complicated – in contrast to technical flow in tubes – by the rheological properties of arteries. First, as already described, the vessel walls are extensible and exhibit nonlinear viscoelastic behavior. Second, the stiffness of the arteries increases from the aorta toward the smallest arteries, which is due to the increase both in wall thickness–radius relationship – commonly referred to as *tapering* – and in elastic modulus. Third, the elasticity of the arterial wall depends on age. All these properties play an important role in hemodynamics.

21.4.3.1 **Systemic Arteries**

The events in the arterial system resulting from the intermittent ejection of blood by the ventricles can be considered with respect either to the mean values of pressure, flow, and volume (or diameter) or to the pulsations of these magnitudes. In the healthy adult, the mean aortic pressure (MAP) is about 100 mm Hg and the mean flow in the ascending aorta – which is the cardiac output (CO) minus the flow rate entering the coronary arteries (5% of CO) – is about $5\,\mathrm{l\,min^{-1}}$. Besides fluid viscosity, within every subsequent part of the circulation the resistance to flow is determined by both the dimensions of each single vessel and the number of vessels arranged in parallel. Owing to the relatively large diameters, and thus small resistances (Eq. (18)), of the large, medium-sized, and small arteries, the mean pressure decreases in this part of the systemic circulation only from 100 to about 90 mm Hg (Figure 21.15). The greatest resistance to flow is experienced in the smallest arteries, the arterioles, and the capillaries; these vessels are therefore often referred to as *resistance vessels*. Although the diameters of the arterioles are markedly greater, the pressure drop over these vessels is about twice that over the capillaries. This is due to the smaller number of arterioles arranged in parallel, and their greater lengths as compared with the capillaries. Within the systemic circulation of the dog, arterioles are estimated to number about 4×10^7 and capillaries about 1.2×10^9.

In total, the mean pressure of blood falls to less than 10 mm Hg by the time it returns to the right atrium of the heart.

In accordance with Eq. (14), the total frictional resistance within the systemic circulation can be calculated by the difference between the MAP and the mean right atrial pressure (MRAP) divided by the CO. Since the resistance to flow is exerted mainly by the peripheral vessels, the total circulatory resistance is called *total peripheral resistance* (TPR). Hence,

$$\mathrm{TPR} = (\mathrm{MAP} - \mathrm{MRAP})/\mathrm{CO} \tag{34}$$

In the human systemic circulation, normal TPR is about $1.5 \times 10^2\ \mathrm{MPa\,s\,m^{-3}}$.

According to Eq. (13), the mean velocity v_m of the fluid flowing along a vessel – or a system of vessels arranged in parallel – is inversely proportional to the (total) cross-sectional area(s) of the vessel(s):

$$v_m \simeq 1/A \tag{35}$$

The larger the A, the smaller the v_m. In the human ascending aorta, the mean velocity of blood is about

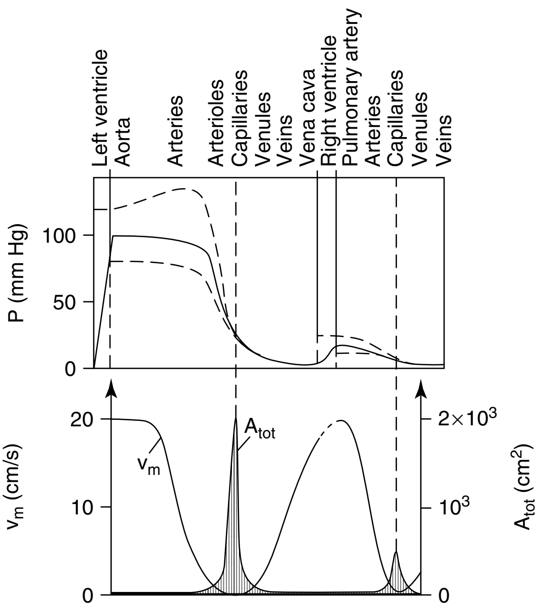

Fig. 21.15 Schematic representation of mean pressure and pressure variations (P), mean velocity (v_m), and total cross-sectional area (A_{tot}) in various parts of the human circulatory system.

0.25 m s^{-1}. Each ramification of the aorta and its branches toward the periphery results in an increase in the total cross-sectional area of the arteries arranged in parallel, since the sum of the cross-sectional area of the branches is always greater than that of the stem. As shown in Figure 21.15, the mean velocity decreases from the ascending aorta to the peripheral vessels. The largest cross-sectional area is found in the capillaries, and in a resting man is about 500 times that of the aorta. Thus, the mean velocity of blood decreases in the systemic capillaries to about 0.5 mm s^{-1}.

21.4.3.2 **Pulmonary System**

The same course of blood pressure and blood velocity is found in the pulmonary circulation, although the pressure levels and resistances are considerably lower than in the systemic circulation (Figure 21.15). The mean pressure in the pulmonary artery is about 15 mm Hg and in the pulmonary veins is about 7 mm Hg. Since the output of the right ventricle equals that of the left ventricle, the TPR of the pulmonary circulation is only about 10% of that of the systemic circulation. The total cross-sectional area of the perfused pulmonary capillaries is 100–150 times as large as that of the pulmonary artery, so that in the pulmonary capillaries the mean velocity of blood is greater than in the systemic capillaries, amounting to about 2 mm s^{-1}.

21.4.3.3 **Arterial Dynamics**

Because of the intermittent ejection of blood into the aorta and pulmonary artery, pulse waves are generated which are propagated in the systemic and pulmonary systems, respectively. The pulse waves are formed by the combined effects of elasticity of the vessel wall and mass inertia of the accelerated blood. Because of inertia, the blood ejected, for example, by the left ventricle resists acceleration. This leads to a local increase in pressure, and thus to elastic distension of the first segment of the aortic wall, so that part of the ejected blood is stored while the rest flows through the aorta. When the pressure decreases, the distended elastic segment contracts and the stored blood is now accelerated and driven into the second aortic segment in which part of the blood is again stored while the rest is in motion. In the following segments the processes of storage and acceleration are repeated. These events take place simultaneously and are propagated continuously along the systemic, and also the pulmonary, arteries as pulse waves having a certain velocity known as *pulse wave velocity*.

The total energy transported by a pulse wave is made up of the potential energy of the distended segment and the kinetic energy of the moving blood. Within a given segment, these two kinds of energy are equal at any given instant, and are perpetually being transformed, one into the other.

For a complete analysis of the relationships between the pulsations of pressure, flow, and vessel diameter, two sets of equations are needed: the equations of motion and continuity of the blood and the equations of motion and continuity of the vessel wall. By means of these equations, the distribution of the velocity of blood within arteries, as well as the propagation of pressure and flow pulses within the arterial system, can be calculated.

Velocity Profiles in Arteries With regard to mean flow in the circulation, critical values of the Reynolds number (Eq. (19)) are exceeded in the ascending and descending aorta and in the initial part of the pulmonary artery. Because of these high Reynolds numbers – and the pulsatile nature of the flow – true turbulence is most likely to occur in these arteries during each pulse cycle – also under normal conditions. In peripheral arteries and in veins, Reynolds numbers are much smaller than the critical value, so that the flow in these vessels is not turbulent.

The pulsatility of flow in arteries – and also in veins – complicates the description of the behavior of flow. In Section 21.2.4.3, a solution to the equations of motion of fluid (Navier–Stokes equations) is given. From this solution, the velocity profiles of oscillating fluid and their dependency on the dimensionless value α_w can be seen (Figure 21.5). In man, the α_w values for the first harmonic of the natural pulses range from 17 in the ascending aorta to 1 in the peripheral leg arteries. Therefore, the velocity profile is not parabolic but more uniform near the vessel axis and also in medium-sized and small arteries in which the flow is not turbulent. Velocity profiles determined in human arteries *in vivo* by means of pulsed ultrasound Doppler devices (e.g., Anliker *et al.*, 1977) confirm these theoretical considerations.

Arterial Pulse Waves For a description of the propagation of waves in the arterial system, both motion of fluid and elasticity of the vessel walls must be taken into account. Since, as mentioned above, the effects of friction do not play too prominent a role in major and medium-sized arteries, the laws of wave propagation can be represented as follows.

In the absence of resistance to flow ($\eta = 0$), Eq. (22) reduces to

$$-\frac{\partial p}{\partial z} = M' \frac{\partial i}{\partial t} \tag{36}$$

when Eq. (13) is employed; $M'(= \rho/A)$ is the effective mass of the fluid per unit of length. Pulsatile changes of the cross-sectional area A of the vessel are not considered.

The flow rate entering a segment of the elastic vessel is the sum of the fluid which – due to the pressure elevation – is stored in this segment per unit of time, and the flow rate leaving this segment. This relationship is expressed by the equation of continuity:

$$-\frac{\partial i}{\partial z} = C' \frac{\partial P}{\partial t} \tag{37}$$

where C' (Eq. (8)) is the compliance per unit of length of the vessel. Differentiating and combining Eqs (36) and (37) result in the wave equations:

$$\frac{\partial^2 P}{\partial t^2} = c^2 \frac{\partial^2 P}{\partial z^2} \quad \text{and} \quad \frac{\partial^2 i}{\partial t^2} = c^2 \frac{\partial^2 i}{\partial z^2} \tag{38}$$

where c is the pulse wave velocity, which is given as $c = (M'C')^{-1/2}$. According to d'Alembert, the solutions of Eq. (38) are

$$P(z, t) = f_1(z - ct) + f_2(z + ct) \tag{39}$$

and

$$i(z, t) = Z^{-1}[f_1(z - ct) - f_2(z + ct)] \tag{40}$$

Z is the characteristic impedance of the arterial wall, which is defined as the quotient of pressure and flow of a wave propagated in one direction:

$$Z = P/i \tag{41}$$

The functions f_1 and f_2 represent pressure pulses of any arbitrary shape, but without discontinuities. $f_1(z - ct)$ is a pressure wave propagated antegrade, that is, in the positive direction of the z axis, and $f_2(z + ct)$ is a pressure wave propagated retrograde, that is, in the negative direction of the z axis. The total pressure is, therefore, the sum of all antegrade and retrograde waves running through the vessel, while the total flow rate is the difference between all antegrade and retrograde waves. In principle, this explains the discrepancies between the pulse contours of pressure and flow pulses in the arterial system.

Generally, arteries can be regarded as hydraulic wave transmission lines. The characteristic impedance of an arterial segment is determined by the inertia and viscosity of the blood, and the viscoelastic properties of the arterial wall. If fluid and wall frictions are neglected, the characteristic impedance of a homogeneous arterial segment can be calculated by means of the equation:

$$Z = \rho c/A \tag{42}$$

where ρ is the density of blood, c the pulse wave velocity, and A the internal cross-section of the artery. In young men, the average pulse wave velocity along the aorta is about 5 m s^{-1}; in the limb arteries c increases from 6 to 8 m s^{-1}, and in the distal leg arteries to even more than 10 m s^{-1}. Because of the increase in pulse wave velocity and the decrease in the cross-sectional area, a strong increase in the characteristic impedances from the aortic root toward the smallest arteries results. This increase is, in part, stepwise, for example, at every branching point of an artery, in part continuous, which is commonly referred to as *tapering*. Reflection occurs at a site at which the characteristic impedance changes. The arterial system therefore represents an inhomogeneous wave transmission line exhibiting multiple internal reflection sites. Thus, the primary pulse wave generated at the aortic root by the contraction of the left ventricle undergoes multiple reflections within the arterial system. At each site and instant, ante- and retrograde running pressure and flow waves are superimposed one upon the other. The different behavior of pressure and flow waves with respect to reflections and the different signs of retrograde pressure and flow waves are responsible for the different contours of pressure and flow pulses within the arterial system.

Models of the Arterial System A major topic in the field of hemodynamics is the development of models that can be used to explain the genesis of the pulse contours of pressure and flow in the various regions of the arterial tree. In the 1960s and early 1970s, a variety of models, represented by real hydraulic, electric analog, or theoretical systems, were developed. Recently, the demand for models of the arterial system has been renewed because of the widespread use of Doppler ultrasound devices that allow noninvasive, transcutaneous recording of blood flow velocity. Today, Doppler ultrasound recordings are routinely performed in a great number of blood vessels, in particular, in those of the head and brain, the method being termed transcranial Doppler ultrasound. Efforts are being made to introduce models as diagnostic tools; these models are required to simulate, and thus determine quantitatively, the influence of disturbances – such as aneurysms, stenoses, or occlusions – on the pulse contours. For this purpose, computer models are particularly convenient, since such models can readily be adapted to any subject. In view of the extreme complexity of the arterial system, any model must necessarily be simplified to a greater or lesser degree. As an example, the simulation of arterial pulses by means of an inhomogeneous tube model (Wetterer, Bauer, and Busse, 1977) is given. Natural pressure and flow pulses recorded at different sites in the arterial system, and pulses calculated at corresponding sites in the theoretical model, are shown in Figure 21.16. The pressure pulses have been recorded as sphygmograms, the flow pulses by means of a Doppler

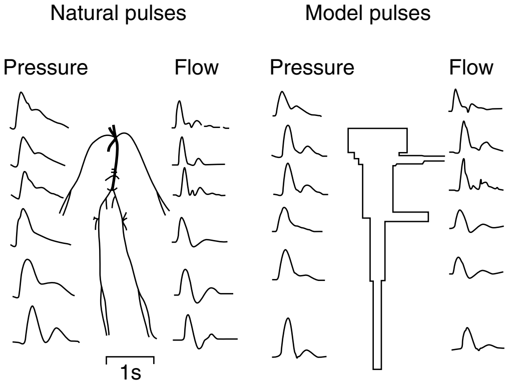

Fig. 21.16 Left: pressure and flow pulses recorded at various sites of the human arterial system. The recording sites are, from top to bottom, carotid artery, brachial artery, radial artery, abdominal aorta, femoral artery, and posterior tibial artery. Right: pulses of a theoretical model as shown schematically in the middle. Pulses are calculated for those sites of the model, which correspond to the recording sites of the natural pulses.

ultrasound device. The model consists of an arterial main stem representing the aorta and its continuation down to the foot arteries and two side branches, one representing the arteries supplying the head and the arms and the other the arteries branching from the abdominal aorta. As seen in Figure 21.16, there is good agreement between the pressure and flow pulses calculated by means of the model and the natural pulses, so that this relatively simple model is, in principle, suitable to explain the genesis of pulse contours in the arterial system.

21.4.3.4 **Pressure and Flow in Veins**

From the point of view of hemodynamics, the venous system differs essentially from the arterial system. When the body is in horizontal position, the venous pressure is generally low, decreasing from about 15 mm Hg in the venules to about 5 mm Hg in the right atrium. During inspiration, the pressures in the intrathoracic veins and the right atrium may even reach subatmospheric values. In the upright position, the pressure in the veins of the foot may, for hydrostatic reasons, be more than 90 mm Hg; while walking this pressure decreases markedly because the deep veins lying within the muscles of the legs are rhythmically compressed, and the valves in the peripheral veins ensure blood flow toward the heart (muscle pump). Furthermore, the walls of veins are thinner and their distensibility is much greater than those of arteries.

In principle, the same laws are applicable to the description of propagation of pulse waves within the venous and the arterial system. Because of the high distensibility and the small wall thickness–radius relationship, however, in the horizontal position the pulse wave velocity in veins is much smaller than in arteries (Section 21.4.3.3, Arterial Pulse Waves). In the vena cava, for example, the pulse wave velocity is about 1 m s^{-1} at a transmural pressure of about 4 mm Hg. In contrast to the arterial system, the pulsations of pressure and flow in the central veins are due to the action of the right heart, while pulsations within the peripheral veins are caused by respiration.

A description of the pressure–flow relationship in veins is complicated by the fact that veins may collapse since their soft thin walls are unable to withstand even small negative transmural pressures. *In vivo*, the pressure in large and medium-sized veins oscillates about a value close to atmospheric pressure, so that conditions in which the pressure can drop below zero may well prevail. As shown in Figure 21.17, collapsible veins lose their circular cross-section when the transmural pressure approaches zero.

The pressure–flow relationship of collapsible vessels has often been investigated by means of a laboratory device, first introduced by Holt (1941). In this device, a soft rubber tube is stretched between two rigid pipes within an airtight chamber that applies an adjustable external pressure to the tube. The pressure (P_1) in front of the rubber tube can be varied by adjusting the level of fluid in a supply tank, while the pressure at the end of the tube (P_2) can be changed by means of an outlet resistance. Relationships between pressure difference $\Delta P (= P_1 - P_2)$ and the flow i through the tube are shown in Figure 21.18 for three different constant external pressure levels. At low flow, ΔP increases with increasing flow. In this range, the rubber tube is collapsed throughout its whole length. As soon as P_1 exceeds the external pressure, the first part of

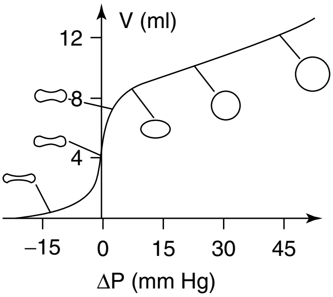

Fig. 21.17 Typical cross-sections of a collapsible tube shown at various points of the volume–transmural pressure ($V-\Delta P$) relationship.

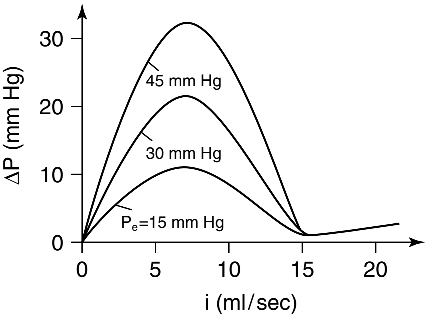

Fig. 21.18 Three transmural pressure–flow ($\Delta P-i$) relationships for a collapsible tube. External pressure (P_e) is a parameter (Modified from Katz, Chen, and Moreno, 1969).

the tube is distended and ΔP decreases, since P_2 becomes greater. A further increase in flow results in an expansion of the next part of the tube and thus a further decrease in ΔP. Finally, the tube is completely distended over its whole length so that, in accordance with Eq. (14), an increase in flow leads to an increase in the pressure difference over the rubber tube. As shown in Figure 21.18, each external pressure exhibits its own $\Delta P - i$ curve. It should be noted that instabilities resulting in self-excited oscillations of pressure and flow can occur in the region of negative slope of the $\Delta P - i$ curves.

Generally, the rheological behavior of veins can be described by means of hydraulic models. However, the applicability of such *in vitro* investigations to the venous system is limited, since *in vivo* the external pressure – and in the central veins also the blood pressure – alternates periodically. Furthermore, the venous wall contains smooth musculature and can therefore change its diameter actively over a wide range.

21.5
Pneumodynamics

Cells generally require a permanent oxygen supply and carbon dioxide removal to maintain their metabolic processes. In mammals almost all oxygen is collected, and carbon dioxide given off, by the blood passing through the capillaries of ventilated lungs. The transport of respiratory gases can be divided into four main components:

1. convective transport of gases between the atmosphere and the lung alveoli;

2. diffusive transport of O_2 and CO_2 between the alveoli and the pulmonary capillary blood;
3. convective transport of O_2 and CO_2 in the circulation to and from cells, respectively; and
4. diffusion of CO_2 and O_2 between the systemic capillary blood and the cells in the tissue.

For a discussion of pneumodynamics, the mechanical properties of the chest and lungs and the gas flow within the airways are of major importance.

21.5.1
Functional Anatomy of the Lungs

21.5.1.1 Airways

The right and left lungs are divided into three and two lobes, respectively. The air inspired at the nose and/or the mouth passes the pharynx, glottis, and larynx to the trachea. The trachea bifurcates into left and right main bronchi supplying the left and right lungs. The main bronchi in turn bifurcate into lobar, then segmental bronchi; these in turn divide successively to form the terminal bronchioles, which are the smallest air tubes without alveoli. The respiratory element distal to a terminal bronchiole is called an *acinus*. The terminal bronchioles branch to form respiratory bronchioles, which already have alveoli in their walls. The respiratory bronchioles further divide into the alveolar ducts which lead to the atria. Finally the air sacs open into the atria; the walls of the air sacs are made up of alveoli, while the walls of all the airways smaller than the terminal bronchioles contain only alveoli. All told, the adult human lungs contain 300–600 million alveoli. The terminal bronchioles have a layer of smooth musculature, the contraction state of which modifies the amount of gas going into and out of the alveoli.

According to Weibel (1963), the tracheobronchial tree is numbered in successive generations of branching airways from the trachea (generation 0) down to alveolar sacs (generation 23). The first 16 generations down to the respiratory bronchioles constitute the conduction zone, the function of which is to conduct the respiratory gases to and from the respiratory zone of the lungs. Since this part of the respiratory tract cannot take part in gas exchange it forms what is known as the *anatomical dead space*, the volume of which is about 150 mL. The last seven generations from the respiratory bronchioles to the alveoli make up the respiratory zone of the respiratory tract.

The total cross-section of the airways increases progressively as the bronchi divide. The cross-sectional area of the trachea is about 2.5 cm^2, while the total alveolar surface is between 50 and 100 m^2. The distance the respiratory gases have to be transported is in inverse proportion to the total cross-sectional area of the airways. The distance from the beginning of the trachea to the end of the terminal bronchioles is about 25 cm, while that from the beginning of the respiratory bronchioles to the most distal alveoli is only about 5 mm.

21.5.1.2 Lung Volumes

The lung volumes can be subdivided as follows. The tidal volume (TV) is the air that enters and leaves the lungs in a respiratory cycle. On normal breathing it is about 500 mL. Only about 350 mL, however, reaches the respiratory zone, the rest remaining in the dead space.

The maximum amount of air that can be inspired from the end-inspiratory position is termed inspiratory reserve volume (IRV); the maximum volume that can be expired from the end-expiratory level is termed expiratory reserve volume (ERV). The residual volume (RV) is the amount of gas remaining in the lungs after a maximal expiration.

A number of lung capacities are also defined: The vital capacity (VC) is the maximum volume of gas that can be arbitrarily ventilated, and is given by VC = TV + IRV + ERV. Only these volumes can be measured using a spirometer. In the normal man, the VC is about 5 L.

The functional residual capacity (FRC) is the amount of gas remaining in the lungs at the resting expiratory level. For the most part, the FRC acts as a buffer against extreme changes in alveolar partial pressures of O_2 and CO_2 on each breath. Finally, the total lung capacity (TLC) is the volume of gas that the lungs contain at the end of a maximal inspiration.

21.5.1.3 **Ventilation**

The normal rate of respiration of adults at rest ranges from 10 to 18, with a mean of 15, breaths per minute. This basal frequency is influenced by many conditions, including age, sex, size or height, work and rest, sleep, change in position, and temperature. At 15 breaths per minute and a TV of 0.5 L, the volume voided by the lungs is 7.5 L each minute; this flow rate is termed the minute volume, or tidal ventilation. Since only 350 mL of the TV reach the alveoli, the alveolar ventilation, which defines the fresh gas entering the respiratory zone per minute, is $5.25\ \mathrm{l\ min^{-1}}$.

The expansion of the lungs is due to lengthening and widening of the fine branches of the airways in the respiratory zone. The most distensible parts are the alveolar ducts, while the alveoli do not change much in volume. Thus, not all regions of the normal lungs dilate uniformly during inspiration. The center of the lungs containing the bronchi and some parenchymatous tissue is only slightly distensible. Distensibility increases in the direction of the surface of the lungs reaching a maximum 25 to 30 mm below this surface. Furthermore, the different parts of the lungs do not expand uniformly during inspiration, so that they do not have the same ventilation. In the upright position, the lower lobes expand more and thus ventilate better than the upper ones. This behavior is mainly due to gravitational effects, and will be discussed later.

During normal quiet breathing, TV only suffices to fill the respiratory tract down as far as the terminal bronchioles, while only a very small portion of the inspired air passes into the respiratory zone. The distance from the terminal bronchioles to the alveoli is covered by diffusion; the velocities of the molecules in the respiratory gas are so great, and the distances are so short, that the gas covers these distances in only a fraction of a second.

21.5.2
Mechanics of Breathing

The lungs – and also other thoracic viscera, for example, the heart – are subjected to passive changes caused by the expansion and retraction of the thoracic wall. For inspiration to occur, alveolar pressure must be less than atmospheric pressure; for expiration to occur, alveolar pressure must be greater than atmospheric pressure. Inspiratory flow of air can be produced by lowering the alveolar pressure to below atmospheric pressure – this is termed natural or *negative* pressure breathing – or by raising the pressure in the external environment above the alveolar pressure – termed *positive* pressure breathing. Normal inspiration is accomplished by the active contraction of the inspiratory muscles, which enlarges the thorax thus decreasing alveolar pressure to below atmospheric pressure. Active muscle contraction is needed to provide the force necessary to overcome the elastic recoil of the lungs and chest, the viscosity of both the tissues of the lungs and chest, and the air flowing through the conducting airways.

The thorax consists of the thoracic vertebrae, the ribs together with their cartilages, and the sternum. In man, the ribs increase in length from the 1st to the 7th, which is the longest, and then decrease to the 12th, which is the shortest. Each rib is attached to the spinal column at two points: the head to the body and the tubercle to the transverse process of the vertebrae. Because of this anatomical arrangement, the ribs can rotate only around an axis joining these two points. During normal breathing the change in the shape of the thoracic cavity is caused by contraction and relaxation of the diaphragm – resulting in a lengthening and shortening of the chest cavity – and the muscles of inspiration, which elevate, and the muscles of expiration, which contract the chest cage.

21.5.2.1 Mechanics of Inspiration

The diaphragm is the principal inspiratory muscle, most fibers of which form a dome-shaped structure descending to insertions on the lower ribs and the sternum. When the diaphragm contracts, the thoracic cavity enlarges mainly downward, but the contraction of its costal fibers may also elevate the lower ribs, thus increasing the circumference of the thorax. On normal quiet breathing, the diaphragm moves downward about 1 cm; when inspiration is maximal, however, its downward movement may be as much as 10 cm. A paralyzed diaphragm behaves as a passive membrane, and thus ascends during inspiration. This is known as *paradoxical* respiration.

The respiratory muscles that raise the ribs can be divided into principal and accessory muscles. The external intercostal muscles are principal muscles and extend from the lower edge of one rib to the upper end of the rib below. When the first five ribs are elevated, the anteroposterior diameters of the chest are increased; the sixth to the tenth ribs, however, effect a considerable increase in transverse diameters as well. In forced inspiration, the upper ribs and the sternum are elevated by the contraction of the accessory muscles, in the main sternocleidomastoid and scaleni. During quiet breathing, these muscles are virtually nonactive.

21.5.2.2 Mechanics of Expiration

During quiet breathing, expiration is largely passive by virtue of the elastic forces of the lungs and thorax. It is only during rigorous breathing that the expiratory muscles are called into action. The main muscles of expiration are those of the abdominal wall: the transversus, the internal and external oblique, and the rectus muscles. When these contract, the pressure in the abdominal wall is raised. The pressure forces the diaphragm up into the thorax and – if the glottis is kept open – gas is expelled from the lungs. In addition, ribs are depressed by the contraction of the internal intercostal muscles and the triangular muscle of the sternum, thus decreasing the volume of the thoracic cavity.

21.5.3
Rheology of the Respiratory Tract

The lungs and the thoracic cage form a functional unit that can do its work only in the intact state. For an understanding of the system, however, an analysis of the passive properties of the two constituent components of the lung–chest system is desirable.

21.5.3.1 Rheology of the Lung

The lungs can be considered as viscoelastic structures having an elastic tendency to contract and therefore pull away from the chest wall. This elastic recoil is caused by two different factors. First, in the lung parenchyma there are elastin fibers that are stretched by lung inflation and thus have a tendency to shorten. Second, much of the elastic recoil is due to surface tension of the fluid lining the alveoli. It has been calculated that the elastic fibers in the lungs account for one-third of the recoil, and the sum of the recoil forces due to surface tension accounts for two-thirds.

The surface tension at a gas–water interface produces forces that tend to reduce the area of the interface. The pressure P within a bubble depends on the surface tension T and the radius R of the curvature of the bubble, and is given by

$$P = \frac{2T}{R} \tag{43}$$

From this equation it can be seen that for a constant T the pressure increase when the radius of the curvature decreases. When two or more bubbles are connected in parallel, the bubbles having the smaller radii empty into the larger, so that instabilities may occur.

The problem of maintaining bubbles in parallel is critical in the lungs where millions of alveoli exist side by side. In alveoli, however, the surface tension is not a constant, but decreases when the radius of an alveolus becomes smaller. This is due to the presence of a surface active material, known as *surfactant*, which is secreted by special cells of the alveolar epithelium. The surface tension is lowered in proportion to the concentration of the surfactant molecules at the interface. During expiration, when the radii, and thus the internal areas, of the alveoli diminish, the surfactant molecules are packed more densely, thus decreasing surface tension and promoting the stability of the alveoli. On the whole, the surfactant lowers surface tension in the alveoli, so that the compliance of the lungs is increased and the work of breathing is reduced. Furthermore, the surfactant helps to keep the alveoli dry; surface tension forces tend not only to collapse the alveoli but also to suck fluid into the alveolar space from the pulmonary capillaries, so that surfactant prevents the transudation of fluid by reducing these forces.

Another mechanism that contributes to the stability of the alveoli is termed *interdependence*. Each alveolus represents a unit in an interconnected mesh.

Therefore, small units that might have a tendency to collapse are supported and stabilized by surrounding parenchyma.

The outer surface of the lungs is covered by visceral pleura. This is in intimate contact with the inner surface of the thoracic cage covered with parietal pleura. The pleural space between these two pleurae is filled with a thin film of fluid. Movement of the thorax leads to movement of the lungs through the linkage of this film of fluid. The pressure in the pleural space which is required to keep the lungs expanded to normal size is subatmospheric; it is usually called *negative intrapleural pressure*. This pressure changes during breathing, ranging from 5 to 8 mm Hg during expiration and from 10 to 15 mm Hg during inspiration. Even in maximum expiration, however, the lungs are still subject to elastic stress.

The pressure–volume curves of the lungs during inflation and deflation differ. As shown in Figure 21.19, at any given pressure the lung volume is larger during deflation than during inflation. Because of this hysteresis, the pressure developed by the lung at a given volume strongly depends on the prior inflation history. The hysteresis is due to the viscoelastic properties of the lung tissues. The area of the loop depends on TV; it becomes progressively greater as TV is increased.

A widely used measure of the mechanical properties of the lungs and chest wall is compliance, that is, the slope of the $P-V$ curve (Eq. (8)). When the viscosity of the lung tissue is not taken into account, compliance is given as the average between compliance during inspiration and that during expiration. Over the range of normal breathing, the compliance of the isolated human lungs is about 0.2 L (cm water)$^{-1}$. At high expanding pressures, the lungs are stiffer, and their compliances are smaller, as can be seen from the decreasing slope of the $P-V$ curve in Figure 21.19.

Owing to the weight of the lungs, in an upright position the alveoli at the apex of the lungs have a larger volume than those at the base. The greater degree of expansion of the alveoli in the upper parts results in a more negative intrapleural

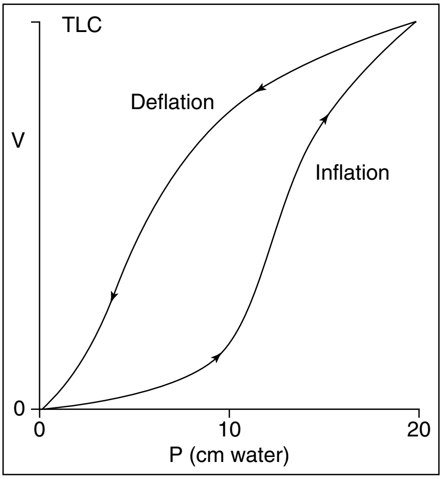

Fig. 21.19 Pressure–volume ($P-V$) curve of the excised lung. TLC Total lung capacity .

pressure which increases steadily down the lung by about 1 cm of water per 3 cm of vertical height. The dependent parts of the lungs are relatively compressed in their resting state, but expand better on inspiration than the upper parts. In consequence, the ventilation is greater in the base of the lungs than in the apex.

21.5.3.2 Rheology of the Chest

An isolated lung will always tend to contract to its minimal volume. In contrast, when the thoracic cage is opened, for example, by putting air into the pleural space – known as *pneumothorax* – the thorax tends to expand to a volume about 1.5 L greater than FRC. Since the thoracic cage contains muscular structures, passive mechanical properties can be considered only when the muscles are relaxed. The chest wall, like all other tissues, exhibits viscoelasticity, but for most purposes the viscous behavior of the thorax itself can be neglected. In analogy to pulmonary compliance, the compliance of the intact thoracic cage is defined as the change in lung volume per unit change in pressure gradient between atmosphere and intrapleural space. The value of static compliance of the chest is about 0.2 L (cm water)$^{-1}$, thus equaling that of the isolated lung.

21.5.3.3 Rheology of the Lung–Chest System

As already mentioned, when the intrapleural pressure is raised to atmospheric pressure, the lungs collapse and the chest wall expands. Thus, under normal conditions, the thoracic cage is pulled inward, while the lungs are pulled outward. Mechanically, the lung–chest system can be represented by two Voigt models or – neglecting the viscosities – by two springs arranged in parallel, possessing different resting lengths. In the intact state the lungs pull the chest wall and diaphragm inward, so that the combined resting length of the whole model is intermediate between the individual resting lengths.

The relationships between pressure and volume can be seen from the static $P-V$ curves of the lung–chest system shown in Figure 21.20. For the determination of this $P-V$ curve, the subject inspires a certain volume from a spirometer and then relaxes against the closed airway while the airway pressure is measured. In Figure 21.20, the $P-V$ curve of the isolated chest wall and that of the isolated lungs are also shown. For any given volume, the sum of the transpulmonary pressure – which is defined as the difference in pressure between the inside and the outside of the lung – and the passive chest wall recoil pressure is equal to the total pressure within the respiratory system (relaxation pressure).

At FRC, the relaxation pressure is atmospheric, so that the tendency of the chest wall to expand and the elastic recoil of the lung are exactly balanced. During inspiration the elastic recoil of the lung increases, while the chest wall recoil decreases; thus the relaxation pressure becomes positive. The chest wall reaches its equilibrium position at about 75% of VC. A further increase in lung volume requires positive pressure to increase the volume of the thoracic cage. At volumes below FRC, the relaxation pressure is subatmospheric. In accordance with Eq. (8), the compliance is inversely proportional to the pressure difference. Therefore, at a given volume change, the compliance of the lung–chest system (C_{tot}) can be calculated from the

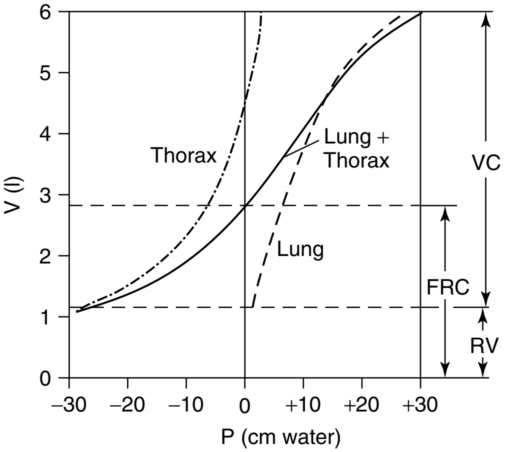

Fig. 21.20 Quasistatic pressure–volume (P–V) curves of the respiratory system (–), the lung (--), and the thorax (-··-).

compliance of the lung (C_1) and that of the thorax (C_t) by using the following expression:

$$\frac{1}{C_{\mathrm{tot}}} = \frac{1}{C_1} + \frac{1}{C_t} \tag{44}$$

Thus, the compliance of the lung and chest of a healthy young man is approximately 0.1 L (cm water)$^{-1}$.

21.5.4
Air Flow in the Respiratory Tract

The air passes in and out of the lungs as a result of rhythmic changes in pressure difference between the pressure at the nose or that at the mouth and the alveolar pressure. In accordance with Eq. (14), airway resistance W_a is defined as $W_a =$ [(nose or mouth pressure) – (alveolar pressure)]/air flow rate. Thus, air flow depends on the extent of pressure difference and airway resistance.

21.5.4.1 Intrapulmonary Pressure

During quiet breathing the alveolar pressure becomes slightly negative with respect to mouth pressure, normally about −1 mm Hg, and during expiration the alveolar pressure rises less than +1 mm Hg. During forced inspiration, alveolar pressure may drop to as low as −100 mm Hg, while during forced expiration (with glottis closed) the intrapulmonary pressure can be increased to as much as 150 mm Hg. The maximum expiratory effort is far greater than that during inspiration; expiration is used for voice production and elimination of foreign particles from the respiratory tract by coughing.

21.5.4.2 Distribution of Airway Resistances

About half of the total airway resistance during quiet breathing is in the nasal region, while there is less resistance to breathing through the mouth. A typical value for the total airway resistance measured during nose breathing would be 4 cm water s/L, while that during mouth breathing would be 2 cm water s/L. This total resistance can be partitioned into a series of resistances, each representing a section of the air-conducting system. On mouth breathing near FRC, the glottis, which is the narrowest part of the airway, accounts for more than 40% of the total airway resistance. From the remainder, the major site of resistance is the medium-sized bronchi, while the very small bronchioles contribute only about 20% to the total resistance. Even though each bronchiole has, according to its small radius (Eq. (18)), a high resistance to air flow, the number of these tubes in parallel is so enormous that their total resistance is lower than that of the larger air tubes.

21.5.4.3 **Pressure–Air Flow Relationship**

Air flow in the respiratory system is determined by the same factors that govern the flow of viscous fluid in tubes or blood vessels, so that the considerations of Section 21.2.4 can, in principle, also be applied to the respiratory tract. Because of the low viscosity of air and the relatively high velocities, turbulent air flow may occur in the trachea and larynx, but never in the bronchioles. In most of the bronchial tree, flow is not turbulent but transitional; if eddies are formed at branches, they are carried downstream some distance before disappearing. Fully developed laminar air flow may only occur in the smallest airways distal to the bronchioles where the Reynolds numbers are 1 or lower.

Taking resistance to include two components, one for laminar and the other for turbulent flow, the total pressure drop ΔP along the airway is, in accordance with Eqs (14) and (20), dependent on both the flow rate $\dot{V}$ and its square:

$$\Delta P = K_1 \dot{V} + K_2 \dot{V}^2 \tag{45}$$

The proportionality constants K_1 and K_2 were obtained by fitting this equation to the experimental data of each subject. For the normal respiratory tract in man, the values of these constants have been found to be $K_1 = 2.4$ and $K_2 = 0.3$ when ΔP is given in centimetre water and $\dot{V}$ in liters per second (Mead and Agostoni, 1964).

Although most fits obtained using Eq. (45) are adequate, the interpretation of the two terms as laminar and turbulent components is more or less arbitrary. Another empirical equation describes the pressure difference between the mouth and the alveoli over a wide range of flow rates as well:

$$\Delta P = K \dot{V}^n \tag{46}$$

where n has a value ranging from 1 with laminar to 2 with turbulent flow, so that n is a useful indicator of the nature of the flow. For the normal human respiratory tract, the constants are found to be $n = 1.3$ and $K = 2.4$ when ΔP is given in cm water and $\dot{V}$ in liters per second. It has been shown by Pedley, Schroter, and Sudlow (1970) that if nonparabolic flow profiles in branching tubes are taken into account, a theoretical expression can be derived in which $n = 3/2$, and K is dependent on density and viscosity of the gas.

Glossary

Aggregation: unspecific reversible conglomeration of erythrocytes or other cells within a saline solution in which proteins are dissolved, for example, blood plasma.

Alveolus: a small cavity, as one of the terminal thin-walled chambers of the lung, surrounded by networks of capillaries through whose walls the gaseous exchange take place.

Aneurysm: a circumscribed dilatation of an artery or a blood-containing tumor, which stands in open connection to the lumen of an artery.

Computed tomography (CT): a medical imaging method employing tomography where digital geometry processing is used to generate a three-dimensional image of the internals of an object from a large series of two-dimensional X-ray images taken around a single axis of rotation.

Doppler Ultrasound Device: an instrument for the measurement of blood velocity, based on the Doppler effect. This effect states that the frequency of sound reflected from moving blood cells is altered in proportion to the velocity of the cells.

Echocardiography: a diagnostic procedure that utilizes the reflection of ultrasound pulses to visualize the heart in a noninvasive manner.

Hypertrophy: excessive development of the size, but not the number, of single cells of an organ due to increased load.

Infarction: necrotic changes in cells resulting from the engorgement of an artery supplying these cells.

Magnetic resonance imaging (MRI): a noninvasive radiology technique that uses magnetism radio waves, and a computer to render images of the inside of an object. It is primarily used in medical imaging to demonstrate pathological or physiological attentions of living tissues.

Norepinephrine: a hormone secreted by both the adrenal medulla and the sympathetic nerve endings in response to sympathetic stimulation; it causes constriction of the blood vessels.

Papaverine: a benzylisoquinoline alkaloid of opium; it causes peripheral vasodilation by inhibiting phosphodiesterase, an enzyme that catalyzes the breakdown of cyclic 3′,5′-adenosine monophosphate, so that the intracellular level of this substance increases.

Parenchyma: the actual cellular substance of a gland or organ, excluding the connective tissue.

Pulsed Doppler Device: an instrument that combines echo ranging and the Doppler effect for the determination of the velocity of blood.

Sphygmogram: an uncalibrated pressure pulse curve obtained by means of a displacement transducer applied, at appropriate pressure, to the skin above an artery.

Spirometer: a device for measuring respiratory volumes. Classically, it is a counterpoised displacement bell chamber floating in a water tank. A stylus fixed to a counterweight is made to write the volume displacement movements of the chamber. The bell contains a breathable gas (air or oxygen). A tube connects the mouth to the chamber. When a test subject breaths in and out of the chamber, the bell rises and falls, thus permitting quantitation of several pulmonary parameters.

Stenosis: a narrowing of an artery or vein.

Acronyms

CE	Contractile element
EP	Ejection period
ERV	Expiratory reserve volume
FRC	Functional residual volume
IRV	Inspiratory reserve volume
PE	Parallel elastic element
PEP	Preejection period
Re	Reynolds number
RV	Residual volume

INTRODUCTION

It was over 20 years ago that buses first became available and used in computers and laboratory data acquisition. The announcement of the Digital Equipment Corporation PDP-11/20 computer introduced the revolutionary concept of a single bus in a computer for all communication between the individual circuit boards that made up the computer. This one bus, the Unibus™, was the single device that connected, physically, logically, and electrically, the CPU, main memory, and I/O boards that made up a fully operational computer. The PDP-11 also introduced the idea that the I/O subsystem of a computer could be treated as memory and thus addressed with the same instruction set.

At about the same time, a number of high-energy physics laboratories in Europe published the specifications for a standard data-acquisition bus system, CAMAC. CAMAC only addresses the I/O requirements of a computer for data acquisition and so the combination of CAMAC and a PDP-11 was a good match. It is interesting to note that the Unibus role has been relegated to a secondary I/O bus and will soon no longer be manufactured, while CAMAC is still being manufactured for and used in new data-acquisition systems.

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

These two buses have been superseded in both capability and performance. However, the current investment in board designs, know-how, and, in the case of CAMAC, software investment keeps the use of these buses effective.

Another bus that had its origins at about the same time is the IEEE 488 bus. This started as a bus to connect up to 15 instruments and was developed initially by the Hewlett–Packard Company. The bus definition was taken over by the IEC and an IEEE committee to develop the bus design further as an international standard. IEEE standard 488 was published in 1975. As with all active standards, further documents were published extending its scope.

Since this early work, there has been constantly increasing activity in designing and using existing and new buses. At the same time, the application areas for buses have increased in size and number with the capabilities. We have reached the position where there is a confusing number of buses described and advertised in the trade journals. This article is an attempt to make sense of this confusion and thus help in the process of making a choice for a new project. We describe all the possible functions of a bus and detail the different implementations where applicable in a general way. The requirements for different applications are described together with software considerations. Current and emerging bus standards are broadly categorized so that a subset can be chosen from this information for further detailed study. Finally, some other considerations to recognize are described. Because of the diversity of buses, manufacturers, and software support, detailed descriptions are impossible in an article of this scope, and the reader should refer to the standards listed in Table 1 and the current trade press.

In principle, any bus for which the specifications are available can be used for computer interfacing but in practice one is often limited by other project constraints. These might be performance, computer choice, availability of board designs either commercially or in-house, or higher-level management decisions.

1. BASIC SUBFUNCTIONS OF A BUS

This section defines and discusses the various kinds of information that are transmitted on a bus and the possible capabilities of a bus. The application and design of an individual bus will define how these kinds of information are transferred and which capabilities are supported.

1.1 Data

The whole purpose of a bus is the transfer of data. All the buses transfer binary data with the significance of the bits clearly defined. The buses differ in the amount of data transferred in each bus cycle or message, and this is normally a multiple of 8 bits.

1.2 Addressing

The bus master, in initiating a data transfer on the bus, must define the address of the device or register to transfer the data from or to. The bus master is the single bus device that initiates the bus cycle. When there is the possibility of more than one bus master, the potential masters of the bus must arbitrate for which will be the single master of the next bus cycle.

The addressing scheme of the bus is an important property of the bus and will reflect the applications for which it is designed. It is interesting to note that a device on the bus which only takes part in bus transactions as a master requires no bus address.

1.2.1 Geographical Addressing. Geographical addressing is implemented when the position on a bus where the device is installed defines the primary address. The geographical address will define the base address for the address space of the device. With geographical addressing, each device slot on the bus has a fixed amount of address space to use. The size of this address space for each device is defined by the specification of the bus.

1.2.2 Logical Addressing. In logical addressing the base address of a device is independent of the position of the device on the bus and is instead determined either by switches or by a register on the device. Logical addressing allows the address space of the bus to be divided up freely according to the needs of the devices and the application. This

form of addressing also allows a device to have two or more base logical addresses.

1.2.3 Broadcast Addressing. Broadcast addressing allows a master to address multiple slaves in a single bus transaction. Different broadcast addresses may be assigned to classes of devices. Broadcast addressed bus transactions are normally data transfers to the bus slaves.

1.2.4 Addressing Conventions. In order to make the use of a bus simpler for both software and hardware, certain addressing and register conventions are often mandated. These conventions might be, for example, the relative addresses for control and status registers as well as the bit allocations and use of those registers.

Some buses separate control and data registers into different address spaces. An obvious example would be the error registers of a computer memory board which clearly cannot be part of the memory address space.

A particular bus specification can use more than one addressing scheme. Consider the problem of establishing the device addresses of a particular system on powering up the system. This is not a problem with geographical addressing so long as the devices are correctly configured on the bus. With logical addressing, the device base addresses could be set by switches, but this is prone to error both in setting up and in repairing the system. A much more flexible scheme is to write the base logical addresses to the devices in the system initialization phase. This is only possible if there is a device address that survives power-up of the system and only a geographical address guarantees a unique power-up device address.

1.3 Control

The control signals of a bus orchestrate the bus transactions and communication. The bus protocol that these control signals implement has to be implemented in a different way for computer networks. In a computer network the control protocol is implemented in the arbitration and transmission protocol and the control bits of the defined message structure. Bus arbitration is dealt with separately in the next section as it is a significant topic.

1.3.1 Timing and Synchronization. The timing signals on a bus are used to synchronize the transaction. There are two basic types of bus transaction, a synchronous or an asynchronous transaction. Synchronous transactions have their timing set by the bus master within the rules of the bus specification. The transaction slave must respond within the time given. Thus the bus master will establish the bus address lines and possibly the bus data and control lines, and then set a timing line to indicate to the bus slaves that the address and data lines are correct and that the address lines should be decoded and acted on. The addressed slave then has a fixed time to respond.

Asynchronous transactions are ones where the master starts the bus transaction and the slave completes the timing of the transaction. The first part of the bus cycle is the same as the synchronous bus cycle but the master then keeps its timing line set until either the slave sets a second timing line to indicate that its response is complete or a timeout occurs. The master would then accept data, in the case of a bus read, and clear its timing line. When the slave sees the master timing line clear, it can remove its response from the bus and clear its timing line.

Thus asynchronous bus transactions can adapt to the performance of the individual devices rather than have the synchronous bus timing set by the worst-case device performance. To balance this advantage, while data only travel one way on the bus, the data transfer synchronization signal has to make a round trip between the master and the slave, adding to the bus timing. Asynchronous protocols also need a timeout mechanism to prevent bus lockup when a device does not respond for whatever reason.

1.3.2 Transfer Mode. In order to implement more than one transfer mode, the bus master must have a mechanism for defining the required transfer mode on the bus. A minimum set of types of bus transfers is read and write. Additional transfer types are the following:

1. Read–modify–write. This mode allows uninterrupted modification of a device register or memory location by one bus master. The definition of this type of cycle provides an interlock mechanism on the bus.

2. Block data transfer. This mode allows a block of data to be transferred at the cost of a single bus arbitration cycle. Each cycle of data transfer is accompanied by an address. The cost of block data transfers is an increase of the maximum bus access latency for the other masters on the bus. When designing systems, care must be taken to ensure that no device will block access to the bus for an unacceptable time.
3. Pipeline data transfer. This mode allows a block of data to be transferred at the cost of a single bus arbitration and address cycle. This transfer mode is only applicable to bus designs that place the time-multiplexed address and data onto the same physical lines of the bus. This transfer increases the data transfer performance at the cost of increasing the bus access latency for the other masters on the bus.
4. Arbitration locked access. This mode allows a bus master to keep the use of the bus for a number of bus cycles. This access mode may not require any dedicated bus lines but rather represent a new bus protocol using existing lines.
5. Increment. This mode is used in data-acquisition systems to accumulate spectra and histograms. This is normally implemented within the memory accumulating the spectra rather than as a defined bus cycle.

In some bus designs, the address and data are time-multiplexed onto the same physical lines of the bus. This can result in a considerable savings in connector pins and bus logic at the expense of the extra time taken for a separate address and data cycle for each bus transaction. This overhead can be significantly reduced by the use of pipelined data transfers.

1.3.3 Device Control. Each bus requires some basic device control lines. At a minimum, a reset signal is required to set all device logic into a known state when the system is initialized. Other bus lines might be these:

1. A busy line, set whenever a bus transaction is in progress.
2. A power-low line to indicate an imminent power failure. This would allow devices to prepare for a safe shutdown and possible transparent start-up after power is restored.

1.3.4 Status. The status lines are basically the response of the bus slave to the bus cycle of the master. One might be defined to indicate a status return from the slave to an enquiry from the master while another might be an indication to the bus master that the transaction was a valid bus request of the slave.

1.3.5 Interrupts. Interrupts are really a mechanism for a device that is usually a bus slave to initiate bus transactions. When a bus slave asserts a bus interrupt, it is indicating to one or more bus masters that it needs attention. Thus the CAMAC standard gave interrupts the name look-at-me's or LAM's. From the master's point of view, a LAM is an interruption to its current thread of execution.

Interrupts can be supported in a bus design at a single level or at multiple levels. Because it is not possible to nest the responses to a series of interrupts from a device during the master's response to an interrupt, further interrupts must be blocked by the bus master. Thus, with a single level of interrupts, an interrupt of lesser importance can block the rapid processing of an important interrupt. This can be overcome if a priority interrupt scheme is defined both for the bus and for the processor which responds to the interrupts as bus master. The interrupt latency is the time between assertion of an interrupt and the start of the processing of the response. In comparing interrupt latency times care must be taken that the same end point for the time is used. Possible end points are a bus interrupt response cycle, a CPU interrupt response cycle, or the first CPU instruction which responds to the specific interrupt. Outstanding higher-priority interrupts and the current processing of other interrupts at the same priority will increase the latency while lower-priority interrupts in any state will not significantly affect the interrupt latency.

For the response to an interrupt to proceed, the interrupting device must be identified in some way to the master responding to the interrupt. For buses using logical addressing, the device will present a vector or some other identification to the interrupt response code in the master as part of an interrupt cycle. This vector can be derived from switches or a register written as part of the system initialization phase. The interrupt response protocol must select a single, highest-priority, interrupting slave to respond to the interrupt cycle. This arbitration can use the general bus arbitration described below (Sec. 1.4) or a separate, possibly simpler and less expensive, arbitration scheme. This is normally the grant chain. It is interesting to note that the Q-bus™ supports four interrupt levels and thus has four interrupt request lines, but it has only a single interrupt cycle grant chain, thus requiring that boards be placed in interrupt priority order along the bus. Although some systems will work with the boards placed in another order along the bus, this level of the interrupt response is defined in the microcode or logic of the computer and misplacing the boards can give hardware errors when two interrupts occur at about the same time.

For buses that support geographical addressing, it is possible that the bus design includes a mechanism for the bus master responding to the interrupt to identify the interrupting stations.

1.4 Arbitration

This area of bus design is by far the most contentious. It is also the most intellectually demanding and many bus board designs have had to be reworked in this area due to poor guidance from the bus specification or poor design and incomplete testing. During a bus cycle, one or more potential bus masters, including the current bus master, may become ready to use the next cycle of the bus. Equally, while the bus is idle, two or more potential bus masters may simultaneously become ready to use the bus. The arbitration scheme of a bus must

1. resolve requests to use the next cycle of the bus from one or more potential bus masters;
2. ensure that the system designer is able to maximize system performance by setting arbitration priorities.

It is about this latter point that much discussion occurs. Should the priority scheme be a fair one, so that at each arbitration each bus master has an equal chance of getting the bus, or should it be a set priority so that a low-priority bus master may be blocked from the bus for a considerable time? Can the priority be set by the task within the potential bus master that requires the use of the bus? Can one mix these schemes?

1.4.1 Bus Arbitration. The overall arbitration circuit of a bus can be either a central arbitration circuit, to which every potential bus master makes a request and one receives a grant, or distributed, where the circuit making the decision is divided between the potential bus masters. The key is the location of the logic that decides if a particular potential bus master next uses the bus. If that circuit is on a single board for all the bus masters, then the implementation is a centralized one. If the arbitration circuit is on each potential bus master, the arbitration scheme is a distributed arbitration scheme even though there may be some centralized bus logic to time the arbitration cycle. The distributed arbitration logic can be designed to be serial or parallel. An example of a serial arbitration scheme is the request/grant chain. In this scheme each priority level has a bussed request line which is monitored by the bus logic. The grant line for each priority level goes in and out of each board on separate bus pins and it is only passed on if that board has no outstanding request at that priority level. A disadvantage of this scheme is that the grant signal has to propagate down the bus, through the arbitration circuit of each potential bus master, until it reaches the potential bus master requesting the bus. This time is a function of the priority of the requesting master rather than the arbitration need.

In a parallel arbitration scheme, all potential bus masters carry out the arbitration algorithm in parallel, thus increasing the speed of arbitration. The arbitration algorithm can be designed such that the time taken is a function of the number of potential bus masters needing access to the bus, thus speeding the process for the majority of arbitration cycles where there is only one requesting bus master.

An example of a parallel arbitration scheme, taken from the S-100 and Fastbus standard, is one where each master on the bus is assigned a unique priority level to use during the arbitration cycle. During the arbitration cycle each master requesting the bus asserts its priority level on the arbitration bus with the following rule: if a master finds that any of its arbitration priority bits differs from the value of the corresponding bit on the arbitration bus, that master inhibits the placing of its data on all arbitration bus lines of lower significance. This process may well go through several cycles and will be complete when one requesting master detects that the value on the arbitration bus is equal to its own internal priority level. In practice, there will need to be some delays built into the scheme which reflect the bus propagation delays.

1.4.2 Network Arbitration. Network arbitration is by nature distributed because of the extended distances covered. For baseband systems, there can be no dedicated arbitration lines or signal paths. On broadband systems, one or more channels of the frequency spectrum can be dedicated to network access arbitration. Two network arbitration algorithms are presently widely used, token ring and CSMA/CD. In a network, all nodes are potential bus masters, where a bus master only writes to the destination node, the slave, or to a group of nodes defined by a group address.

1.4.2.1 Token Arbitration. Token ring is the network equivalent of the request/grant chain. The difference is that the token, or permission to transmit on the network, is continuously circulated on the network between the nodes of the network. The minimum average access latency is half the token rotation time while the maximum access latency is the token rotation time plus the maximum message transmission time multiplied by the number of nodes on the network. It is this defined maximum access time that attracts many to this network arbitration scheme. Clearly, the token arbitration algorithm has to take account of nodes being added and removed from the network and for tokens being lost for whatever reason. The protocol to detect and replace lost tokens defines the absolute maximum access time.

1.4.2.2 CSMA/CD. The origin of the Collision Sense Multiple Access with Collision Detect (CSMA/CD) is a radio-based computer network, Aloha Net, developed by the University of Hawaii. The network scheme was developed into Ethernet by the Xerox Corporation, which holds patents on the network. In this scheme, each station or node of the network is able to

1. detect if any other node is transmitting;
2. while it is transmitting, detect if another node is also transmitting, a collision.

With this capability, a node that wishes to transmit simply starts transmission if no other node is detected as transmitting. However, two nodes some distance apart could start before the signal from one node can reach the other. If this happens, then both nodes will detect the collision and thus abort that transmission. Both nodes then enter a back-off and retry algorithm which is designed to minimize future collisions.

With CSMA/CD, bus or network average access latency is a function of the loading of the network. It can be effectively zero for a lightly loaded network and theoretically infinite in a very extreme case.

1.5 Cache Coherency

A cache is a local copy of recently used instructions or data that is stored in a local, fast memory on the basis that, once having been used, it is very likely to be used again. Thus, in a multiprocessor system with some common main memory, it is possible that some data have one or more copies stored in local caches as well as in the main memory. What then happens if another processor writes a new value to the main memory? Clearly, it is unacceptable that the other processors continue to use the old data stored in their local cache. Thus, some mechanism is needed to detect updates to the data in the main memory and invalidate the local cache copy. Only the most recent bus standards incorporate a cache coherency protocol.

1.6 Error Detection and Correction

High-performance buses used to build computer systems operate in a well-controlled environment. As a result, they generally have very low error rates due to electrical noise and thus either have no error-detection facility or have some level of simple parity checking. On the other hand, computer networks are quite prone to errors, especially those using common carrier facilities, and as a result extensive error-detection and correction facilities are needed. This correction of detected transmission errors can be within the message, using error-correcting codes, or by a retransmission scheme, or both.

1.7 Bus Device Fault Handling

Devices on the bus will fail. If the system using the bus is designed to be fault tolerant, other devices on the bus must, at least, be able to continue operation and possibly take over the functions of the failed module while that module is found and replaced. At a minimum, this puts the requirement on the bus design for live removal and insertion of devices and the initialization of newly inserted devices in an otherwise running system. A bus that uses a request/grant chain for bus arbitration will not tolerate the removal of any device from the bus without some back-up protocol.

2. ELECTRICAL AND MECHANICAL CONSIDERATIONS

2.1 Signal Propagation

The key to high performance is to maximize the actual signal bandwidth of the chosen transmission medium. This is done by several means:

1. The choice of the medium.
2. The electrical signal standards for driving the medium and receiving the signal. Here the cost and circuit board area taken by the chosen technology are important in local bus systems.
3. The use of medium bandwidth. This is less critical in local bus systems where the cost of the connections to the backplane is not great. However, for computer networks, the arbitration and network management overhead can become an important factor.

2.2 Mechanical Design

For local bus systems, the mechanical design defines the circuit board area available for the logic of a device and thus the cost of providing a board for a given function. The mechanical design also defines the connector scheme, and here, for local bus standards, the trend has been away from printed-circuit edge connectors to manufactured connectors mounted on the circuit board. This trend is because the manufactured connectors have greater reliability resulting from tighter quality control, and their use eliminates the need for gold plating in the circuit board production process. The standards here are the Eurocard mechanics, IEEE Standard 1011, and the DIN connector standard, IEC 603-2.

2.3 Cooling

High-performance systems invariably use considerable power and thus require well-designed cooling. A bus system providing defined, uniform cooling will simplify the board designer's and system builder's task considerably as well as adding to the reliability of the system.

3. SOFTWARE CONSIDERATIONS

In the process of designing and building a system there will be many choices to be made between the available components on the market that meet the basic system performance requirements. One of the factors that can help to eliminate some of these choices is the cost of completing and maintaining the system once the components have been acquired. This section addresses the software component of these costs.

3.1 Device Access Software Protocol

A bus specification describes how data are written and read by a bus master, usually a processor. These data are, to the bus, just words made up of bits. At the other end of the system is a stream of computer instructions that are defined by a high-level language. The questions here are these:

1. Are there any other considerations in a bus design that need to be taken into account in order to simplify the application software?
2. Are there any other related standards needed to simplify the use of the bus, to bridge between the low-level bus protocol and the high-level language application program?

Where the devices on the bus are mapped into the memory space of the bus, just as is processor main memory, the software problems are those set by the operating system or executive of the processor. On the other hand, those buses that are designed solely as I/O or instrumentation buses are likely candidates for standardization. There are two areas of standardization:

1. Device command and data protocols. These will allow devices with similar functions to use the same software.
2. High-level language extensions to add access to the devices on the bus. These extensions can take the form of new statements added to the language or a set of subroutines or functions with which to link the program.

Examples of the first are the function definitions of CAMAC, and Fastbus, Recommended Practice for Code and Format Conventions for Use with IEEE Standard 488, and the emerging ISO standards for network software (ISO, 1984). Examples of the second software standardization are the Subroutines for CAMAC and Real-Time Basic for CAMAC.

3.2 Real-Time Executive and Development System

Careful consideration should be given to the choice of the real-time executive and, in particular, the software development system that will allow the design, coding, and testing of the software to complete the system. Not all systems on the market support all the combinations of CPU board, I/O controller, and network controller. A basic decision is between independent development on the system or cross-development using another computer system. The former choice is less expensive but is usually less productive for the programmers compared to the latter choice.

4. BUS REQUIREMENTS

In this section we consider the requirements for particular applications of a bus. Where a bus is required to meet a number of these requirements, they will need to be combined. Table 2 summarizes the functional requirements.

4.1 Single-Processor Bus

The requirement for a processor bus is to provide the connection between the CPU and the memory. The address width of the bus must be at least the physical addressing capability of the CPU, and the performance of the bus should not be the limiting system performance factor. The data width of the bus is a system design option where the tradeoff is between cost and performance. With RISC architectures for processors, the requirement for memory access bandwidth increases dramatically because of both the increased number of instruction bytes required per clock cycle and the increased clock frequencies. The provision of cache memories on the processor boards can reduce the required bandwidth by a factor between 10 and 100, depending on the application.

A processor bus has no requirement for interrupt support and, as memory is always a slave in bus transactions, a single-processor bus needs no bus arbitration.

4.2 Multiprocessor Bus

The requirements added to support multiprocessing are those that support more than one master on the bus accessing the memory. In addition, on the assumption that the processors are cooperating as part of a single sys-

Table 2. Requirements for different bus functions.

Bus function required	Interlocks	Arbitration[a]	Distance[b]	Cache coherency
Single-processor bus			S	
Multiprocessor bus	Y	F	S	Y
Peripheral bus		P	S/M	
I/O bus		P	S/M/L	
Intercomputer bus		F	M/L	
Instrument bus		P	M	

[a] Arbitration: P=Priority; F=Fair.
[b] Distance: S=Crate or rack; M=Room or building; L=Campus.

tem, there will need to be a mechanism for interlocking access to common data structures.

The new requirements are thus a bus arbitration scheme, a cache coherency feature, and a read–modify–write or similar bus cycle to implement a processor interlock instruction such as test-and-set.

Depending on the application, the bus arbitration scheme needs to be fair, for general data processing, or priority based for deterministic real-time systems.

4.3 Computer Peripheral Bus

Computer peripherals, such as disk, magnetic tape, and terminal controllers, have different requirements from those of the processor bus. The peripherals will use direct memory access for the data transfer and will thus require the same addressing capability as the CPU–memory bus. This address width can be provided by the bus interface with mapping registers, thus mapping an assigned region of the computer peripheral bus address space to the appropriate region of the full address space.

There will be the need for a program running in the computer to define the I/O operation to the peripheral and then read the status of the completed operation. This is often provided by the peripheral having registers which can be read and written in the memory space of the computer. Another technique is to establish a block of memory which defines the operation required and then point the peripheral to the block. This technique is used in computer systems having high I/O bandwidth requirements.

Unlike main memory, computer peripherals do not work at the same speed as the CPU and thus interrupts are needed to notify the CPU of the completion of an I/O operation. Equally, the peak data-transfer bandwidth is usually at least a factor of 10 less than the memory bandwidth. The arbitration required is usually a priority arbitration scheme in order that the needs of the computer I/O subsystem are filled and it is kept busy.

4.4 I/O Bus

The I/O bus is here assumed to be the computer's real-time connection to a device, experiment, industrial plant, etc. These connections may measure temperature, pressure, voltage, position, intensity, status, etc., and also control similar parameters. The requirements for this bus are a reasonable address width so that each electronic module can have a number of data and control registers, and a data width that will allow all measurements to be read in a single bus operation.

For this application, direct memory access for the modules to the computer memory is not a requirement but could find application in some systems. This direct memory access facility is then implemented by the controller of the I/O bus, which is processor dependent. Where the I/O bus is also the processor bus, direct memory access facilities can be implemented on the I/O modules.

An I/O bus does require an interrupt facility for all but the simplest, non-real-time applications. This will allow the computer to respond to events in a predictable manner without requiring the computer to continually look for the possibility of an event, a process called polling.

Some application may require that some of the I/O boards in the system be remote or are required to be, for example, in a high-voltage enclosure. In these cases, a standard is required where crates can be connected with communications, normally serial to reduce costs, implemented with fiber optics.

4.5 Intercomputer Bus, Networks

The requirement here is the ability to pass blocks of data between the computers that make up the network. For reasons of reliable data transmission, that is, the assurance that the data were received and were correct, and the need to share one physical link for many uses, other protocols are usually layered on top of the basic message passing system.

The Open Systems Interconnect [OSI (1984)] reference model defines seven layers of protocol for the interconnected computer system. The lowest two layers are the physical layer and the data-link layer. Between these layers implemented on different computers, logical links are established over the single physical link. The OSI model allows the protocols and interfaces between the layers to be independent of the data link used. Thus, different data links are available depending on the distance between the computers and the data-transmission rate required. The shortest distance, within a computer room, can use a bus with many wires and a simple low-level protocol. Within a building, the cabling costs become more important and thus network connections use either a single coaxial cable connection or one or two twisted pairs. Campus-wide networks also use coaxial or twisted-pair cable. Both the building-wide connections and the campus-wide connections transmit data at a raw rate of 1 to 10 MHz. Wide-area connections emphasize low-cost transmission media at the expense of the cost of the devices that connect the transmission media to the computer. From these considerations it will be seen that, in general, the needs of a network are simple, from the bus point of view, and thus most buses can support intercomputer communication. However, outside the computer room the emphasis is on the lowest cost of cabling for a given data rate.

4.6 Instrumentation Bus

It is generally assumed that instruments here are self-powered, free-standing instruments. For communication they need a bus that is a simple cable to connect them together and connect them to the computer or other controller. In the past, many instruments have had a simple terminal interface but the simplicity of the connection often had to be traded for complexity in the communication protocol.

5. CURRENT STANDARDS CATEGORIZED

Table 1 shows the key characteristics of the currently available and newer buses. This table concentrates on the general characteristics of interest to the system designer and is intended to enable the system designer to narrow the choice for detailed study.

6. SYSTEM DESIGN CONSIDERATIONS

All this information is input to the key decisions involved in designing and building a system. The system requirements must be weighed against the choices and decisions made based on a broad picture of how the system will be implemented. There are, however, other considerations to be recognized and evaluated. These are discussed in the remainder of Sec. 6.

6.1 Desires and Technical Capabilities of the Staff Available

Work with any of these buses will involve gaining some understanding of the operation of the buses and the devices that are connected to them. At least there will be a need to establish testing facilities so that faulty modules can be identified and returned for repair. The higher-performance buses are more complex and generally difficult to trouble-shoot. To balance this, recent designs have emphasized the self-testing of modules. Thus, the ability to assemble, test, and maintain the system during its life by the staff available is an important consideration.

Another consideration is the opinions of the staff that will be building the system and maintaining it during its life.

6.2 Technical Culture

This covers the previous experience of the group of people involved, and both the type of support they expect and how this matches with the support that the vendors are able to give. Some people are used to integrating their systems and even designing and building many components, while others require service and are able to pay for it. Equally, the use of a particular bus in other parts of the same organization will mean that there are people available for consultation who understand the application.

6.3 Availability of Boards and Support Software

The newer buses do not have the broad range of board designs and support software available, while the older buses require fewer, if any, designs of special boards and are easier to use. If one is planning to use a relatively new bus, one is making the decision based on a judgment of the future support for the bus. This introduces some risk into the decision, and this risk must be recognized.

6.4 Longevity of the Bus

Many systems are built to have a long operational life, and, should they need upgrading because of obsolete buses or computers, there will be many years of refinements and additions to be reengineered in the replacement system. Often, the difficulty introduced by this continual improvement of the system makes a necessary upgrade very difficult. Good technical judgment is needed here to ensure that the support for the technical choices made will be available for the life of the system.

6.5 Compatibility

It is an unfortunate aspect of many of the bus standards that the specification leaves choices for the board designer that can make different boards that meet the bus standard incompatible with each other. The system designer therefore has to identify these aspects of the chosen standard and ensure that the components purchased are compatible with each other.

GLOSSARY

Address Space: A range of addresses, normally contiguous and with each address defining a single byte.

Baseband: Where the transmission medium is dedicated to a single channel of communication and thus the carrier frequency of the signal on the medium is also the fundamental frequency transmitted.

Bus: That which provides the electrical communication between components of a system. Devices connected to a bus must conform to signal standards and protocols. A bus can also provide electrical power and mechanical support.

Bus Cycle: A nondivisible data-transfer operation in the bus.

Bus Master: The device on the bus that initiates the bus cycle. When there is the possibility of more than one bus master, the potential masters of the bus must arbitrate for which will be the single master of the next bus cycle.

Bus Transaction: A bus cycle or a message.

CPU: Central processing unit, the section of a computer that fetches, decodes, and executes instructions.

Executive: Operating system software that provides the basic arbitration of and access to the computer hardware resources, the CPU, and the I/O devices.

False: Boolean state represented by a voltage in logic systems.

IEC: International Electrotechnical Committee, an international standardization body.

IEEE: Institute of Electrical and Electronics Engineers, an international professional society based in New York.

I/O: Input/output.

Message: A nondivisible data-transfer operation in the bus or network.

Multicast: The sending of information to a group of devices defined by a common group address.

Negative Logic: Logic implemented with the true state being represented by the less positive voltage.

Parallel: Information for one logical bus transaction is provided at one time on a separate electrical connection for each bit of information.

Positive Logic: Logic implemented with the true state being represented by the more positive voltage.

Real Time: The time in the world to which the computer is connected.

Real-Time System: A system that is driven by and responds in a predictable manner to external events.

RISC: Reduced instruction set computers, a central processor design which restricts the instruction set and the addressing modes to the simpler ones to allow the implementation of the CPU on a single chip with the emphasis on instruction execution in about one clock cycle.

Serial: Information for one logical bus transaction is provided in time sequence on one or a few electrical connections.

True: Boolean state represented by a voltage in logic systems.

INTRODUCTION

Calibration and maintenance of measuring devices have been practiced since measuring devices were first developed. The Egyptians used master length standards based on the length of the Pharaoh's right foot during the construction of the pyramids, with a penalty of death to whoever failed to recalibrate their linear measuring instruments on schedule. Today's calibration and maintenance systems are designed to encompass all the phenomena encountered in modern science and even to anticipate measurements not yet reduced to practical application. Standards and measuring instruments have grown in complexity along with the world's technology. While the current penalties for failure to calibrate them on time are more likely to end in litigation than death, there are still occasions where the latter is a possible consequence of using uncalibrated critical hardware.

The topic of calibration and maintenance of standards and measuring equipment is broad in scope. It covers all the measurable phenomena encountered in science. Test and measuring equipment and the standards to which they are referenced are active in the life cycle of all scientific efforts. It is the collection of equipment that generates and detects the parameters of processes and devices to determine their attributes. It performs research

measurements, confirms designs, makes production and process monitoring measurements, executes product test measurements and inspections, performs calibration measurements, injects signals for troubleshooting, and makes maintenance measurements. (Because the term will be used often in this article, the acronym TME will be used also to denote this composite population of test and measuring equipment.)

Typical TME populations encompass spectrometers, standard gas samples, standard reference materials, digital multimeters, ac voltage sources, Zener voltage standards, spectrum analyzers, signal generators, pulse standards, coordinate measuring machines, gage blocks, interferometers, force machines, load cells, mass standards, accelerometers, shake tables, acoustic reciprocity standards, frequency counters, maser frequency standards, rf power meters, microwave sources, power calorimeters, fiber-optic reflectometers, light sources, thermal black bodies, platinum resistance thermometers, freezing points of metals, etc.

This article has not been written for the metrologist or calibration expert; it is aimed at the practicing physicist, engineer, scientist, or technologist. These are individuals who may have had extensive contact with measurement applications, but minimal involvement with TME maintenance and calibration. The article is intended to provide a straightforward, practical reference on the concepts and applications of TME calibration and maintenance. However, it also speaks to the subject of tests and measurements, since calibration is, itself, a test and measurement process. Because of this, the term "testing/calibration" will be used at times to remind the reader when the two processes are essentially inseparable. For a quick overview, the early stages of the article provide the what, why, when, where, and how of the calibration and maintenance process, with more detail appearing in later sections.

The adequacy of decisions and designs made from measurement data is crucial to the success of experiments and to the quality and reliability of products and systems. Both calibration and maintenance are essential elements of today's technology. Calibration is critical to the control of uncertainty growth of TME. Lack of such control leads to wrong measurements, wrong decisions, wrong experiments, and wrong designs. Maintenance is critical to prevent operational failures and the danger, cost, and disruption that failure causes.

1. TEST AND MEASURING EQUIPMENT CALIBRATION

1.1 Objectives of Calibration

1.1.1 What is Calibration? There are a variety of definitions of calibration. In its simplest form it is the comparison of two measurement devices or systems, one of known uncertainty and one of unknown uncertainty, to estimate the correct value of the unknown and to determine its uncertainty. The initial calibration of TME is usually performed when and where it is manufactured. This involves scribing scales, adjusting circuits, setting digital indicators, and estimating characteristic uncertainties and long-term stabilities. This new population of TME then is used in lifetime applications where recalibration is necessary to assure that it continues to operate within its performance specifications. Recalibration is performed to detect and correct any insidious out-of-specification conditions that may exist through performance decay. These calibrations typically provide a good/bad or go/no-go test of the parameters of the TME. If the measuring equipment is found to perform to within assigned specifications (a good or "go" condition), it passes calibration (sometimes adjusted or corrected, sometimes not, depending on local calibration practices) and is returned to service. If it fails calibration (a bad or no-go condition), it is repaired and/or corrected (adjusted) to restore it to within its performance specifications.

1.1.2 Why Calibrate? The initial calibration of TME provides a basis for the performance claims made when it is sold to the user. The parameters generated or measured by the devices (length, flow rate, voltage, intensity, power, etc.) are referenced to standards of measurement that stem from a common source. If they are not, there is no reliable basis for their use. Subsequent measurements made without such references would bear no definable relationship to those made with them.

Recalibration is essential to maintain control of the measurement processes made by the TME. It assures a continuous common reference and retains the performance benefits gained by the initial calibration. With rare exception, the uncertainty concerning the values of TME attributes increases with usage and time. The gradual growth in uncertainty beyond designated limits typically goes undetected by users. Recalibration is essential to assure reference to a common measurement base, such as that afforded by an unbroken chain of calibrations extending from the TME through institutional, company, and national standards to international standards at the Bureau International des Poids et Mesures (BIPM), located on the outskirts of Paris, France. For simplicity and want of a better term, this unbroken chain of calibrations has become known as traceability. Traceability plus calibration is essential to measurement control and international commerce. It is specified in many national and international procurement and quality assurance specifications as a necessary element of any research, design, and production activity and especially for final test, alignment, and calibration of products and instruments prior to delivery. Traceable calibrations also assure that measurements made to specified uncertainties at one part of a process or location can be reproduced and depended upon at another part of the process or location.

The validity of research measurements depends upon accurate estimates of the phenomena being studied and requires sound knowledge of the uncertainties involved. Calibration of the TME used in research, as in other applications, defines its uncertainty and controls the growth of that uncertainty to known limits. It aids the researcher in assuring that research results reflect actual changes in the phenomena and are not due to inaccurate estimates of measurement uncertainties. The need for more reliable and traceable measurements and calibrations has grown as experiments, designs, and processes have become more precise and demanding.

1.1.3 When to Calibrate. One of the most significant decisions regarding calibration is when to do it. If done too often it is a waste of time and money—remember, the TME is frequently found to be within specification. Yet, if done too seldom, it is a waste of experiment or product—the measurement uncertainties cause wrong decisions based on misleading measurement results. The objective is to recalibrate at the optimum interval to get a balance between the cost to calibrate and the cost not to calibrate. Unfortunately, there is currently too little known about how to weigh these factors accurately enough to use cost as the criterion for determining time intervals between calibration.

Present objectives focus on setting intervals based on a target of a certain percentage of TME expected to be found within specification upon recalibration. The larger this percentage, the smaller the chance that wrong measurements are being made by the entire population of TME. While some users seek to keep the percentage above 95% to assure tight measurement quality controls, others allow as little as 70% within specification at the end of the calibration interval. The percentage is a quality management decision usually reflecting some overall quality policy, assuming the significance of the target is understood by the decision makers. Usually, the percentage target is selected by default and 85%–90% within specification is accepted as a comfortable figure. Better ways to select these targets are being explored.

The process of determining recalibration intervals is a difficult mathematical and statistical process, requiring accurate and sufficient data taken during the calibration process. How to treat this data and select appropriate calibration intervals is discussed in greater depth later in this article and in the references (Castrup, 1989a).

1.1.4 Where to Calibrate. Calibrations have been performed traditionally in the confines of a carefully controlled laboratory environment. While this practice is still true of primary or reference standards laboratories, calibration laboratories are involved increasingly in doing calibrations in place at the site where TME is used. On-site calibrations have been made possible by better environmental controls at use points, better temperature compensation circuitry or software being used in newer TME, and automation of calibration systems. With on-site calibration,

1. the user retains custody of the equipment with minimum down time and operational disruptions;
2. the TME suffers less in-transit stress;
3. simpler, less expensive calibrations are pos-

sible because they can be tailored to the user's express needs at the point of use.

However, there are still many instances where in-place calibration is unsuitable because of

1. environmental considerations (the calibration equipment is too environmentally sensitive),
2. size considerations (the calibration equipment is too bulky), or
3. cost considerations (more calibration systems may be needed to handle the dispersed workload.)

Development continues on smaller, less sensitive, computer-aided, automated calibration systems that will promote on-site calibration. The computer has been an especially valuable tool in the control of calibration systems and in the collection and processing of measurement and calibration data.

1.1.5 How to Calibrate. High-quality, cost-efficient calibrations depend on calibration methods that achieve a balance between a brief calibration process that would check only a few points of an instrument over a limited spectrum versus an elaborate calibration that would check hundreds of points over a wide spectrum of parameter values.

Calibration procedures are the documents most commonly used to accomplish the "how" of calibration. Enough points on each range need to be checked at properly selected frequencies to confirm that the equipment is operating within performance specifications. Wherever possible, the TME should be calibrated in terms of how it is used. If only a limited portion of a range is used, calibration should be limited to only those attributes. Furthermore, all attributes of the TME may not need calibration or examination at each servicing interval. Proper examination of calibration and maintenance data can reveal where the preponderance of out-of-specification incidents occur. Calibration procedures and servicing interval systems can be tailored to accommodate these situations at significant savings.

1.1.6 Risks in Testing/Calibration. Using TME that is operating in an out-of-specification state invites serious consequences. Such usage increases the risk of making wrong decisions, such as whether experimental results derive from real phenomena or are an artifact of measurement errors or whether to accept or reject products being tested. The whole purpose of selecting adequate TME for a given task is based on minimizing the risk of making wrong decisions from measurement data (Castrup, 1980). The more uncertain the measured value, the greater the risk of wrong decisions. Wrong decisions cost time, money, lives, and reputations.

As an example, the ball component of a ball bearing is to be measured to confirm that it was manufactured to specifications. The specifications require the ball to be round to within a given plus or minus value—in this case a microinch. It is determined that a special dimensional measuring machine will be needed to test the ball. The question is raised of what uncertainty should be specified for the measuring machine. This raises yet another question as to how much risk, how much uncertainty, the process can endure. The least risky approach would be to select a machine with minimum uncertainty—say, to plus or minus one tenth of a microinch (10 to 1 specification to uncertainty ratio). Unfortunately, that calls for an extremely expensive machine. For half the price, a machine with twice the uncertainty, or 0.2 microinch (5 to 1 ratio) can be obtained. Which machine should be bought? Will the higher risk of using the cheaper machine create offsetting production costs through wrongly rejected bearing parts because of increased measurement uncertainties? Will wrongly accepted bearing parts lead to in-use failures and resulting warranty or litigation costs that far exceed the savings incurred by using the cheaper machine? Figure 1 shows the relationships involved.

The "Center Spec" represents the desired diameter of the ball. The bell-shaped curve straddling the "Center Spec" represents the production process distribution of balls being manufactured, where most of the balls being produced have sizes that are expected to cluster near the center spec with fewer and fewer expected to be found beyond the "Perf Spec." This is known in statistics as a "normal" distribution. The "+Perf Spec" represents the performance specification upper limit, or +1 microinch greater than the "Center Spec." The "−Perf Spec" represents the lower limit of −1.0 microinch less than the "Center Spec." The upper and lower "Test Spec" typify a test procedure where the test specifications have

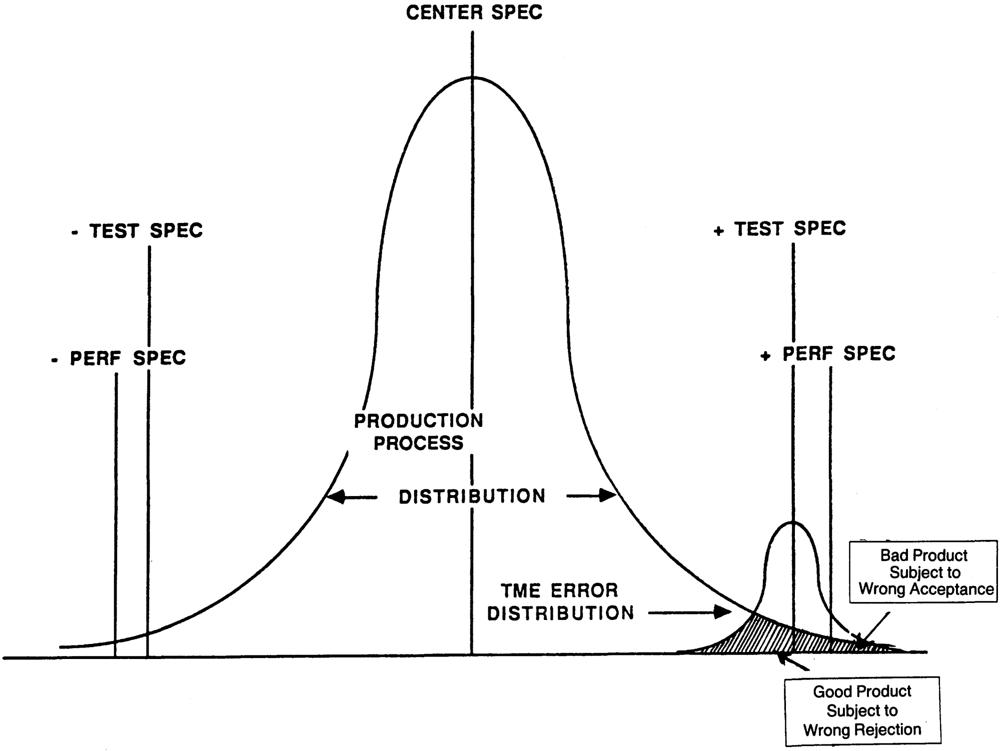

FIG. 1. Relationship of production yield, specifications, and testing errors.

been offset slightly from the performance specifications to compensate for unknown testing errors. Setting the test specifications inside the performance specifications reduces the risk of accepting nonconforming, or bad, measured values, but increases the risk of rejecting good ones. Setting the test specifications outside the performance specifications reduces the risk of rejecting conforming, or good, values, but increases the risk of accepting bad ones. The curve at the right-hand side of the figure, which represents the "TME Error (uncertainty) Distribution," has been made small to depict the size of TME uncertainty in relation to the "Production Process Distribution" (in the case of the example, it is either one tenth or two tenths the size, respectively). When the spread of the "TME Error Distribution" grows relative to the spread of the "Production Process Distribution," the risk of making wrong testing decisions grows. The words in the boxes point out the areas where those decisions take place and are most critical. As can be seen, the larger the "TME Error Distribution," the greater the quantity of wrong test decisions. As the "TME Error Distribution" increases, "Good product subject to wrong rejection" increases at a far faster rate than "Bad product subject to wrong acceptance." Thus, in the ball bearing example case, were the TME uncertainty allowed to grow to nearly the size of the "Production Process Distribution," the "Good product subject to wrong rejection" would be a sizable portion of the entire production of balls and would run a high risk of wrong rejection by the measuring machine, while at the same time, many of the balls beyond the "Perf Spec" would be wrongly accepted. Controlling the proper size of the "TME Error Distribution" in relation to the "Production Process Distribution" is one of the principal elements in controlling the risks of measurement, testing, and calibration (Hayes, 1955). Periodic calibration of the selected machine would assure that its uncertainty and the amount of its wrong test data was controlled.

Thus, in the example given earlier, the decision of which measuring machine to buy depends upon the impact that an uncertainty of 0.2 microinch versus 0.1 microinch would have on wrong testing decisions. Later in this article, material will be presented that quantifies these relationships, which are known as uncertainty ratios or accuracy ratios, i.e., the ratio between the size of the product test limit and the size of the TME uncertainty (Ferling, 1984).

Before leaving this subject, the reader should be aware of the pitfalls of misusing or miscalculating the uncertainties of testing/calibration processes. As was mentioned previously, the correct estimate of the magnitude of the uncertainty of a measurement is of great importance to the quality of the test being made. Many unsuspecting people select TME for a measuring process without a real awareness of the uncertainty being introduced. They observe the manufacturer's published specifications and presume wrongly that the advertised "accuracy" is transferred unchanged to the measurement process.

The terms "uncertainty," "accuracy," and "error" tend to be used interchangeably. Error is the reciprocal of accuracy and indicates a specific deviation from a "true" value with no indication of the degree of confidence to which that figure may be known. Uncertainty is a more meaningful term that has an error component and a "sureness" component. It depicts the combination of parameter generation and measurement errors in a test or calibration process and the degree of "sureness" in estimating the magnitude of each of those errors.

A properly stated uncertainty of measurement includes both components—the estimated error component (the ±0.1 microinch in the foregoing example) and another component which states the probability that the error component has been correctly defined (expressed as one or more standard deviations). Thus, a complete uncertainty statement would read, "When measuring one microinch, there is an uncertainty of ±0.1 microinch at three standard deviations." Thus, the statement expresses an error and a "degree of sureness" as to how well that error is known. Three standard deviations is roughly equivalent to providing an assurance that the error will be within the limits stated at the time of measurement with 0.997 probability. Had the estimate been made to, say, one standard deviation, the error would be within the limits given at the time of measurement with 0.67 probability. (An even more accurate and useful statement would also include the rate of uncertainty growth with time, or the time period over which the uncertainty statement applies, such as one week, six months, one year, etc.)

To determine the overall uncertainty of a testing/calibration process requires that all of the error components and their companion estimation components be combined in a consistent fashion. Some controversy currently exists as to the precise way these errors should be combined. Some experts say to add the errors algebraically without regard for the estimation uncertainties in order to get a "worst case" combination. This clearly makes sense where no estimation values are available or where the estimator is very insecure about the error estimate. Yet, other experts argue that it is best to sum the errors in quadrature [by the root sum of squares (RSS) method] and present a statement for the combined errors for a specified number of standard deviations. (See ERROR ANALYSIS.)

The balance of opinion has been shifting most recently to use of the RSS method. All things being equal, the RSS method gives smaller estimates of error than does algebraic summing. For example, given a measurement system comprised of, say, three equal-error components, an algebraic summation would yield an uncertainty estimate 1.73 times larger than the RSS combination would yield. This number would grow to 2.64 were seven such error components combined. While RSS combining could mean higher risks, it is considered by many to be the more realistic method. A second benefit of applying the RSS method is that it provides a consistent statistical basis for estimating the confidence level associated with stated uncertainty limits.

Table 1 provides an example from the calibration of two rf voltage standards. At 10 MHz, the RSS method results in an intercomparison uncertainty of 53 parts per million at one standard deviation for three years. The algebraic method yields an uncertainty of 116 parts per million at this frequency, the number of standard deviations is undefined, and the estimated limit of time on the estimate is three years.

More research is being done to determine the most mathematically correct methods of combining uncertainty estimates. National and international standards bodies [American So-

Table 1. Uncertainties in voltage source intercomparisons by RSS and algebraic combination methods.

Error source	Error estimates in parts per million (all random errors @1 s.d.) @10 MHz	@50 MHz

Algebraic combination	116	544

ciety of Testing Materials (ASTM), Institute of Electrical and Electronic Engineers (IEEE), and the Bureau International des Poids et Mesures (BIPM)] are seeking consensus methodology to resolve current disagreements. Whatever method is used, the important thing is that the error sources be listed, the uncertainty of estimation stated, and the method of combination documented. Then others will be able to interpret correctly the uncertainty statement for replication and for their own applications.

1.1.7 Factors Influencing Testing and Calibration Integrity

1.1.7.1 Measurement Uncertainty versus Testing/Calibration Specifications. Accuracy or uncertainty ratios are a representation of the relationship between the measurement uncertainty of the testing/calibration process and the performance, test, or calibration specifications of the device under test or calibration. For simplification, call this the ratio between the measurement uncertainty and the test specification. What happens when this ratio changes? This is equivalent to a situation in Fig. 1 where the "TME Error Distribution" is expanded to the size of the "Production Process Distribution" or contracted to being barely visible. Figure 2 represents the relationship of these values and is based on the following typical set of conditions:

1. the device under test came from a production process distribution that is normal (Gaussian);

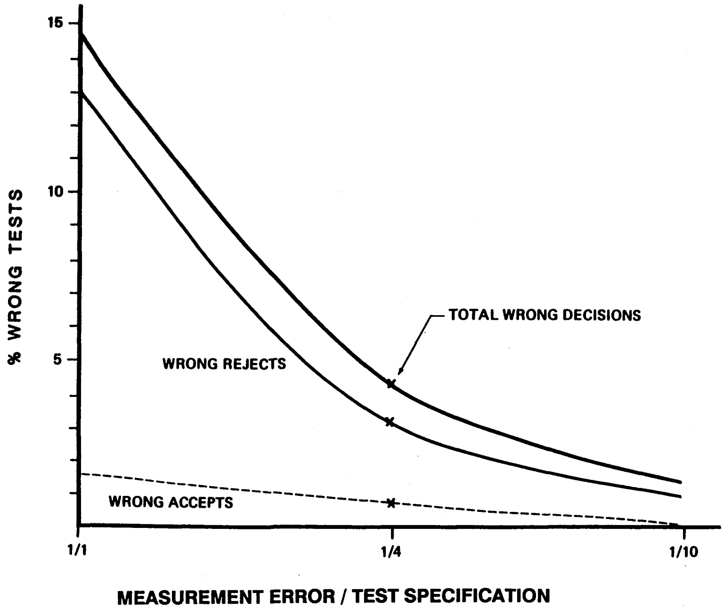

FIG. 2. Effect of varying measurement errors.

2. the performance specifications have been set at 2σ confidence limits of the production process distribution;
3. the measurement uncertainty has a normal (Gaussian) distribution with limits at two standard deviations or at 2σ confidence.

Figure 2 shows the effect of increasing or decreasing the measurement error in relation to the test or performance specification. At the point where the error is as great as the test specification (1/1 ratio), nearly 15% of the tests conducted result in wrong acceptances or rejections. At a ratio of 1/4, the percentage of wrong tests has been reduced dramatically to less than 5%. Below this point, the rate of reduction in the percentage of wrong tests slows as the ratio approaches 1/10 or less. These figures typify the impact of diminishing measurement error on test or calibration risks. At ratios greater than 1/4 (1/3, 1/2, 1/1.5), the percentage of wrong tests increases sharply. If one is required to make measurements under such conditions and these higher risks cannot be tolerated, compensation schemes should be used, as will be discussed later.

Another underlying assumption here is that the measurement error represents the uncertainty that characterized the measurement process at the time the measurement was made, not at some earlier time when calibration was performed. Thus, the uncertainty statement should include estimates of error growth over the time between calibrations. Stated another way, the longer the TME is into its calibration interval, the more uncertain its measurement.

1.1.7.2 Testing/Calibration Specifications. The control of testing/calibration risk also depends upon the relationship between performance specifications and the test or calibration specifications used to confirm performance compliance. What happens as the relationship of specifications is changed? Refer again to Fig. 1. The small bell-shaped curve to the right of the figure represents the total combined uncertainty of the TME and test system used to test a typical product. Note that the "Test Spec" is located inside the "Perf Spec" limit. The location of the "Test Spec" in relation to the "Perf Spec" has a significant impact on the number of wrong test decisions that a given test process will produce.

These wrong test decisions are made up of wrong acceptances (sometimes called buyer's risk) and wrong rejections (sometimes called seller's risk). Wrong acceptances hurt the buyer and damage the seller's reputation; wrong rejections hurt the seller and raise costs to the buyer. If the TME uncertainty is large enough to create unwanted testing risks, the "Test Spec" can be moved inside or outside the performance specification to reduce the unwanted risk. By looking at the shaded areas in Fig. 1, one can see that the further the "Test Spec" is inside the "Perf Spec," the greater the amount of "Good product subject to wrong rejection" and the smaller the amount of "Bad product subject to wrong acceptance." In this instance, the seller is taking a much larger risk than the buyer to compensate for the TME uncertainty. Were the seller willing to pass the testing risk on to the buyer at some risk to his reputation, the seller would locate the "Test Spec" outside the "Perf Spec." Refer now to Fig. 3. It shows the effect of varying test specifications in relation to performance specifications for a given TME error distribution. Figure 3 is based on the same conditions as Fig. 2 and reflects the percentage of wrong tests that result when the location of the test specification is moved.

Note that the "Wrong Rejects" increase to 10% as the "Test Spec" is located further and further inside of the "Perf Spec," while the "Wrong Accepts" diminish to below 1%. As the "Test Spec" is moved to the outside of the "Perf Spec," wrong rejections go to zero while wrong acceptances increase to a peak of about 3%. Thus, one method available to control testing/calibration risk is to reposition test and calibration specifications, especially where TME uncertainties are too large and create unwanted risks (Eagle, 1954; Grubbs and Coon, 1954).

1.1.7.3 Other Factors Influencing Testing/Calibration Risks. While uncertainty ratios and tolerance positioning strongly affect testing/calibration risks, other factors have significant influence as well. They are as follows.

1. *The quality of units yielded from the production process.* The production quality variable has one of the strongest influences on testing/calibration risk. This variable is reflected in Fig. 1 as the "Production Process Distribution." The more units that are produced which lie within the performance specifications, the higher the quality

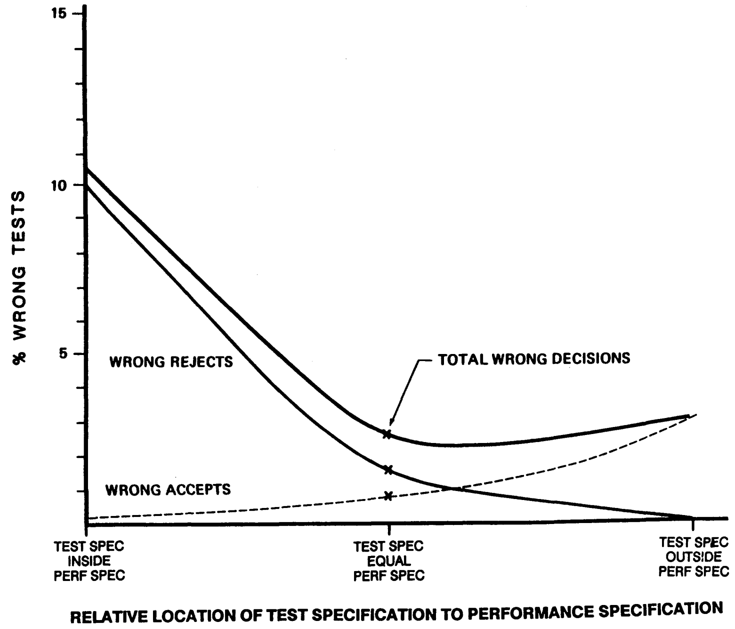

FIG. 3. Effect of varying test specifications.

and the lower the measurement risk. This is true whether the product is a ball bearing or an item of TME. This quality indicator is usually expressed in terms of statistical confidence limits. The higher the confidence limit is, the greater the amount of product within the limit and the higher the quality. A 3σ limit would indicate that 99.7% of yielded product was being produced within the stated performance specifications; a 2σ limit, 95.5%; a 1σ limit, 67%.

2. *Length of test intervals.* The longer the time between tests on a population of products or devices, the greater the likelihood of making wrong test decisions. For example, the within-specification probability for most simple electronic devices usually decays exponentially with time. Thus, devices in the population move toward and beyond their performance specifications with time. The majority of wrong test decisions are made on devices operating near their performance specifications. Thus, the risk of making wrong test decisions increases with the elapse of time between tests due to performance decay of the devices under test.
3. *Length of calibration intervals.* The longer the time between calibrations of TME, the larger the uncertainty associated with its measurements. The performance of the TME decays in the same manner as the devices under test. Thus, TME uncertainty grows with time as does the risk of making wrong measurement decisions.
4. *Number of independent tests or calibrations performed on the same device or TME.* It is not uncommon for devices to be tested independently at several points in a production process, then tested further following stress induced to simulate usage and environmental conditions. The more tests that are performed on devices or TME, the greater their exposure to wrong test decisions. Marginally bad devices are eliminated in successive tests, which reduces the opportunities to make wrong acceptances, while more and more marginally good devices are exposed to wrong rejections. Thus, increasing the number of independent tests performed increases the probability of wrong rejection and decreases the probability of wrong acceptance (provided the induced stresses do not create impending failures—yet another risk). This impact also applies to the number of test points and parameters that are tested or calibrated. Testing/calibration decisions regarding device or TME acceptability are normally based on a policy that if one test point is beyond specifications, the entire device or TME is considered to be beyond specifications. Thus, the impact of testing the device at multiple test points and mul-

tiple parameters is similar to that of performing repeated tests. All three decrease wrong acceptances and increase wrong rejections. (Ferling, 1987).

1.1.7.4 Interrelating the Seven Risk Factors. Because of the complex mathematics and considerable computational facilities involved, it is very difficult to give exact figures for the mutual interaction of the seven factors affecting test and calibration integrity (Hayes, 1988). However, Fig. 4 provides a generalized representation, showing the combined impact of the seven interrelationship factors. They are presented as follows.

1. The *y* axis depicts the typical spread of wrong test decisions that result from the interactions, ranging from less than 1% up to greater than 10%. It identifies separately the wrong acceptances and wrong rejections that make up total wrong decisions, since the two elements react differently.
2. The *x* axis shows four factors with their typical ranges in parentheses as follows:
   (a) "% TME In-Tolerance": the amount of TME in a testing population found in-tolerance at the end of their calibration intervals (i.e., when submitted for calibration).
   (b) "Test Intervals": the length of time between scheduled operational tests of devices during their life cycle.
   (c) "Calibration Intervals": the length of time between scheduled calibration of the TME population during its life cycle.
   (d) "Test Accuracy Ratios": the ratios between the test or performance specification of a device under test or TME and the uncertainty of the TME or calibration system used to test or calibrate it.
3. Arrows on the curves include three additional factors as follows.
   (a) "More Tests": the number of independent tests and/or independent parameters involved in the test or calibration (multiple test points can be regarded as extrapolations of "more tests").
   (b) "Higher UUT Quality": the quality of units under test in a production process (usually expressed as a percentage expected or found to be within

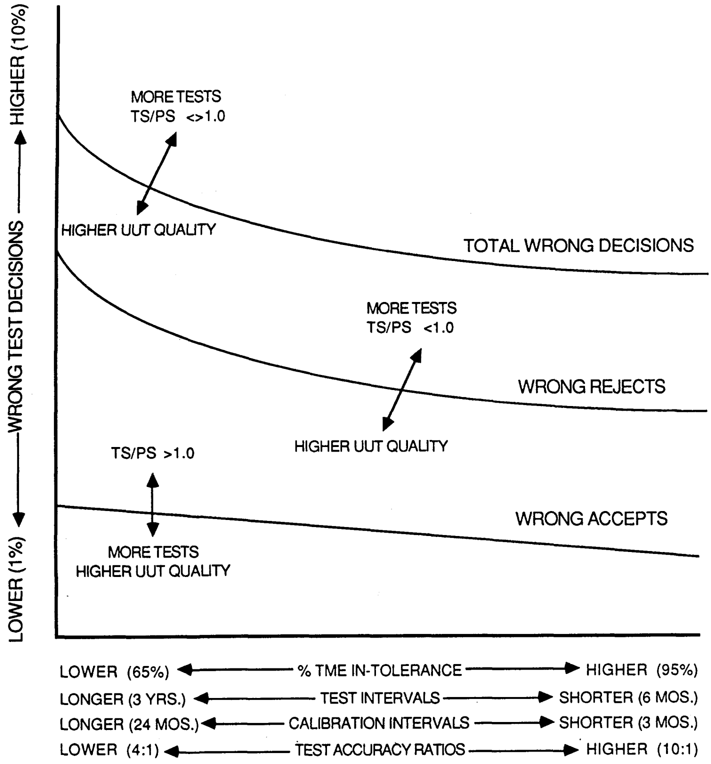

FIG. 4. Effect of test decisions on testing quality.

specified confidence or probability limits stated in σ's or standard deviations).

(c) "TS/PS": the ratio between the location of the test specification (TS) to the performance specification (PS) of a device under test or TME. At 1.0 the TS is located equal to the PS; at < 1.0, the TS is located inside the PS; at > 1.0, outside.

A careful review of these interrelationships will give the reader a better sense of the combined impact of the factors on testing/calibration risks and the need to control all seven to achieve targeted risk levels. Efforts have been under way since the early 1950s to quantify these relationships. Several combinations have been worked out (Castrup, 1989b), but a mathematical model that smoothly interrelates all seven factors has yet to be completed, programmed, and made operational on desktop or work-station-type computers.

1.2 Designs for Calibration

A properly designed calibration will fulfill the objective of retaining measurement control by detecting out-of-specification TME with known risks and restoring it to acceptable limits. Armed with an awareness of the factors that create risks in measurement and the what, why, when, where, and how of calibration, the design of successful calibrations can now be undertaken.

1.2.1 Determining Calibration Requirements. This first state of calibration design is aimed at determining if an item of TME actually requires periodic calibration. While almost all of it will, the following are situations where it will not.

1. It is not used to make quantitative measurements or provide known outputs.
2. It is obvious to the user when the TME fails to operate within performance specifications.
3. It makes measurements or provides outputs, but is monitored by other calibrated items of TME during use.

Once the TME requiring calibration has been identified, its performance specifications need to be pinned down. Assure that the parameters, ranges, and stated uncertainties are known and ambiguities eliminated. Then, find out which of the parameters and which of the ranges within the parameter are actually being used. (Minimizing the number of parameters and ranges calibrated reduces costs and the risk of wrongly rejecting adequate TME.) Next, establish the degree of uncertainty that can be tolerated based on the uncertainty ratios discussed earlier. If the allowable application uncertainties are larger than the TME performance specification, these can be used to expand the TME's calibration tolerances, which will, in turn, result in longer calibration intervals. Next, the environment in which the TME will be used is crucial for determining if any environmental compensation circuits need testing.

The final step involves selecting an adequate number of calibration points on each required range and parameter. The objective is to select enough points to assure that there are no hidden "holes" in the parameter where a discontinuity might exist. Meeting this objective calls for a balance between the minimum number of points to characterize a range and the time and added risk of not selecting more points. A minimum of two points is needed for the simplest of linear parameters, and from five to several hundred points where complex, nonlinear parameters are involved. A rule of thumb is that the greater the number of points selected, the less the risk of making wrong acceptances, but the greater the risk of making wrong rejections. A reasoned balance should be found for this important design decision (U.S. Navy Metrology Engineering Center, 1983).

1.2.2 Selecting Calibration Equipment. Calibration equipment that has sufficient parameters, range, and calibration point precision and sensitivity capabilities to match the defined TME requirements needs to be selected. Also, consideration should be given to the use of computer-aided calibration systems. These are helpful where the number of calibration points required create tedious measurement processes that often result in human error. Automated calibration systems are especially useful to process high quantities of TME using lower-skilled personnel and to collect and process large volumes of data.

To assure controlled testing risks, calibration equipment whose own uncertainties are significantly smaller than the TME performance specifications should be selected. For new equipment, the standard deviation of the uncertainty claim should be obtained from the manufacturer; otherwise, an estimate will be needed. Confidence limits of at least two standard deviations are suggested. For existing calibration equipment, its tolerance limits and the respective percentages in tolerance from calibration records should be used. Calibration equipment uncertainties smaller than one-fourth of the TME uncertainty have become the target for most calibration designs. (Larger TME uncertainties require that correction data, tolerance adjustments, repeated measurements, or shortened calibration intervals be used to reduce the influence of calibration errors. Figure 4 may be of help in suggesting avenues of escape from excessive risks caused by calibration equipment uncertainties.)

The site where the calibration is to be performed may have an influence on the equipment selected. Calibration equipment for in-place and on-site work requires more transportable, rugged, environmentally compensated, and easily operated systems than those found in the typical standards or calibration laboratory. Consideration should be given also to the difficulties that might be encountered in providing calibration support to the calibration equipment about to be selected. Often, acquisition of a new calibration capability creates a need for new standards capabilities to keep pace and to maintain measurement control through the traceability chain.

1.2.3 Establishing Calibration Traceability. Earlier, mention was made of the importance of maintaining common international measurement references. This is needed for measurements of all parameters for the worldwide exchange of goods, products, and technology. Transferring these common references in a controlled manner throughout the world to millions of individual measurements made by calibration equipment and TME is the objective of traceability. This goal requires a measurement support system of international, national, and grass-roots proportions.

Typical support hierarchies begin at the international level at the Bureau International des Poids et Mesures (BIPM) in France, where international standards of measurements are maintained. Then, their units of measurement are disseminated through reference standard artifact exchanges or comparisons with national standards laboratories. These laboratories, in turn, exchange standard artifacts with a larger number of government and commercial standards laboratories within each country. These standards laboratories then may exchange standard artifacts with an even larger number of locally operated calibration facilities, where calibration equipment transfers the units of measurement to their final destination during TME calibration.

The chain of traceability is completed at this state; it assures that measurements made on one side of the world mean, within uncertainty limits, the same thing as on the other side of the world. It also means that measurements made during research in one facility are relevant during design and production at another facility and when subsequently tested by a customer at yet another facility.

A typical example of a traceability chain would involve, for instance, a digital voltmeter as the item of TME requiring calibration support. It would be calibrated, typically by an automated calibration system comprised of a voltage source monitored by a more accurate digital multimeter with both source and meter controlled by a computer/controller, which also collects and processes calibration data, makes out-of-specification decisions, and establishes uncertainty estimates. (The multimeter would have built-in reference standards of voltage and resistance that the several internal circuits of the multimeter would use to update and correct the worst of the uncertainty drifts so as to extend calibration intervals.) During periodic calibrations, the multimeter's voltage references and complete voltage circuits would be calibrated against ac voltage transfer standards and dc voltage references, such as a bank of Zener diodes and ratio comparators with sensitive detectors. These Zener references would then be calibrated and certified by comparison with a bank of Josephson effect junctions, submerged in a special cryogenic bath, serving as voltage references and operating at microwave frequencies. (At cryogenic temperatures, these junctions resonate at frequencies known to a few parts in a billion of the international standards of time and frequency. They produce extremely stable and predictable voltage levels from which primary and national voltage standards are maintained. See CONSTANTS, FUNDAMENTAL.) As added protection, the Josephson junctions are intercompared internationally with BIPM and other national standards laboratories through a voltage measurement assurance program (MAP), which uses monitoring and data exchange schemes and intercomparison techniques. The MAP confirms measurement control of the references over long time intervals. Thus, traceable control and dissemination of the measurement unit of voltage are assured throughout the support hierarchy. The traceability and control of other measurement units are maintained through similar artifacts and processes.

To accomplish credible traceability, every effort must be made to transfer the measurement units down the chain with minimum increase in uncertainty. Because the artifacts normally are fixed in value, the use of uncertainty ratios between links in the chain is not usually applicable. Typically, at these stages in the process, corrections are included in certificates of calibration, and measurement uncertainties are combined as they pass along the links of traceability. Accuracy ratio protection is not required for these intercomparisons as long as the combined uncertainties are finally included at each progressive stage until they are included in the calibration equipment's estimate of uncertainty.

Somewhere along the chain and for convenience, the process usually changes from a one-to-one comparison of fixed-value standard artifacts to go/no-go (tolerance comparison) type calibrations. When this happens, alternative action must be taken to ensure that uncertainty growth is controlled and meaningful traceability is retained. Accuracy/uncertainty ratios have typically been the vehicle used to assist in traceability control for tolerance comparison calibrations.

Increasingly, there are processes where measurements are being linked to reference standard artifacts that embody physical constants. These have come to be called "intrinsic" standards; that is, they intrinsically embody the international value of the parameter they describe without direct reference to national or international laboratories. Some of the units of length, voltage, time, frequency, and temperature are represented by these intrinsic standards. Intrinsic standards do not follow the traditional traceability process of passing measurement units on through the use of standard artifacts. These standards are considered by some to be attractive because they allow the owning laboratory more freedom to maintain standards of measurement over longer periods of time. Their use also avoids the necessity of sending them to national or international standards laboratories for intercomparisons. However, they are expensive, require highly skilled personnel to operate, and require MAPs (data exchange schemes and intercomparison techniques) with national laboratories to assure that the equivalent of traceability is being achieved. MAPs can provide a significant quality benefit. They create a positive auditing function on all interacting laboratories (local, national, and international), which helps to detect human or equipment errors at any point in the traceability system that might go unnoticed otherwise.

Standard reference materials issued by some national laboratories are considered to be a form of intrinsic standard. These are specially prepared artifacts that embody a selected characteristic (hardness, spherical size, particle size, gas, chemical composition, etc.) and that disseminate traceable measurements from the national reference standards level to all other levels in the traceability hierarchy.

Sometimes, traceability is not possible because of a lack of capability at national or international levels. This problem appears most often where research efforts and discoveries have moved into new measurement parameters and ranges. Such inadequacies necessitate the temporary designation of an interim reference standard at a manufacturer's facility, a government laboratory, or a university. Other interim solutions include a round-robin intercomparison of an interim reference standard artifact that substitutes until a more rigorously devised national standard can be completed. The earliest possible detection of traceability gaps and the reporting of these to national standards agencies helps to minimize these traceability voids.

1.2.4 Designing Calibration Procedures. The design and development of calibration procedures is at the heart of competent and useful calibrations. Wrong calibration methods will readily negate even the best calibration equipment selection methods and calibration traceability schemes. The following are the elements of properly documented calibration procedures.

1. *Style.* The style of writing is intended to communicate with calibration personnel. It takes into account their level of education, their general experience in the field, and their experience in dealing with calibration processes.
2. *Identity of TME.* The item of TME is clearly identified as to model number, nomenclature, and any special configuration or production sequence.
3. *Identity of calibration equipment.* The required calibration equipment is identified, along with substitute items, hook-up diagrams, and details of the calibration configuration.
4. *Testing conditions.* Testing conditions are specified, including safety precautions, cable routing, switch positions, computer status, and interface settings.
5. *Test steps.* Sequential and sufficient test steps are listed for each measurement parameter that the calibration requirements effort has identified. Functional tests are also identified that confirm the operational adequacy of the TME without regard for tolerance tests.
6. *Pass-fail specifications.* The individual specifications and uncertainties of the TME are defined, including specific pass-fail criteria for each test point.
7. *Data collection.* The specific data to be taken have been identified (for on-site and future analysis), and data forms have been designed to collect it efficiently and accurately. Care must be exercised to take only enough data to execute the calibration, yet to take enough to allow for calibration interval assessment, parameter failure analysis, repair diagnostics, and part replacements, and management information such as time and material data.

There are a variety of sources for design guidance. TME and calibration equipment manufacturers often prepare calibration procedures for the instruments they produce. Government facilities prepare and distribute a large variety of procedures and guidance documents (U.S. Navy Metrology Engineering Center, 1984). The Government-Industrial Data Exchange Program (GIDEP) of the U.S. Navy at Corona, California, maintains a library of calibration procedures from many military and industrial sources. U.S. trade and technical societies, such as the American Society of Testing Materials (ASTM), American National Standards Institute (ANSI), Instrument Society of America (ISA), and the Institute of Electrical and Electronic Engineers (IEEE), have repositories of selected calibration procedures as do counterpart documentation standards institutions in most countries. Whatever the source of the procedure, it should meet the requirements discussed in this section to assure the integrity of the calibration process.

1.2.5 Defining Calibration Servicing Intervals. The design of a calibration support system would be incomplete without some established means of determining how often to calibrate TME and calibration equipment. A calibration performed only once establishes a one-time reference of uncertainty. Recalibration is necessary to detect uncertainty growth and to maintain the uncertainty within limits specified. A properly selected interval assures, to a known risk target, that TME is receiving recalibration at the proper time.

For a very few devices, the interval is based on stresses such as the number of uses or passes, or on wear attributable to abrasion or physical distortion. On most TME, the interval is based on elapsed time since last calibration, reflecting the tendency of its uncertainty to drift beyond established specifications as a function of time. Mathematical models have been developed that describe this. The exponential and gamma (Γ) models fit the behavior of most TME (other models include Weibull, log-normal, random walk, and drift, which relate to a significant minority of items of TME). These models establish the rate at which the TME moves out of specification and predict the time at which a given percentage of TME will be found to remain within specification. Stated another way, the models establish the functional relationship between time elapsed since the last calibration and the probability that an individual TME, selected randomly from its population, will be out of specification at the next calibration.

The design objective for a calibration interval determination system is to generate the proper calibration interval in the shortest possible time. The quality and quantity of data obtained by the calibration procedure have a major impact on the timeliness and accuracy of the designated intervals. Approximately 30 bits of data are required before reasonably confident intervals can be selected. To achieve that much data requires 30 separate calibrations of a single item of TME or, because that may take several years, the calibration of 30 items of TME of nearly identical configuration. Thus, for such practical reasons, data are acquired from TME by serial number, but compiled by identical or similar model number and manufacturer to accelerate the interval decision process. Because of this, most rigorous systems designate intervals at the manufacturer/model number level of identity (U.S. Navy Metrology Engineering Center, 1986; Castrup, 1989b).

Figure 4, presented earlier, reflects the effect that intervals have on percentage of wrong test decisions. Any interval setting system needs to select a target for the amount of out-of-specification TME that the process or facility can tolerate. This target will have a major impact on the length of calibration intervals.

Calibration intervals are listed in very few published-for-release documents. U.S. military services have extensive interval listings for their inventory of TME (U.S. Army Test, Measurement and Diagnostic Equipment Support Group, 1991; U.S. Air Force Aerospace Guidance and Metrology Center, 1991; U.S. Navy Metrology Engineering Center, 1991), as do industrial activities with military contracts.

2. TEST AND MEASURING EQUIPMENT MAINTENANCE

2.1 Objectives of Maintenance

TME maintenance focuses on technical activities intended to keep TME in satisfactory working condition and to avoid catastrophic failures. Unlike calibration, which is designed to control uncertainty growth beyond specified limits and to detect insidious failures unnoticeable by an operator, maintenance is designed to avoid accelerated wear-out and catastrophic operational failures.

The objective of maintenance is to assure that there will be no breakdowns of TME systems and that they can continue to operate safely. Typically, the cost to maintain is traded off against the cost to suffer TME breakdowns and increased safety risks. To quote some currently popular terminology, "If it ain't broke, fix it before it is." That succinctly represents the objective of maintenance.

While maintenance is an independent function, for convenience much of it is performed during calibration. Typically, maintenance intervals are longer than calibration intervals. Accordingly, many TME managers schedule maintenance to be done at every second or third scheduled calibration.

2.2 Designs for Maintenance

2.2.1 Defining Maintenance Requirements. The requirements for maintenance are usually defined in manufacturer manuals where specific activities are indicated to keep TME operable. Other requirements are acquired from data taken during calibrations and repairs, and from user complaints made to repair/maintenance personnel. These requirements attempt to define the circuits, parts, mechanisms, and devices whose failure could be avoided by detecting diminished capability, fluid loss, dirt and grease accumulation, environmental stresses, and wear. In addition, TME use should be reviewed to find out the experience level of users, their opinions regarding TME functional reliability, the environment in which it is used, and whether maintenance can be divided between the user and the maintenance facility.

2.2.2 Selection of Maintenance Equipment. Typically, maintenance performed during the calibration process uses much of the same equipment used for calibration. In addition, special facilities are needed for cleaning, lubricating, and stress testing for safety hazards and imminent failures.

Some items categorized as TME may require only maintenance and no calibration, yet require special tests or actuations to confirm operability of emergency circuits and actuator equipment for more complex tasks or non-uncertainty-related measurement capabilities, such as indications of presence or absence of signal, pressure, flow, etc.

As with calibration equipment, the site where maintenance is to be performed will have an influence on the equipment selected.

Much routine maintenance can be conducted on-site where the TME is located.

2.2.3 Designing Maintenance Procedures. Clearly written and logically sequenced procedures are essential to successful maintenance operations. Where these procedures are scheduled in conjunction with calibration operations, they should be integrated to follow the flow of the calibration process; however, many maintenance operations should precede calibration to assure functional adequacy of the TME before subjecting it to more time-consuming calibrations. Maintenance procedures should have the same characteristics previously outlined for calibration procedures (Sec. 1.2.4). The better and more clearly written these procedures, the less costly the continued maintenance operations will be. A small investment in well-prepared procedures will pay large dividends in the long run.

2.2.4 Defining Maintenance Servicing Intervals. One of the more difficult design problems is to develop a system that determines the most desirable time to perform maintenance. Done too frequently, maintenance is a waste of time; done too infrequently, it results in earlier failures with costly losses to both TME and the operations in which it is used. Many owners schedule TME maintenance at multiples of the TME calibration interval—a practical approach based on the fact that typical calibration intervals are shorter than maintenance intervals. As more knowledge accrues about calibration interval systems and calibration risk targets, basing maintenance intervals on calibration intervals may prove to be unwise. Calibration intervals are based on partial failures of TME, known more accurately as "soft" failures, whereas functional failures are known as "hard" failures. Therefore, preventive maintenance intervals lend themselves to somewhat different mathematical models for servicing interval estimates than do calibration intervals.

Ideally, maintenance interval analysis should stand alone and be based on mathematical and statistical correlation of historical functional failure data that focus on types of maintenance performed, time between maintenance, failed components/parts, and time between failures. From these data, mean-time-between-failure (MTBF) figures can be developed for each model-numbered TME. These figures reflect the reliability index of the TME and can be related to a MTBF target of the TME population. Thus, MTBF reliability targets can be established for which appropriate maintenance intervals can be designated.

3. SUMMARY

Control of tests and measurements is essential to the quality of development, design, manufacturing and industrial processes. Calibration of test and measurement equipment is a critical measurement control tool to assure that measurements are traceable to a common reference and to restrict test/measurement risks. Seven factors affect measurement risk. These factors include the initial quality of the product, the tolerances used in testing the product (as they relate to its design specifications), the uncertainty of the measurement equipment used in the tests (as it relates to testing tolerances), the number of tests performed, the time elapsed between tests, the percent of measurement equipment out of tolerance when used for tests, and the time elapsed between measurement equipment calibrations.

Well-designed test and calibration programs provide monitoring and control of the risk factors. Measurement assurance processes are a partner of calibration and help detect loss of measurement control. Maintenance programs assure that test and measurement equipment operates with minimum failures. They prevent untimely and costly operational disruptions. Collectively, these processes assure the cost-effective control of test and measurements throughout technology.

Future trends in calibration and maintenance include more intensive efforts to develop calibration systems that reduce measurement uncertainties and improve efficiencies. Measurement science research projects will continue to be of paramount importance to define, develop, and produce reference standards that keep pace with technology. Greater use of built-in and external computer systems will assure improved control and operation of calibration and maintenance systems. Special software and artificial intelligence technology will provide major assistance in configuring calibration systems, providing calibration and maintenance procedures, and analyzing and controlling measurement risks.

GLOSSARY

Accuracy: See measurement uncertainty.

Accuracy Ratio: See measurement uncertainty ratio.

Attribute: The quantity, parameter, or characteristics of products or devices being tested or of TME being calibrated (voltage, pressure, viscosity, etc.).

Calibration: The process of measuring and testing attributes of TME to estimate the error or measurement uncertainty of the TME. For the majority of TME, the error is then compared to calibration specification limits; if found beyond specification, corrective repair and/or adjustment and recalibration is performed; if not found beyond specification, compensation or adjustment is optional. For fixed-value-type TME, such as reference standards, the attribute value and calibration system measurement uncertainty is determined and reported in a calibration certificate.

Calibrational Interval: The maximum allowable period of time for TME to remain in use before being calibrated. Sometimes referred to as "calibration period."

Error: The amount to which an attribute's measured value differs from its international reference or "true" value.

Maintenance: A process that cleans, adjusts, services, measures, diagnoses, and restores TME to such satisfactory working conditions as to avoid early wear-out and catastrophic operational failure.

Maintenance Interval: The maximum allowable period of time for TME to remain in use before being maintained. Sometimes referred to as "maintenance period."

Measurement Uncertainty: The magnitude of limits that bound a measured value and that contain its "true" value with a specified probability.

Measurement Uncertainty Ratio: The ratio of TME calibration tolerance limits (normally, TME uncertainty limits) to calibration equipment uncertainty limits, or, the ratio of a device's testing tolerance limits to the uncertainty limits of the TME testing it.

Test and Measurement Equipment (TME): Items of test, calibration, diagnostic, monitoring, simulating, and measuring equipment used in research, design, manufacturing, process monitoring, testing, and calibration operations.

Testing/Calibration Performance Limits or Tolerances: *Two sided:* Assigned values, symmetrically located on each side of the nominal value of a device or TME attribute, that represent the maximum acceptable limits for the value of the attribute. *Single sided*: An assigned value (upper or lower) that represents the maximum (or minimum) acceptable limit for the value of a device's attribute.

Testing: The process of measuring attributes of devices with TME and comparing the measured values with the devices' performance limits. If the device is found beyond performance limits, corrective repair and/or adjustment and retesting is performed.

Traceability: The ability to relate individual, working-level measurement results, through a contiguous sequence of measurements and intercomparisons, to nationally and internationally accepted measurement standards (e.g., reference standards, standard reference materials, intrinsic/quantum-mechanical standards, etc.).

INTRODUCTION

Carbon, the sixth element of the periodic table, has an atomic mass of 12.011 15 ±0.000 05. It consists of 98.89% of the isotope ^{12}C, 1.11% of the isotope ^{13}C, and several unstable isotopes with nuclide masses between 9 and 16. The isotope ^{14}C, which is formed in the atmosphere by the reaction $^{14}\mathrm{N}(n,p)^{14}\mathrm{C}$, is used in archeology for age determination and for tracing of chemical compounds; the half-life of this β emitter is about 5570 years (Gmelin, 1967, 1968).

Carbon is the thirteenth most frequently occurring element. The earth's crust, including the lithosphere, hydrosphere, and atmosphere, contains about 2.9×10^{16} t of carbon, which equals 0.087 wt % or 0.152 at. %, mostly as compounds and only a small portion in elementary form. The carbon content of sea water, atmosphere, and biosphere is about 3.8×10^{13}, 3.8×10^{11}, and 2.8×10^{11} t, respectively.

Carbon exists in several allotropic modifications (Fig. 1). *Chaoite*, the most frequent member of the *carbyne* group, was found in small quantities together with graphite in the rocks of the Nördlinger Ries, Federal Republic of Germany, which were transformed by meteoritic impact (Goresey, 1968). Small quantities of other members of the carbyne group are formed together with graphite by condensing carbon vapor generated from laser-heated carbon on substrates, and also in meteorites. Carbyne carbon forms are also found mingled with graphite material in natural carbon deposits all over the world. Like diamonds, they are thermodynamically unstable under ordinary conditions, but have a kinetic barrier for transformation to graphite. A common feature of the numerous members of this group is the presence of triple bonds (*sp*). The crystals have trigonal symmetry. A few of these forms, like chaoite, for example, are very hard; others are as soft as graphite or even softer (Whittaker, 1979; Whittaker *et al.*, 1983).

Graphite is characterized by its layered lattice structure, but only a few natural graphites and hot-worked pyrographite samples are nearly perfect crystals. Most graphitic materials deviate more or less from the perfect crystal structure. The differentiation between

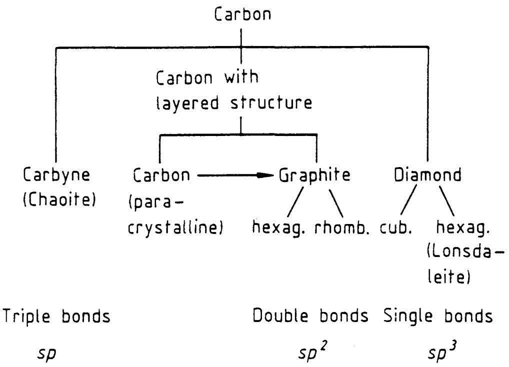

FIG. 1. Allotropic carbon modifications.

graphite and carbon, a term for less ordered species, e.g., metallurgical coke, carbon black, or charcoal, is only for the sake of convenience.

Diamonds are most frequently cubic. The hexagonal diamond (lonsdaleite) was first found as a product of diamond synthesis but meanwhile has also been discovered in meteorites. Graphite is the stable phase at standard conditions; diamond can be transformed into graphite by heating above 2000 K. At atmospheric pressure, graphite vaporizes without melting at ca. 3895–4020 K. By use of a laser heating technique, a graphite–liquid–vapor equilibrium pressure of 10.7 ± 0.2 MPa at a temperature of about 4000 K has been found (Haaland, 1976). The density of liquid carbon is about 1.37 g/cm^3. The graphite–diamond–liquid triple point amounts to ca. 4020 ± 50 K and $(11.0\text{–}14.0) \times 10^3$ MPa. The heat of sublimation depends on the vapor composition. It amounts to 711, 825, and 788 kJ/mol for monatomic, diatomic, and triatomic molecules, respectively. At 4000 K, about 80% of carbon vapor consists of C_3 molecules.

Fullerenes are distinct carbon clusters characterized by a cage structure. C_{60} (buckminsterfullerene) and C_{70} have been identified in soot and condensed carbon vapor. Other stable members of the fullerene group should be C_{20}, C_{24}, C_{28}, C_{32}, C_{36}, C_{50} (Kroto, 1988), C_{76}, C_{84}, C_{90}, and C_{94}.

The fullerenes are obviously important intermediates in the formation process of soot. The structure of C_{60}, buckminsterfullerene, is shown in Fig. 2.

The variations in bonding of the carbon atoms inaugurate a broad spectrum of carbon species, including conductors and insulators having extraordinarily high or low hardness and stiffness. Carbon materials accordingly offer a broad range of properties that are exploited in numerous applications.

1. DIAMOND

For many centuries, diamond has been appreciated as a valuable gem and investment. The first center of mining and cutting was India, which was replaced by Brazil (18th century), South Africa (19th century), and most recently Zaire. The output amounts to ca. 50 megacarats (1 carat=0.2 g), which is not sufficient to satisfy the increasing need for industrial diamonds. Diamonds have been synthesized since the mid–20th century [General Electric Co., ASEA (now ASEA Brown Boveri AG)]. The estimated capacity for synthetic diamond production exceeds 100 megacarats.

1.1 Properties and Structure

Diamond is characterized by its hardness (Mohs hardness 10) and luster. The mineral is usually colorless, but may be pink, light blue, or even black (carbonado) as a result of incorporated impurities. The density is 3.515 g/cm^3 (that of graphite is 2.266 g/cm^3). The lattice of the cubic modification is face-centered with the space group $Fd3m\text{–}O_h^7$ and the lattice constant $a = 0.356\,683$ nm (Fig. 3).

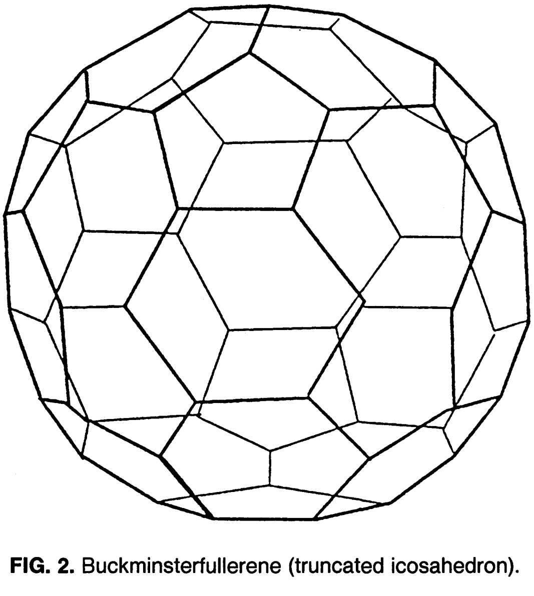

FIG. 2. Buckminsterfullerene (truncated icosahedron).

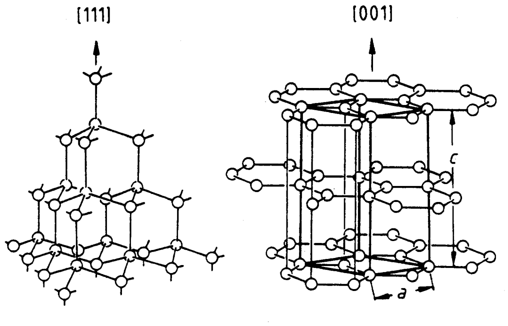

FIG. 3. Lattices of the cubic diamond and the hexagonal graphite crystals.

Each carbon atom has four nearest neighbors at a distance of 0.1544 nm and is linked by sp^3 hybrid bonds; the bonding angle of the covalent bonds is 109.5°. Distinction must be made between type-I and type-II diamonds (and several subgroups) (see DIAMONDS AND DIAMONDLIKE MATERIALS), which have different absorption spectra. The electrical resistivity at room temperature is about 10^{18}–10^{20} Ω cm (type I) and 10–10^3 Ω cm (type II) with larger deviations for contaminated or doped species. Type-II crystals are typical semiconductors; the resistivity decreases with temperature according to $\log \rho \sim 1/T$. Diamonds are excellent conductors of heat. The thermal conductivity at room temperature amounts to ca. 10 W cm^{-1} K^{-1} (type I) and ca. 20 W cm^{-1} K^{-1} (type II), which is about 3 times greater than that of copper. The specific heat is 6.20 (300 K), 13.55 (500 K), and 21.60 (1000 K) J g^{-1} K^{-1}, and the coefficient of linear thermal expansion (between 0 and 100 °C) is about 1×10^{-6} K^{-1}. Crystals cleave well parallel to the (111) plane. The cutting hardness is different for different crystal faces, which must be taken into consideration when cutting. The coefficient of friction depends on the purity of the surfaces. With increasing degasification, the coefficient rises from ca. 0.1 to 0.6 (Field, 1979). Natural diamonds contain up to 0.2% nitrogen (types Ia and Ib), 10 ppm Al, and 0.25 ppm B (types IIa and IIb). Diamond is resistant to most chemical substances at normal temperatures. At higher temperatures, it is attacked by oxygen, oxidizing agents, and carbide-forming elements. At temperatures of ca. 2000 K and above, diamond converts into graphite both internally and on the crystal surfaces. The rate of phase transformation increases rapidly with temperature. See DIAMOND AND DIAMONDLIKE MATERIALS.

1.2 Natural Diamond

The sources of diamonds are probably ultrabasic rocks, especially eclogite, consisting essentially of omphacite and pyrope. The famous blue ground of the Kimberlite slots is a decomposed eclogite rock containing ca. 1–2 carats of diamonds per ton of rock material. Placers—e.g., Lüderitz Bay, Namibia—are also important deposits.

While about one-quarter of the mined diamonds can be used for gems, the greater part is used in industry (bort, carbonado).

1.3 Diamond Synthesis

Graphite can be converted into diamond by first dissolving it in melted metal and then crystallizing at pressures above equilibrium. At pressures above 12.5×10^3 MPa and temperatures in the 3000-K range, graphite spontaneously collapses into polycrystalline diamonds (Bundy *et al.*, 1973). Figure 4 shows the phase and reaction diagram with the pressure–temperature regions used for synthesis.

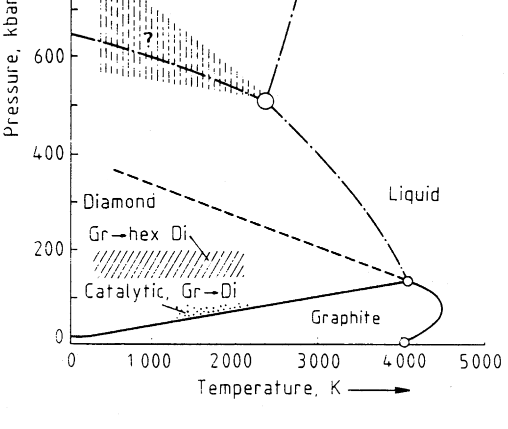

FIG. 4. Carbon phase diagram (Bundy *et al.*, 1973).

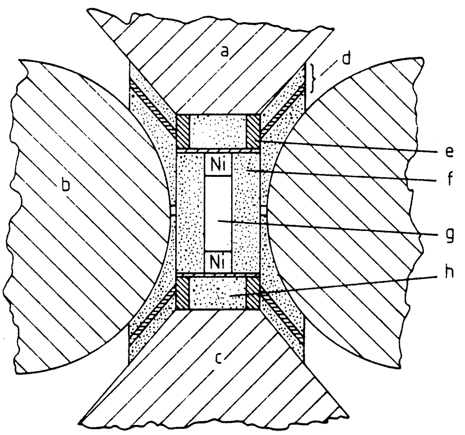

FIG. 5. Belt-type pressure apparatus (Bundy *et al.*, 1973). *a*, top piston; *b*, cylinder; *c*, bottom piston; *d*, gasket assembly; *e*, current ring; *f*, sample holder; *g*, graphite; *h*, insulating pill.

For synthesis, special high-pressure and temperature-resistant apparatus have been developed. The "belt"- and "multipiston"-type apparatus are the most commonly used. The belt-type apparatus is illustrated in Fig. 5. It consists of two truncated conical pistons and a prestressed cylinder assembly, which compose a reaction chamber. The circular gaps between the sections are filled with conical gaskets made of pyrophyllite and steel. The gaskets act as seals, pressure transmitters between the segments, and electrical and thermal insulators. The reaction sample contains stacked graphite and metal plates, or a mixture of graphite powder and nickel powder or other group-VIII metals, and is heated by resistance heating. The current is supplied via pistons and current rings. The lifetime of this apparatus with a diameter of up to 40 mm is ca. 100–1000 cycles when properly operated. After cooling, the diamonds are separated by dissolving the metal matrix with acids. The average size of synthetic diamonds is ca. 0.05–0.5 mm. For the production of semiconductors, doping of the crystals with boron is possible. Smaller diamonds also can be produced by shock waves (see Fig. 4).

1.4 Diamond Thin Films

A wide variety of methods based on activated chemical vapor deposition is proposed for the generation of diamond thin films. Hydrogen gas containing a few percent of methane, ethane, or other hydrocarbon compounds is activated by thermal plasma, ion-beam, laser-beam, microwave plasma, and other techniques at pressures of about 0.01–0.1 bar and temperatures of about 800–1300 K. The difficulties of diamond nucleation and growth are the short lifetime of the excited carbon atoms and the suppression of the formation of nondiamond carbon. Nucleation kinetics, film growth, and film properties depend strongly on the deposition conditions. The deposition rate can be as high as 20 μm/h; it seems to be possible to increase this rate. Diamond thin films contain, besides diamond (sp^3 bond), variable amounts of graphite (sp^2 bond), even carbynes (*sp* triple bond), and hydrogen.

Because of their outstanding hardness, it is proposed that cutting tools be coated with diamond thin films. Other expected applications are optical films and windows for x-ray equipment, semiconductor components, and temperature sinks for semiconductor devices (Angus, 1990).

1.5 Applications

Because of its hardness and toughness, diamond is well suited for all cutting and grinding operations. About 35% of industrial diamonds are used in grinding and honing tools, 20% for saw edges, 20% for drilling heads, 20% for loose grinding, lapping, and polishing powders, and about 5% for drawing dies, bearings, and turning tools. The powdery diamond usually must be bound into a metal or resin matrix, which is fixed in a support. Single diamonds are used for drawing dies, bearings, and tactile devices, as well as for diamond jewelry.

2. GRAPHITE

Graphite has been used for the production of refractory crucibles since at least the 15th century, and for pencils since about 1550. It is named after the Greek word γραφειν (to write). The history of graphite has been closely associated with the development of electricity. Sir Humphry Davy, in 1800, was probably the first to use carbon electrodes for his studies on the electric arc. The increasing demand for electric arc-light carbons after about 1870 gave rise to several processes for the manufacture of artificial carbon (Carré, Brush, Siemens). At the beginning of the 20th century, important electrolytic and electrothermic processes using carbon or graphite electrodes became available, e.g., aluminum electrolysis (Hall, Héroult), alkali-chlorine electrolysis (Castner *et al.*), calcium carbide (Willson), electric steel (Héroult), and silicon carbide (Acheson). See also GRAPHITE.

2.1 Single-Crystal Graphite

The ideal crystal lattice of hexagonal graphite is illustrated in Fig. 3. Each carbon atom has three nearest neighbors within the layer plane at a distance of 0.1421 nm and a bonding angle of 120°. Within the layer planes, the bond energy due to the trigonal sp^2 hybridization of the bonding orbitals is far greater than that of the nonhybridized orbitals, which form weak π bonds vertical to the layer planes. The layer or basal planes of the hexagonal modification are stacked in the sequence *ABAB*..., and those of the rhombohedral modification are in the sequence *ABCABC*... . Natural graphite normally contains both modifications, in some cases up to 30% of the rhombohedral modification. The proportion of this modification may be increased by milling and shearing and is decreased by thermal annealing. The space groups of the graphite modifications are D_{6h}^4–$P6_3/mmc$ and D_{3d}^5–$R\bar{3}m$, respectively.

The interlayer spacing depends on the degree of disorder and amounts to 0.3354 nm in an ideal crystal, 0.344 nm for crystals with turbostratic structure (random stacking sequence), and even more for less-ordered structures. One indicator of the disorder is the width of the x-ray diffraction lines. Most theories explaining the broadening are based on the assumption that aligned layer stacks only correlate in parallelism of the layers. The broadening is then due to translation and rotation of the layers (Franklin, 1951).

Other models only accept translation parallel to the layer planes, caused by clusters between the layers and larger vacancies within the layers (Ruland, 1968). These defects yield to deformations of the layers and deviations from the ideal *AB* sequence, respectively.

Because of the layered structure, all vectorial properties are to a large extent controlled by direction. Some properties of single graphite crystals, their dependence on the crystal direction, and, for purposes of comparison, some common properties of diamond are shown in Table 1. The anisotropy of thermal expansion is particularly remarkable since the crystal expands in the *c* direction and contracts in the *a* direction at temperatures below 400 °C. Parallel to the basal planes, graphite is a metallic conductor whose resistivity increases with rising temperature. In the *c* direction, graphite behaves like a semiconductor. The thermal conductivity strongly decreases with decreasing temperature. At room temperature, the thermal conductivity in the *a* direction is better than that of copper. The properties shown in Table 1 strongly depend on the type of samples; therefore the original publications or manuals should be consulted for a deeper understanding (Kelly, 1981; Reynolds, 1968).

[a] The properties of diamond crystals vary considerably.

2.2 Natural Graphite

2.2.1 Mining and Properties. It is currently supposed that organic matter was the origin of most natural graphites, with the probable exception of the Sri Lanka deposits. Graphite inclusions in plutonic rocks can be traced back to the accumulation of insoluble carbon within the residual melt. The decomposition of inorganic compounds, e.g., carbide, carbonyl, and cyano compounds, is less important for the genesis of graphite deposits.

Crystallinity, refractoriness, and other properties of natural graphite from different deposits may vary enormously as a result of differences in the precursor materials and the conditions of metamorphosis. In general, natural graphite is a ductile soft mineral that easily cleaves parallel to the basal layer. The flaky grades (plumbago or vein graphite) show a typical metallic luster; the microcrystalline "earthy" grades have a duller black appearance. The most common accompanying minerals are quartz, mica, and feldspars; accessory minerals may include pyrite, magnetite, pyrrhotite, and calcite.

Natural graphite is mined in open-pit and underground mines. Crude ores with a carbon content sufficiently high for industrial use are only crushed, dried, graded, and, if necessary, milled. In general the carbon content is only about 30% to 50%, and graphite must be enriched, preferably by flotation processes.

Carbon enrichment by flotation yields up to about 96% C for flake graphites. The mineral components of graphite may be further reduced if the graphite is purified by treatment with hydrofluoric acid, melted sodium carbonate, or chlorine and fluorine at temperatures up to 3000 °C. The ash content can be reduced by these processes to less than 50 mg/kg.

2.2.2 Uses. Natural graphites vary widely in flakiness, refractoriness, toughness, durability, bulk density, etc., and meet the requirements of various processing industries: 24% are used in foundries, 24% in the steel industry, 15% for the production of crucibles, 12% in the electrical field, 8% in the refractory industry, 5% for lubricants, 4% for pencils, and 3.5% for batteries.

Graphite crucibles are used in foundries for melting steel, nonferrous metals, and precious metals. Bricks for open-hearth furnaces, ladle plugs, and tap spouts are other examples of the use of natural graphite in metallurgy. When compared with other refractory materials, graphite-containing grades have generally better thermal conductivity, thermal shock resistance, and resistance against corrosion.

In the production of dry cells and storage cells, graphite powder is mixed with the active mass to increase the electrical conductivity. The conductivity of natural graphite powder is also used in plastics (against static charge buildup), explosives (against ignition by friction), and conductive lacquers.

Natural graphite is also used as a lubricant. Fine-grained graphite powders often having a particle size less than 1 μm are suspended in liquid carrier media, such as oils, greases, alcohols, or water. Most self-lubricating bearings and packings contain natural graphite as a lubricant; pencils function through the gliding and lubrication of their graphite component. Other applications that use these properties are the smoothing of the surface of molds to facilitate the removal of castings after cooling, blackwashes, and additives decreasing the friction during the compaction of powders.

Natural graphite is also used for carburization, deoxidation, and the covering of metal melts. Plastics, ceramics, porcelain, and concrete are colored with graphite, particularly with microcrystalline grades, and it also serves as a pigment in temperature-resistant paints. Well-crystallized flake graphites are a precursor for graphite intercalation compounds, expanded graphite, and graphite foils (see Secs. 2.4.4 and 2.4.5).

Purified flake graphite has been proposed as a moderator and reflector material for nuclear fission reactors. To some extent, natural graphite is used for the production of fuel elements for high-temperature nuclear reactors.

The world production of natural graphite amounts to about 500×10^3 t. The most important countries mining graphite are the following:

- flaky graphite grades: USSR, China, Malagasy, Sri Lanka, Germany, and Norway;
- earthy graphite grades: Korea, Mexico, and Austria.

2.3 Artificial Graphite and Carbon with Layered Structure

2.3.1 Structure and Pyrolysis. Artificial graphite is produced by heating carbon compounds or carbon powder to 2500–3000 °C. By this treatment the structural order is increased, depending on the structure of the precursor materials. One distinguishes between soft (or graphitizing) carbons and hard (or nongraphitizing) carbons by the fact that the preordering of the first type is distinctly better than that of the second. Examples of the two types are petroleum coke and charcoal, respectively. Usually, solid carbon material heated above ca. 2500 °C is designated as an artificial graphite, irrespective of its real crystal structure. Other methods for the production of artificial graphite are CVD (chemical vapor deposition) processes or the condensation of carbon vapor (pyrographite), crystallization of carbon melts at pressures above 15 MPa, precipitation from oversaturated metal melts (kish graphite), the decomposition of carbide crystals, and nitrogenation of calcium carbide, as well as the electrolytic decomposition of carbonate melts. All these processes are economically less significant than thermal graphitization.

All carbon-containing materials are, in principle, suited as a raw material for the production of carbon and graphite. In the first step, the raw material is decomposed by pyrolysis, and in the second step, the intermediate carbon product is graphitized by further heat treatment. During pyrolysis, the intermediate material may be solid, liquid, or gaseous; it is obvious that the mobility of the molecules determines the degree of microstructural ordering.

It is, therefore, customary to distinguish between solid-, liquid-, and gas-phase pyrolysis, although transitions between the pure reaction types exist. Examples of *solid-phase pyrolysis* are chars and vitreous or glassy carbon. Because of the structural disorder and the small average crystal size of their precursors, the ability to transform these materials into highly ordered graphitic structures is low. The precursor material of carbon fibers, e.g., thermally stabilized polyacrylonitrile or pitch, also does not melt during pyrolysis, but an ordered microstructure is achieved by stretching the fibrous material below the pyrolysis temperature and preserving this degree of order by the above-mentioned stabilization treatment.

An example of *liquid-phase pyrolysis* is petroleum coke, which is the most important raw material for the manufacture of carbon and graphite products. Brooks and Taylor (1968) first discovered the formation of optically anisotropic spherulites (*mesophase*) during the pyrolysis of petroleum pitch, coal tar pitch, and softening coal. During heat treatment, pitch gradually forms an isotropic melt and develops small spherulites. The spherulites are nematic liquid crystals composed of large lamellar aromatic molecules. The isotropic phase is finally exhausted, and the spherulites touch each other and coalesce. Formation and structure of mesophase are essentially governed by three limiting conditions:

1. The shape of primary molecules must favor the formation of liquid crystals;
2. the system must have sufficient fluidity;
3. the reaction or condensation rate must be smaller than the ordering rate.

Other factors influencing the structure of the mesophase that eminently affects structure and properties of coke materials are the amount of nonmelting constituents and/or impurities (Marsh and Walker, 1979).

The chemistry of the pyrolytic conversion of hydrocarbon compounds to solid carbon involves numerous chemical reactions. Generalized schemes have been developed by studying simpler models (Fitzer, Müller, and Schäfer, 1971). The major reactions involved are

1. bond cleavage and formation of free radicals,
2. molecular rearrangement,
3. thermal polymerization,
4. aromatic condensation, and
5. elimination of side chains and hydrogen.

A general scheme is shown in Fig. 6. Through the formation of volatile products during pyrolysis and structural transformation, pores and shrinkage cracks are generally developed. Carbon must be heated to ca. 3000 °C to be transformed into graphite. The degree of graphitization, which is an indication for a perfect graphite crystal, the spatial distribution of the crystallites, and the amount and distribution of porosity determine the properties of the

final product. Lattice disorder as well as porosity can be reduced by high-pressure treatment at temperatures above 2500 °C.

Gas-phase pyrolysis is characterized by thermal cracking of gaseous hydrocarbon compounds and deposition of carbon on a substrate. Examples are pyrocarbon (see Sec. 2.4.3), carbon films, and carbon black. Stress annealing of pyrocarbon at high temperature yields nearly perfect graphite crystals.

2.3.2 Carbon and Graphite Artifacts

2.3.2.1 Manufacture. Most methods for the manufacture of carbon artifacts consist of a two-stage process. In the first step, raw materials, especially coke, are produced by pyrolysis of carbon-containing substances, e.g., pitches and coals. In the second step, the coke, together with a binder, is processed to carbon in a manner similar to the manufacture of ceramic materials. The carbon can be transformed into graphite by subsequent heat treatment (Ishikawa and Nagaoki, 1984; Blackman, 1970).

Petroleum coke, pitch coke, metallurgical coke, anthracite, and carbon black are commonly used as raw materials. Coal tar pitches are the most commonly used binder material; less common are petroleum pitches and resins. Mixtures of these materials are shaped by extrusion, vibration molding, die molding, or isostatic molding and are baked at temperatures of ca. 1000 °C in an inert or reducing atmosphere and may be graphitized by further heating to 3000 °C. The manufacturing process is shown in Fig. 7.

Raw Materials. The range of raw materials extends from well-ordered *natural graphites* and *needle cokes* with nearly completely two-dimensional ordered layer stacks to less-ordered materials such as chars and certain

types of *carbon blacks*. The properties of carbon and graphite products and their performance depend to a large extent on the properties of the raw material. Therefore the selection of raw materials is an important step in the manufacture of carbon and graphite.

The purpose of *binder materials* is to wet the surface of carbon grains, give mixtures of high plasticity when mixed with grains, and give high-yield carbon residue after pyrolysis. Coal tar pitches, the residues from the distillation of crude tar produced while coking bituminous coal, are most suited. Petroleum pitches processed from decant oils and aromatic extracts have also been proposed as binding and impregnating materials. Thermosetting resins are also reliable binders and impregnating agents, although their use is limited to the production of smaller carbon and graphite shapes because of higher costs. Phenolic and furan resins are frequently used.

Grinding and Sizing. The bulk density of carbon and graphite shapes depends on the porosity of the coke grains and the packing density of these grains (Mrozowski, 1956). These variables are controlled by crushing and grinding the coke and sizing the milled product. Large grains are generally used for the production of large shapes and smaller ones for small bodies. The maximum grain size is ca. 15–20 mm for large electrodes and less than 20 μm for spectroscopic carbon grades. The microstructure of the artifacts improves with decreasing grain size.

Mixing. Mixing is generally performed at temperatures at least 50 K above the softening temperature of the pitch binder. The proportion of the filler material and binder determines the fluidity of the mixture, which also depends on the grain size of the filler material and the forming procedure. The average binder content is about 15%–30%. A green mixture consists primarily of filler, binder, and some air bubbles.

Forming. Elongated shapes are usually formed by *extrusion*. The cross section may be circular, rectangular, or more complicated, e.g., for finned tubes. The cross section ranges from a few square millimeters (battery carbon, spectroscopic carbon) to nearly 1 m^2 (electric furnace electrode). The hot carbon mixture is charged into the cylindrical chamber (mud cylinder) of a conventional hydraulic press, evacuated, and compacted. The mixture is forced through a forming dye by an advancing ramhead or piston. The mud chamber is up to ca. 1.5 m in diameter and up to 3 m in length, and the pressing force up to 60 MN. Smaller bodies, as well as some of the anode blocks used in the electrolysis of aluminum, are frequently produced by *molding*. Because of the smaller amount of binder, the shrinkage of these bodies can be better controlled, and forming to the final size is possible ("press to size"). Pressures as high as 200 MPa (2 kbar) are necessary for compacting.

In *isostatic molding* the compacting forces are transmitted by a fluid acting equally from all directions. Accordingly, the density gradient is smaller and the uniformity of the pressed form is better. The dies (bags) consist of an elastomeric material, e.g., silicone rubber. They are usually evacuated during or after being filled with the pressing powder and are attached to the pressure tank (dry bag) or are freely removable (wet bag). The pressure tank is up to 1 m in diameter and more than 2.5 m in height. The pressure is up to 200 MPa (2 kbar). During compacting, all anisometric particles are aligned perpendicular to the direction of force, yielding a quasi-isotropic body.

During the last decade, *vibration compacting* has steadily increased, particularly for the production of carbon electrodes used for aluminum electrolysis and the production of other large shapes containing coarse-grained carbon. To achieve sufficient compaction, the pressing mixture must be loaded with top weights and then evacuated. The vibration frequency is ca. 1000–2000 cycles per minute. *Jar molding* and *tamping vibration molding* methods with a low frequency, but large amplitude, are used to form large-diameter carbon electrodes.

Other forming methods are less common. Carbon shapes with a high bulk density can be produced by explosion impact or by implosion into a mold. Spin molding is used especially for mixtures containing clay for the production of graphite crucibles.

Baking. In the baking process, the binder material of the shaped artifact is pyrolyzed, and a binder coke is formed that joins together any coke particles. Volatile products are generated, which must be removed from the carbon shape. The process is governed by the following steps:

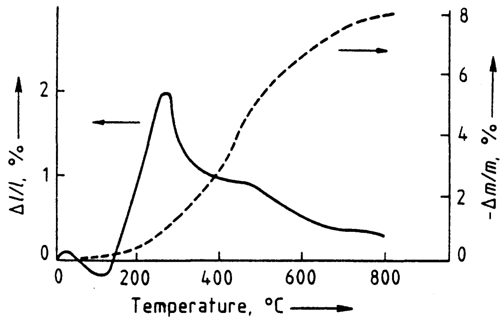

FIG. 8. Variation in length and mass of pitch-bonded carbon shapes during baking.

1. the heat transfer from the outside into the shape,
2. the pyrolysis reactions, and
3. the removal of volatile products from the shape

(Hüttinger, 1972). In addition to the mass loss, the shapes undergo complicated volume changes during baking that depend on the type and amount of the binder, the heating rate, and the volume of the body (Fig. 8). To prevent deformation and oxidation during baking the carbon shapes are enveloped by selected packing materials.

In general, all furnaces are suited for baking carbon bodies, provided the temperature is adjustable. Each furnace also must have devices for collecting and purifying the volatile pyrolysis products, e.g., electrostatic precipitators or incinerators. Most frequently *ring furnaces* are used, consisting of 10–30 identical brick chambers or pits being heated with oil or natural gas. A baking or heating cycle is shown in Fig. 9. Several types of *single-chamber furnaces* and *tunnel kilns* are also used for baking. The baking cycle time can be reduced by applying pressure during heat treatment (pressure baking).

Graphitization. Graphitization is the transformation of disordered carbon material into better-ordered graphitic structures; the heat treatment of carbon shapes at temperatures above ca. 2500 °C is referred to by this term. During this heat treatment, the average interlayer distance decreases, and the height and width (L_a and L_c, defined in the caption of Fig. 6) of the ordered areas increase. The attainable order or degree of graphitization depends on the structure of the precursor material. Structural ordering is a relatively rapid process (Fig. 10). All volume properties, such as bulk density, resistivity, strength, etc., depend not only on the maximum temperature, but also on the heating rate. The heating rate of larger specimens may be limited by insufficient thermal shock resistance. The actual rate is shown in Fig. 11. During heat treatment, the impurities within the artifacts react with the carbon to form carbides, which mostly decompose and vaporize at higher graphitizing temperatures. At temperatures of ca. 1600–1700 °C, the sulfur contained in the carbon bodies is promptly emitted, thereby increasing the body's volume (puffing). To avoid the formation of cracks, puffing must be reduced by adding inhibitors.

Graphitization is performed almost exclusively with Acheson and Castner furnaces. In both furnace types, the heating is accomplished by means of electric current passed through the bodies. Inductive and radiation heating is used only for the production of specialities.

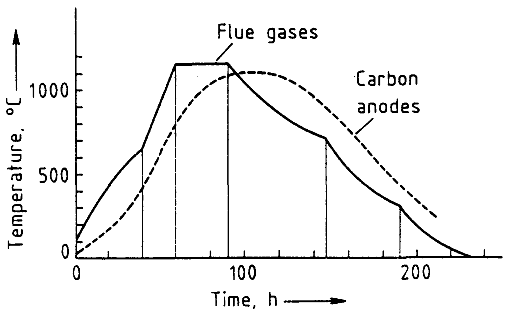

FIG. 9. Ring furnace heating cycle.

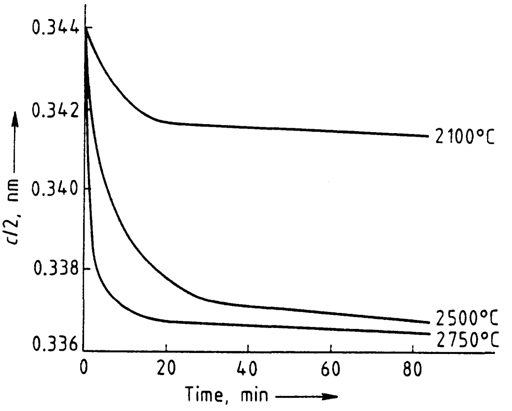

FIG. 10. Change of interlayer spacing during graphitization.

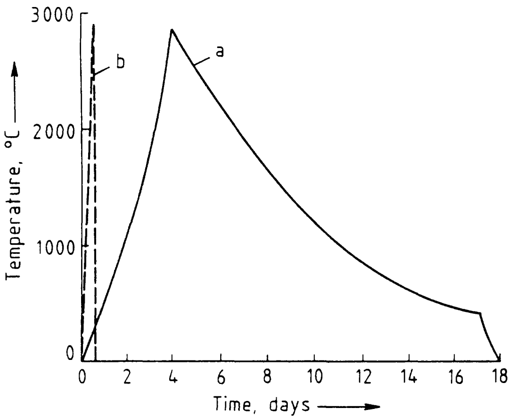

FIG. 11. Temperature cycles of (curve *a*) the Acheson furnace and (curve *b*) the Castner furnace.

The *Acheson furnace* consists of a horizontal bed of refractory materials, furnace heads carrying the current load to the furnace, and long sidewalls made of concrete blocks, steel sheets, or steel grids. The bottom is cooled by air and loaded with a layer of insulating materials, e.g., granular silicon carbide, metallurgical coke, sand, or sawdust. The same materials are used for insulating the sidewalls and the surface of the furnace. Carbon bodies that are to be graphitized are stacked between the furnace heads, usually horizontally and transversely to the flow of the electric current. The bodies are separated from each other and surrounded by a granular resistor medium, e.g., coke–graphite mixtures. The maximum capacity of Acheson furnaces is about 100 t, and the electric load 0.1–1 MW/t. The energy consumption of larger furnaces amounts to 3–4 kW h per kg graphite material.

Castner furnaces do not contain granular resistor materials. One or more carbon artifacts are clamped between head electrodes, these forming the path for the heating current (lengthwise or longitudinal graphitization). One or both ends of the column are subjected to a mechanical or hydraulic pressure device to maintain a tight connection during the heating cycle. Insulation is similar to that of the Acheson furnace. Much higher heating rates are possible, and heat losses are accordingly smaller. The heating time is less than 10 h, and the energy consumption is about 2–3 kWh per kg of graphite material.

Purification. Coke and binder materials used for the production of graphite artifacts contain various quantities of impurities that may prevent some applications. By thermal, thermochemical, and chemical purification the ash content can be decreased considerably, e.g., as low as 1 mg/kg for spectroscopic carbons.

Machining. Graphite is readily machinable. Lubricants or cutting fluids are not necessary. It can be sawed, turned, bored, drilled, planed, shaped, and milled. Surface roughness decreases in this sequence from ca. 25–125 to 1–6 μm. A fine-grained grade is always smoother as a result of the smaller pores revealed through cutting. The same machines are generally used as in metal working.

Impregnation and Surface Coating. About 25% of the volume of carbon or graphite artifacts consists of pores that are sometimes detrimental to the bulk properties. The pores may be filled at least partially or closed by impregnation with a solid material whereby strength, conductivity, and resistance against oxidation are improved. Pitch is the most frequently used impregnating agent. Graphite grades used at lower temperatures may be impregnated with curable resins, particularly phenol-aldehyde and furan resins. The tolerated application temperature of these grades is at the most ca. 200 °C. The pores of carbon and graphite bodies may also be filled with carbon formed by CVD processes. Coatings containing refractory materials, e.g., carbides, silicides, borides, or nitrides, protect carbon artifacts against oxidation. Coatings are brushed or sprayed onto the surface, and the deposited layer is sintered, or the coating is applied by flame or plasma spraying or CVD techniques.

2.3.2.2 Properties. Artificial graphite and carbon bodies differ more or less from the graphite single crystal. This difference is due to structural disorder, imperfect alignment of the crystallites, and porosity. Other parameters influencing the properties of graphite artifacts are the size and size distribution of the coke grains, the shape of the grains, the pore size distribution, the interaction between the components, and the content of impurities. Each parameter can be changed through the selection of raw materials and production methods. For instance, needle coke consists of highly ordered and aligned crystallites, regular petroleum coke is less ordered, and carbon-black products are not ordered at all.

Physical Properties. The variation of properties of carbon and graphite products is

Table 2. Properties of carbon and graphite products (with grain).

	Bulk density ($g\ cm^{-3}$)	Open porosity (%)	Young's modulus ($kN\ mm^{-2}$)	Flexural strength ($N\ mm^{-2}$)	Resistivity ($\Omega\ \mu m$)	Thermal conductivity ($W\ m^{-1}\ K^{-1}$)	Coefficient of thermal expansion ($10^{-6}\ K^{-1}$)
Carbon block for furnace linings	1.55	17	11	10	50	3	3.5

Carbon fiber (high modulus)	1.95	0	400	3000	1	>100	−1.0

illustrated in Table 2. The mechanical properties are similar to those of ceramic materials, whereas the thermal conductivity and electrical resistivity correspond to those of metals (Pacault, 1965).

The unique combination of refractory and metallic properties is useful for electrothermal and electrolytic processes performed at higher temperatures. In progressively loaded graphite artifacts, a rising number of noncritical microcracks is generated, propagating preferentially normal to the applied stress and causing relief of internal stress. The propagation of the cracks is restricted by pores or structural elements that are oriented transversely to the direction of propagation. When a critical crack length is reached through linking of microcracks, macrofailure will occur. The Weibull approach can be used to give a reasonable prediction of failure. The fracture toughness K_c of common graphite grades is about 1–15 MN/m$^{3/2}$ (Jenkins, 1974).

Graphite is a semimetal (see ELECTRONIC STRUCTURE OF SOLIDS) in which the highest filled valence band overlaps the lowest empty conduction band (Spain, 1973). There is no simple relationship between the conductivity of single graphite crystals and that of polygranular artifacts. The resistivity (with grain) of the latter is more than 20 times greater than that of a single crystal (in the *a* direction), and it decreases with temperature up to ca. 350 °C for graphite grades and up to ca. 1000 °C for carbon grades. The sign of the temperature coefficient of resistivity changes above these temperatures because increased scattering of the charge carriers compensates their rising number in the conduction band. The thermal conductivity of carbon and graphite artifacts is determined by phonon scattering at the crystal boundaries. Conductivity is at its maximum at about room temperature. More informative for users of carbon and graphite artifacts may be the change of these properties with the temperature. Strength and Young's modulus of graphite artifacts reach maxima at temperatures of ca. 2500 °C, where they are 50%–100% larger than at room temperature. Above 1400 °C, the specific strength (strength/density) of graphite is better than that of metals and most other refractory materials. The coefficient of emissivity amounts to 0.8–0.9.

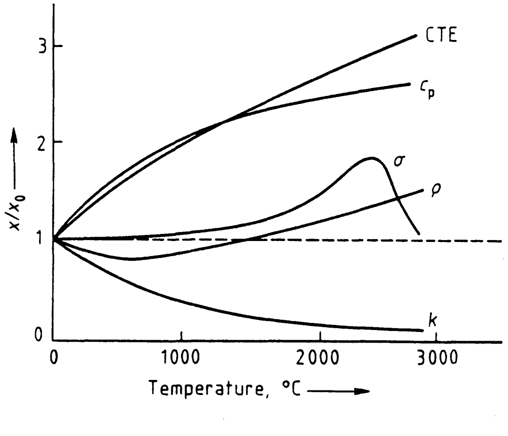

FIG. 12. Relative properties of polygranular graphite grades vs temperature (schematic). CTE, coefficient of thermal expansion; c_p, specific heat capacity; σ, tensile strength; k, thermal conductivity; ρ, electrical resistivity.

Table 3. Average thermal-stress-resistance factor R' (W/m). $R' = k\sigma/(1-\mu)E\alpha$, where k=thermal conductivity, μ=Poisson's number, E=Young's modulus, α=coefficient of thermal expansion, and σ=tensile strength.

Graphite	50 000
Titanium carbide	1 000
Magnesia	50
Alumina	1

The temperature dependence of strength and several other properties is illustrated in Fig. 12. Types used at high temperatures are often exposed to sudden temperature changes or large temperature gradients, both including mechanical stresses. Table 3 shows the favorable thermal-stress-resistance factor R' of graphite compared to that of several refractory materials.

Chemical Properties. Carbon and graphite products are resistant to most corrosive substances, except strong oxidants, substances forming intercalation compounds, and carbide-forming substances. At higher temperatures, graphite is, in fact, less reactive to oxygen than most metals. But since the reaction products CO_2 and CO are volatile, no protective oxide film can be formed. The reactivity depends primarily on the degree of crystalline order. At lower temperatures, the reaction is not limited to the outer surface of the artifact but includes practically the entire inner surface, because of pore diffusion. With increasing temperature, the depth of the reaction zone decreases. In air, the average loss of small graphite artifacts in the temperature range between 500 and 600 °C is ca. 1% per day. Impurities such as alkali metals, vanadium, and lead accelerate the reaction rate considerably. The burn-off may be decreased by impermeable protective coatings, e.g., carbides or silicides, or by the addition of substances which inhibit oxidation.

2.3.2.3 Applications. *Electrodes for Arc Furnaces.* About 90% of graphite products are electrodes used for the production of electric arc furnace steel. Graphite electrodes up to 700 mm in diameter consist of cylindrical sections up to 2700 mm in length, which are joined with tapered, threaded nipples. The electrical load is up to 30 A/cm^2, and the surface temperature increases along the length of the electrode up to 2300–2800 °C (Weng and Seldin, 1972).

Electrodes for Electrothermal Reduction Furnaces. Electrothermal reduction furnaces are used for the production of calcium carbide, ferroalloys, phosphorus, silicon, and refractory oxides. Because of the relatively low current density of ca. 6–10 A/cm^2, adequate results can be achieved with carbon electrodes, particularly Söderberg electrodes (selfbaking electrodes). Söderberg electrodes consist of a sheet metal casing that is filled with a pasty mixture of electrode raw materials. The lower part of the electrode is baked by the excess furnace heat. Because of their higher electric conductivity, semigraphite electrodes are used, especially for the production of silicon.

Electrodes for Molten Salt Electrolysis. Carbon anodes and cathodes are used for the electrolytic production of aluminum. The anodes are partially submerged into a cryolite melt containing several percent of alumina. During electrolysis, the anodically produced oxygen reacts with the anode material and CO and CO_2 are formed. The ratio CO_2:CO determines the current efficiency. Because of the operation temperature of 950–970 °C, the parts of the anode extending out of the melt are attacked by oxygen in the air. Consumption greatly depends on the properties of the carbon anodes, especially their permeability and reactivity (Keller and Fischer, 1981). The average consumption of carbon anodes is ca. 0.47 kg per kg of Al (theoretically 0.33 kg per kg of Al). Current supply rods are connected to the anode by carbon-containing cements or metal solders. The edge length of the anodes is up to 1500 mm.

The bottom and sidewalls of the Héroult–Hall cells, which protect the pot and the ceramic insulation against the cryolite melt, also consist of carbon material. Carbon blocks that form the bottom have longitudinal grooves in which cathodic bus bars are inserted. For the winning of alkali, alkaline-earth, and rare-earth metals and fluorine, graphite anodes are used.

Electrodes for Aqueous Electrolysis. During the past several years, titanium anodes have been increasingly substituted for graphite anodes. Accordingly the use of graphite anodes for chlorine, chlorate, and hydrochloric acid electrolysis, for the production of manganese dioxide and hydrogen peroxide, for electrolytic pickling and polishing processes, and for protection against cathodic corrosion is decreasing.

Linings, Casting Molds. Because of their temperature resistance and their resistance to most metal melts and slags, carbon and graphite blocks are widely used as a lining for metallurgical furnaces. For use in blast furnaces, resistance to alkali attack and wear is required. For each refractory material, a critical temperature, which must not be exceeded during furnace operation, has been defined. To obtain sufficient lifetime from the lining carbon, grades with high critical temperature should be used (refractory approach), or the cooling of the lining must be increased by using semigraphite or graphite grades (thermal approach) (Herron and Beechan, 1981).

Because of its thermal conductivity, thermal shock resistance, and low wettability by molten metals and slags—the wetting angle for most metals is 120°–140°—graphite is an outstanding material for foundry molds, ingot molds, and crucibles for the casting of aluminum, magnesium, iron, steel, copper, brass, bronze, and other metals. Continuous casting devices for steel generally consist of materials containing natural graphite and corundum. For nonferrous metals, high-density and high-strength graphite grades are used. Railway wheels are die cast in graphite dies. Graphite molds can even be applied for precision casting.

Graphite is also used for the production of cemented carbide and diamond tools, such as die, boat, crucible, and auxiliary devices for the production of semiconductor materials, and for the refining of metal by feeding gases into the melt. Graphite rods, tubes, or slotted hollow cylinders have a uniform resistance and are preferred as heating elements. Graphite heating elements must be used in an inert atmosphere or under vacuum, keeping in mind that the vapor pressure of carbon is 0.5 kPa at 3000 °C.

Process Equipment. One outstanding property of carbon and graphite is their resistance to corrosion. Graphite also has a relatively high thermal conductivity. For use as heat exchangers and chemical equipment, permeability is considerably reduced by impregnation, especially with thermosetting resins. The permeability of impermeable graphite grades is less than 10^{-6} cm^2/s. The temperature at which it can be used is, of course, restricted by the decomposition temperature of the resins, but the limit of 200 °C is adequate for most chemical processes. Examples of impervious carbon and graphite grades are absorbers, columns, heat exchangers, pumps, valves, pipes, fittings, towers, tower packings, and rupture disks.

Nuclear Reactors. Carbon has a low absorption cross section for thermal neutrons and a favorable moderation coefficient. Since Fermi's Chicago pile reactor, graphite has been used successfully as a moderator and reflector material for gas-cooled reactors. The operation temperature is limited by the nature of the cooling media and is far lower for CO_2-cooled Magnox reactors than for helium-cooled high-temperature reactors (HTR). The neutron absorption cross section is particularly affected by such impurities as boron and rare-earth metals, which are reduced by purification. During neutron irradiation, graphite undergoes remarkable dimensional changes, which depend on structural disorder and the coefficient of anisotropy. The degree of damage can be considerably reduced through selection of raw materials and processing conditions (Nightingale, 1962; Delle *et al.*, 1983). The dimensional changes of the structural elements of graphite during the lifetime of an HTR are now small enough to be compensated by structural design.

Mechanical Engineering Applications. The self-lubricating characteristic of carbon is a fundamental property. The coefficient of static friction is 0.1–0.25 at normal humidity. Carbon and graphite are, therefore, widely used as mechanical seals and bearings if the use of lubricants is not possible because of contamination (food), contact by aggressive substances (chemical industry), or operation at high temperatures. Examples are radial and axial bearings and bushings, seal rings, and vanes.

Miscellaneous Electrical Applications. Carbon and graphite are classical materials for electric contacts and electrodes. Arc-light carbons had a comparatively short history as a street illuminant. They are now almost exclusively used in film projectors and as arc cutting and welding rods. Welding carbons are preferred for spot-welding sheet metal.

For spectroscopic emission analysis, the sample is vaporized and the atoms are excited in an arc between two carbon electrodes. These electrodes tolerate only little contamination, which is also true for crucibles and boats used in atomic absorption spectroscopy. Graphite tool electrodes are juxtaposed with a workpiece in an electric-discharge machine (EDM), both immersed in a dielectric liquid. The workpiece is eroded by a series of electric pulses. The size of EDM electrodes, which can be easily machined, ranges between a few millimeters and more than 1 m.

Graphite electrodes are also used as anodes for mercury-vapor rectifiers and power tubes. Sparking can be avoided if the electrode consists of high-density graphite grades that were heat treated under vacuum at temperatures above 2000 °C. Graphite grids for high-power electron tubes improve the power handling capacity.

Carbon is applied to various types of primary batteries (battery carbon) and fuel cells. Carbon acts as a corrosion-resistant conductor, as an electrocatalyst in air-consuming electrodes, as a catalyst carrier, and as an intercalate-forming active mass (Watanabe *et al.*, 1988). In Leclanché cells, the carbon rod is surrounded by a depolarizing mixture containing MnO_2 and graphite powder or carbon black. The rod is often impregnated with waxes or fats to prevent evaporation of the electrolyte and permit the diffusion of gases. Leakproof cells are provided with additional seals.

Stacked carbon plates or disks are used as pressure-sensitive pile resistors. Examples are voltage regulators for sewing machines and illumination equipment. The high contact resistance of carbon granules, their invariability against atmospheric conditions, and the reproducibility of the resistance–pressure curve make carbon granules a satisfactory material for microphones.

Carbon and graphite are important materials for use as electrical contacts (Holm, 1967). Carbon contacts have an excellent arcing resistivity; they neither weld nor form insulating oxide films. Examples of stationary contacts are switches and circuit breakers for sliding contacts, as well as brushes and current collectors for trolley shoes and wheels. Pantograph shoes are sliding contacts that transfer electric energy from a wire or rail to a moving device (vehicle). Carbon shoes do not wear out trolley cables, wear slowly, have adequate resistance to impact, and cause little radio interference. The shoes are adjusted to special pantographs that maintain nearly constant contact pressure. Examples are electric locomotives (engines), tramways, trolley buses, and mobile cranes.

In most electric motors and generators, the revolving part of the machine and the stationary part are electrically connected by brushes. Brushes must be able to "absorb" the roughness of the commutator or slip ring surface, control film formation on the metallic counterpart, and absorb current pulses that result during current reversal (commutation) (Shobert, 1965).

2.4 Monogranular Carbon and Graphite Products

Carbon and graphite products described in Sec. 2.3 consist of an agglomeration of single carbon particles and can be regarded as a polygranular structure. During recent years, industrially important products have been manufactured from essentially monogranular carbon materials (Fitzer, 1980).

2.4.1 Carbon Fibers. Carbon fiber materials are produced and used as yarns, short filaments, fabrics, or felt. The commercial production of the fibrous materials is based on the carbonization of polymer fiber precursors, in the course of which the fiber form has to be preserved. Therefore thermoplastic fibers have to be converted into a nonmeltable intermediate before carbonization. With this stabilization process additional cross-links are formed, and linear polymers are converted into ladder polymers.

The most important precursor materials for the production of carbon fibers are polyacrylonitrile (PAN) fibers and pitch fibers, particularly fibers converted into mesophase pitch (MPP) before spinning; isotropic pitch fibers are also used, especially for low-end applications. Cellulosic materials (rayon fibers) are used less frequently.

PAN and pitch fibers are first heated up to about 300 °C—generally under tension, in order to avoid shrinkage—and then contacted with cyclization agents, e.g., oxygen. By this treatment, cyclization of the thermoplastic chains to naphthydrine ring systems occurs, and conjugated double bonds are formed by dehydrogenation. The resulting stabilized intermediate preserves the original fiber structure, is infusible, and can be pyrolyzed analogously to polygranular carbon grades (Jenkins and Kawamura, 1976; Fitzer and Heine, 1986).

The properties of the carbon fibers and their behavior depend strongly on the type of precursor and its degree of orientation along the fiber axis. Carbon fibers are outstanding in stiffness and strength. Their stiffness is based on the high C–C bonding energy within the aromatic ring systems ($\sim$600 kJ/mol), whence the maximum preferred orientation in direction of the fiber axis yields the highest stiffness. Typical mechanical properties of the most important commercial PAN- and pitch-based carbon fibers are given in Table 4. With MPP-based fibers Young's moduli even up to 800 kN/mm^2 can be achieved, i.e., 80% of the theoretical C–C bonding strength.

Because of their superior stiffness, combined with high strength and low weight, carbon fibers are predominantly used as reinforcement of duroplasts and thermoplasts in the production of so-called advanced or high-performance composites. *Carbon-fiber-reinforced plastics* (CFRP) are superior to metals and other composite materials (*q.v.*), especially in respect to the specific-strength data (related to the low weight). Therefore high-tech applications such as aerospace and aircraft structural materials give the highest technical and economic benefit. Other application fields are sports goods, engine parts, and the automotive industry, a very promising field for the future.

Carbon fibers are also used for the reinforcement of carbon matrices. These *carbon-fiber-reinforced carbon shapes* (C/C composites) combine the unique high temperature resistance of polygranular carbon with the

Table 4. Mechanical properties of commercial carbon fibers.

	Density (g/cm^3)	Tensile strength (kN/mm^2)	Young's modulus (kN/mm^2)	Breaking strain (%)
Pan-based				
HT (high strength)	1.75	1.95	1.95	1.60
HM (high modulus)	3	2	2	1
Pitch-based				
Anisotropic MPP (mesophase based)	200	400	400	70
Isotropic	1.5	0.6	0.8	3.5

superior strength of carbon fibers: high-tech fiber ceramics with high tensile strength (100–200 N/mm^2) and fracture toughness ($K_c = 20$–$30\ MN/m^{3/2}$). Important applications are aerospace structures, nozzles, aircraft brake disks, high-temperature insulation, linings, and heating elements. To a lesser extent carbon fibers are also used as reinforcement of metals and ceramics. Because of the superiority of the carbon fibers, the demand is increasing rapidly.

2.4.2 Glassy Carbon. Glassy carbon is formed by pyrolysis of thermosetting resins, e.g., phenol, furan, polyimide, and polyphenylene resins (Jenkins and Kawamura, 1976). Glassy carbon is impermeable to liquids and gases and its fracture exhibits glossy shell-like planes. The highly disordered structure consists of a network of branched and twisted ribbons and microfibrils, which are interconnected at several points, with an average height and length of ca. 3 and 10 nm, respectively. The ribbons surround micropores of 5–10 nm diameter.

Because of its cross-linked microstructure, glassy carbon is isotropic and stronger and harder than polygranular carbon grades. The oxidation rate is considerably lower, since the pores are not accessible to reagents. These properties are advantageous for laboratory equipment, e.g., crucibles, boats, bowls, trays, electrodes for electroanalysis, and tubes for evaporation and smelting, as well as for the decomposition of materials for chemical and spectroscopic analysis. Resistance-heated tubes are used in atomic absorption spectroscopy, molds for glass forming, electrodes for organic electrochemical synthesis, and other shapes for numerous other uses. Because of its compatibility with human tissue, glassy carbon has also been successfully used for implants, e.g., bile ducts, and as stimulating electrodes for cardiac pacemakers.

2.4.3 Pyrocarbon and Pyrographite. Pyrocarbon and pyrographite are products of the decomposition of gaseous carbon-containing compounds, a process known as chemical vapor deposition (CVD) (*q.v.*). Parameters influencing this process are the type and concentration of the carbon donor, the temperature of pyrolysis, contact time, and gas flow (Bokros, 1969). Hydrocarbon compounds are favored as reaction gases, especially methane, propane, and propylene. At low temperature and low concentration, the deposited pyrocarbon layers have a laminar structure. At high concentration and a low temperature gradient, the gas is supersaturated and optically isotropic layers are formed. High temperature and low partial pressure promotes the formation of granular and columnar microstructures. The pyrocarbon is deposited on substrates that have the contour of the desired final body. The deposition rate is 10–2000 $\mu m/h$. The bulk density depends primarily on the deposition temperature; it is lowest at temperatures of ca. 1400 °C (1.3 g/cm^3) and increases to 2.23 g/cm^3 at 2700 °C. Through structural variation, it is possible to adjust the coefficient of thermal expansion of the layer to that of the substrate, thereby minimizing stresses caused by temperature gradients.

Highly oriented pyrographite (HOPG) is obtained by thermal or stress annealing of pyrolytic carbons (Moore, 1973). This process decreases the proportion of disordered layers considerably. Interlayer spacing, which is the distance between the single graphite layer planes, can be as low as 0.3354 nm. Accordingly, the properties of this type of pyrographite are similar to a single graphite crystal. HOPG plates are used as flat and bent x-ray monochromators, as neutron monochromators, and for the polarization of high-energy photons. Nuclear fuel particles for high-temperature nuclear reactors are coated with less-ordered pyrolytic carbons impermeable to fission products at high operating temperatures (coated particles) (Delle *et al.*, 1979). The carbon is deposited in a fluid bed, and the deposition conditions are altered so that the coating consists of several layers differing in microstructure and properties.

2.4.4 Graphite Intercalation Compounds. At relatively low temperatures, graphite forms intercalation compounds (*q.v.*) with numerous substances. Graphite oxide with the ideal formula $C_8O_2(OH)_2$ was the first compound investigated. The following rules are valid for these intercalation compounds:

1. Only highly ordered graphite or graphitizable materials yield homogeneous intercalation compounds;
2. the atomic arrangement within the carbon layers is preserved;
3. the intercalated substance is regularly distributed between the carbon layers; and
4. most compounds can be reconverted into graphite.

The reagents capable of intercalation with graphite can be divided into two classes: electron donors (alkali metals, alkaline-earth metals, lanthanides, metal compounds containing hydrogen or polar molecules, and aromatic compounds) and electron acceptors (halogens, halides, oxyhalides, and acids). The number of electrons in the conduction band changes accordingly, eventually reducing the electrical resistivity considerably. Because of reagent penetration, the graphite crystal swells in the *c* direction and the identity period *I*, the height of the repeat unit in the layer sequence (in nanometers), changes according to $I_n = d_i + (n - 1)0.3354$, where 0.3354 nm is the interlayer spacing of graphite, d_i is the period of a first-stage intercalation compound, and n is the stage number. "First-stage" compound implies that all intervals between the carbon layers are occupied. In a second-stage compound, each intercalated layer is separated by two carbon layers, etc. A defined sublattice is associated with each stage conserving the tridimensional structure (Ubbelohde and Lewis, 1960; Hérold, 1979).

Graphite intercalation compounds have only limited stability. Compounds containing electron donors are easily oxidized when exposed to air—some are even pyrophoric—and compounds containing electron acceptors decompose easily or are strongly hygroscopic. The use of graphite intercalation compounds is, therefore, very limited. This is not true for graphite fluoride, CF_x, since this compound is adequately stabilized by the formation of sp^3 bonds.

The proposed application of graphite intercalation compounds as low-resistance conductors has especially been studied with SbF_5 and $SbCl_5$ intercalants (Wu and Vogel, 1982). At room temperature, the electrical resistivity is as low as 3×10^{-8} Ω m, and perhaps even lower.

2.4.5 Graphite Foils. Highly ordered graphite flakes with stack heights of at least 75 nm are used as a raw material. The precursor flakes are usually treated with an oxidizing agent, e.g., mixtures of sulfuric acid and nitric acid at ca. 100 °C. After the graphite intercalation compound is formed—in this example graphite hydrogen sulfate—the particles are thoroughly rinsed with water and then rapidly heated to ca. 1000 °C. The gas pressure of the vaporized and trapped intercalants partially contributes to the exfoliation of the stacked layers. The exfoliated particles (expanded graphite) can be molded to sheets, laminates, and other useful shapes in the absence of a binder. During compression, the particles interlock and form nonrigid bonds.

Properties. The large coefficient of anisotropy is due to the nearly complete alignment of the layer planes perpendicular to the compression force. Sheets are good thermal and electrical conductors parallel to the surface, and semiconductors in perpendicular planes. Graphite foils have considerable flexibility; they can, for example, be wrapped around cylinders. Like other graphite grades, graphite foils are resistant to temperature, aging, and most corrosive media. Graphite foils have a smooth surface, they are impermeable to fluids, under most conditions they are resistant to wear, and the coefficient of friction is about 0.08–0.1. They are not wetted by melts of glass, ceramic, or metal.

Applications. Flexible graphite is an extraordinarily good packing and sealing material, suited to replace asbestos. Examples are cylinder-head gaskets reinforced with metallic inserts and stuffing box seals consisting of flexible graphite tapes wrapped around the shaft of a pump or valve. Preshaped lamellar rings are used as gaskets, e.g., for exhaust system piping. Other applications are linings, blackwash, and heat shields often in combination with carbon felt sheets.

INTRODUCTION

This article provides an overview of cartography, the art and science of maps and mapping. It also reviews geographic information systems (GISs), a "new cartography" that has developed over the last three decades from cartography as well as from other disciplines.

Definition of cartography. The British Cartographic Society has proposed two definitions of cartography (Harley, 1989, p. 2):

"Cartography is the art, science and technology of making maps."

"Cartography is the science and technology of analyzing and interpreting geographic relationships, and communicating the results by means of maps."

They state that the former is "for use in communication with the general public," whereas the latter is for professional or practicing cartographers. Harley (1989) has spoken strongly against such a dichotomy, which even if accepted begs the question for audiences of researchers and practitioners from other disciplines and professions, such as the majority of readers of this encyclopedia.

Since cartography is a rather technical term, it is reasonable for its practitioners and their associates to provide definitions. But

note that the word "map," which is an essential component of both of the above definitions, is not defined. As might be expected, cartographers have at times attempted to redefine the term "map" to fit their technical needs. However, "map" seems to be a basic-level word in the English language, and its definition really lies with the native speakers of that language [see the works of Rosch (1973, 1978) and of Lakoff (1987) for a discussion of "basic-level" terms and concepts].

Recently, Vasiliev and others (1990) have examined the meaning of "map" using the conceptual framework of radial categories (see Lakoff, 1987). Data gathered by Vasiliev and her co-authors suggests that the prototypical map is presented on a flat or folded piece of paper, and depicts part of the Earth's surface. Features of the Earth are represented on the map by symbols that have been crafted by a human operator, and the map bears a scale, a north arrow, and a legend. Almost any English-speaking observer will consider such a thing to be a map. Other maps and maplike things are related to such a prototypical map by departures of various kinds. For example, a globe does not have the flatness property, and so a few subjects consider that globes are not maps. An image on a computer screen may be judged less of a map because it is not on paper, and has been termed a "virtual map" because it does not have a "permanent tangible reality" (Moellering, 1984), whereas prototypical maps do. At a greater distance from the prototype, most people do not consider a printed verbal script of how to get from one place to another to be a map; likewise, a digital data file containing coordinates from which a graphic map could be plotted is not a map to most people. However, they certainly have some similarities to maps, and some academics consider them to be maps. Much closer to the border between maps and non-maps are air photographs and satellite images. Since they are not crafted, selected, and drafted, some people do not consider them to be maps, whereas others do. Such maplike forms are treated elsewhere in the *Encyclopedia*. The first part of this article will concentrate primarily on prototypical maps.

Over the last century or two, cartography has diverged in a number of ways. Two fundamentally different types of maps are *reference* maps, which attempt to portray concrete, measurable features of the Earth's surface as accurately as possible, and *thematic* maps, which portray georeferenced data, often rather abstract, in a way that allows people to comprehend patterns and distributions. These kinds of maps are sufficiently different that they will be treated in separate sections below.

Maps have traditionally fulfilled at least three roles. First, maps were used as a sort of analog data base, as a device for cataloging geographic information, for storing information about relative locations of things. A second function, related to the first, is to support navigation and wayfinding; one can speculate that the very first maps were drawings in the sand or mud, intended to guide others to sources of water, other resources, or danger. And thirdly, maps have served as what would now be called visualization aids, helping map users to grasp spatial patterns and to make conjectures about spatial relationships and processes.

Technological change in the second half of the twentieth century has led to a change in the role of maps. Computers will in the future dominate in the area of spatial data storage; geographic information systems (GISs) have this as a central part of their utility. And on-board microcomputers already dominate in aircraft navigation, and can be expected to play an increasing role in vehicle navigation for automobiles as well. Thus, as cartography and GIS diverge, cartography's chief role may well be as a visualization aid.

Geographic Information Systems. Geographic information systems represent an important area of computer technology that is strongly related to cartography and mapping. Currently, a geographic information system is usually defined to be a computer system for the storage, retrieval, manipulation, and display of geographic data. But technically, such a definition would include all computer mapping software. Experts seem to agree that the essence of GISs is the ability to conduct simple analyses, especially the logical (Boolean) overlay of two or more spatial distributions. Integration of analytical techniques into a GIS framework is an important element in the research agenda for geographic information systems. But, even if cartography is narrowly defined, graphic map display is a common form of GIS output, and so the links to cartography are inescapable. Furthermore, one of the several roots, or academic "ancestors," of GISs is the computer-assisted cartography that developed in the 1950s and 1960s.

Relation to Academic Disciplines. Cartography as a profession stands in its own right. However, cartography is rarely seen as an academic discipline, in the form of a "Department of Cartography" at a college or university. Part of the essence of maps is their depiction of geographic phenomena and their distributions and locations; part of their essence is their graphic representation *per se*; and part of the essence of many maps is their relation to precise measurements and plotting of geographic objects. Thus it is not surprising that cartography finds a home in several disciplines. In the United States, Canada, and many other countries, most cartographers are found, and trained, in geography departments. However, there are cartography programs in surveying engineering, civil engineering, geodetic sciences, and other fields. In many other countries, a place in the engineering sciences dominates, and cartography and related courses are even found in computer science departments.

The closely related field of GISs is becoming a fundamental research tool in many disciplines, especially in the natural sciences. And despite the fact that most GIS courses are taught within geography departments, GIS is being taught in many academic settings, including those mentioned above, as well as geology and earth sciences, landscape architecture, environmental sciences, forestry, and many others. This trend toward disciplinary diversification of GIS training and research can be expected to increase, especially in academic institutions without geography departments.

1. CARTOGRAPHY

1.1 History of Cartography

Maps have been used by human beings for a very long time. Perhaps the oldest known map to have survived to the present day is one from central Italy that is believed to have been made about 5000 B.C. (Abler, Adams, and Gould, 1971, p. xix). The map was carved on a large rock overlooking a neolithic village. Thrower (1972) showed maps on clay tablets, dating from Mesopotamia, about 2500 B.C. This is about the same time and place as that from which earliest written versions of human natural language survive, but this probably does not indicate a simultaneous development of written language and of mapping. Rather, it suggests that when clay tablets were developed as a new technology for the representation and storage of information, that technology was used to represent both linguistic and graphic information. Similarly, the printing press was used for mass production of printed maps very soon after its use for text.

Geographical knowledge blossomed in ancient Greek times, and probably was accompanied by maps. However, few maps from that period have survived. One noteworthy accomplishment of the period was the first accurate estimate of the size of the Earth, made by Eratosthenes around 250 B.C.; Eratosthenes used the difference in the angle between the noonday sun at two sites of known distance apart to estimate the circumference of the Earth to within about 1%. But later, Europe lagged behind in cartographic development. Relatively modern-looking reference maps were produced in China around 1100 A.D., and the first known paper map was made in China around 1155 A.D., some three centuries before paper maps were made in Europe (see Fig. 1). Geographically accurate maps were also being made in the Arabic world at this time. In contrast, European maps of this period were as much cosmographic statements, typically centered on Jerusalem and with east at the top, as they were attempts to accurately portray known geographic facts (see Fig. 2). From ancient Greek times until the Renaissance, the cardinal directions and latitude could be determined in clear weather from the observation of the sun and stars; however, in cloudy conditions, only "dead reckoning" was available before the widespread adoption of the magnetic compass.

Between 1300 and 1600 A.D., European cartography developed rapidly, in conjunction with the great navigators of Spain, Portugal, England, and other European cultures. Mercator's world map projection, published in 1569, was a landmark in the refinement of rules for transforming locations from the globe to the plane (see Sec. 1.2). Many of the innovations that began what we might call "modern" cartography were in fact developed by someone who would commonly be considered to be a physicist and astronomer: Ed-

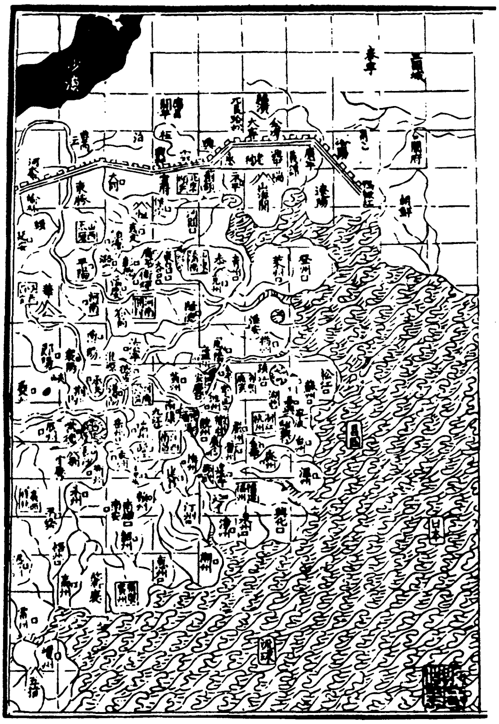

FIG. 1. Atlas map of eastern China, showing part of the Gobi (solid black area), the Great Wall, and the China Sea.

mund Halley, who worked with Isaac Newton in the late 17th and early 18th centuries in England. Halley's work at the Greenwich observatory included applied work for the British Navy. Within this context, Halley produced a generalized map of world wind patterns (1686) (Fig. 3) and another generalized world map of the divergence between magnetic compasses and true north (1701) (see Fig. 4) (Thrower, 1972, pp. 65–68). The wind map is generally considered to be the first meteorological chart, and perhaps also the first thematic map; the magnetic map, using isogones, is the first known published use of isolines to portray statistical surfaces.

From 1700 on, mapping progressed steadily and continuously toward its present state. Perhaps the greatest innovations since 1700 are those involving the digital computer. For a much more detailed discussion of the history of cartography and its relation to the development of science and culture, the reader is referred to Thrower's (1972) book.

1.2 Map Projections

Most maps are presented on flat (planar) media such as pieces of paper, or computer display screens. (The chief exceptions are globes.) However, it is impossible to flatten out a portion of the surface of a sphere without some distortion or stretching. A *map projection* is a formula or geometric construction procedure for transferring locational information from the spheroid which approximates the Earth's surface to a plane. Most map projections either preserve some particular geometric property of interest exactly (while distorting other aspects), or represent a compromise which tries to minimize several different distortions simultaneously, without completely eliminating any of them.

1.2.1 Properties of Map Projections. One property of considerable interest in mapping is the preservation of relative areas. If regions of equal area on the Earth's surface always have equal areas on some particular map projection, regardless of shape or location, then that projection is referred to as an *equal-area map projection*. Conventional cartographic wisdom suggests that equal-area projections should be used as base maps for the plotting of most thematic information, so that the areas represented are not distorted. But many commonly used world maps are not equal-area, and often present polar areas at relatively larger scale than the equatorial areas; this has led to systematic distortions of people's "mental maps."

A second property, also of great interest, is the representation of angles and shapes. If all

angles on the Earth's surface are preserved on the map, then that map is said to be a *conformal map projection.* Conformal maps are useful for some navigation tasks, and furthermore, if all angles are preserved, then so are the shapes of relatively small forms or outlines. (Larger shapes may still be distorted on a conformal map by changes in the local map scale.)

A map that was both equal-area and conformal would be highly desirable. However, it was proved by the French mathematician Tissot that such a projection cannot exist. The properties "equal-area" and "conformal" are mutually exclusive, because of the necessity of some distortion as the geometry on the surface of a sphere or spheroid is transferred to the plane.

Other map properties could be of interest in choosing a projection. The shortest surface distance between two points on the surface of a sphere is defined by a segment of a *great circle.* (A great circle is a circle formed by the intersection of the surface of a sphere with a plane through its center.) A map on which all great circles appear as straight lines would be very valuable in navigation. Another property would be preservation of relative distances among points, but this is impossible in general; however, projections which preserve distances to one or two central points of interest can be constructed.

1.2.2 Classification of Map Projections.

Map projections are called "projections" because many of them could, in principle, be constructed by shining a light through a transparent globe, casting an image onto some other surface, and then flattening that surface. A *developable surface* is one which can be flattened without distortion; commonly used developable surfaces are cones, and two special cases of the cone, namely the plane and the cylinder. Map projections originally were classified according to the nature of the developable surface involved in their construction. Still today, the terms *cylindrical, conic,* and *planar* (or *azimuthal*) are used for three groups of map projections.

Three of the *azimuthal projections* could, in principle, be constructed by the projection method. The planar surface is placed tangent

to the sphere at some point, which will form the center of the resulting map. Then the light source is placed along the line from the tangent point through the center of the sphere. If the light source is placed at infinite distance, the result is the *orthographic projection* (Fig. 5). This projection has no important mathematical properties, but it "looks good." Since it appears as would a picture of the globe, it is useful as an illustration, or as a location key map at a hemispherical scale. If the light source is on the surface of the sphere at a point directly opposite the tangent point, then the *stereographic projection* results (Fig. 6). The stereographic is the only conformal projection in the azimuthal family. The stereographic projection is not commonly used in cartography, but is important in geology and crystallography, for plotting orientation data. (The property of conformality allows angles to be measured from the diagram.) The third interesting place to put the light source is at the center of the sphere. This produces the *gnomonic* projection (Fig. 7), which looks strange, but on which all great circles plot as straight lines, and *vice versa.* Thus the gnomonic is very important in air or ship navigation for planning routes over long distances.

Two other common azimuthal projections cannot be created by projecting with a light source, but can only be constructed mathematically. An *azimuthal equidistant* projection preserves relative distance to the center point; the polar case would be easily approx-

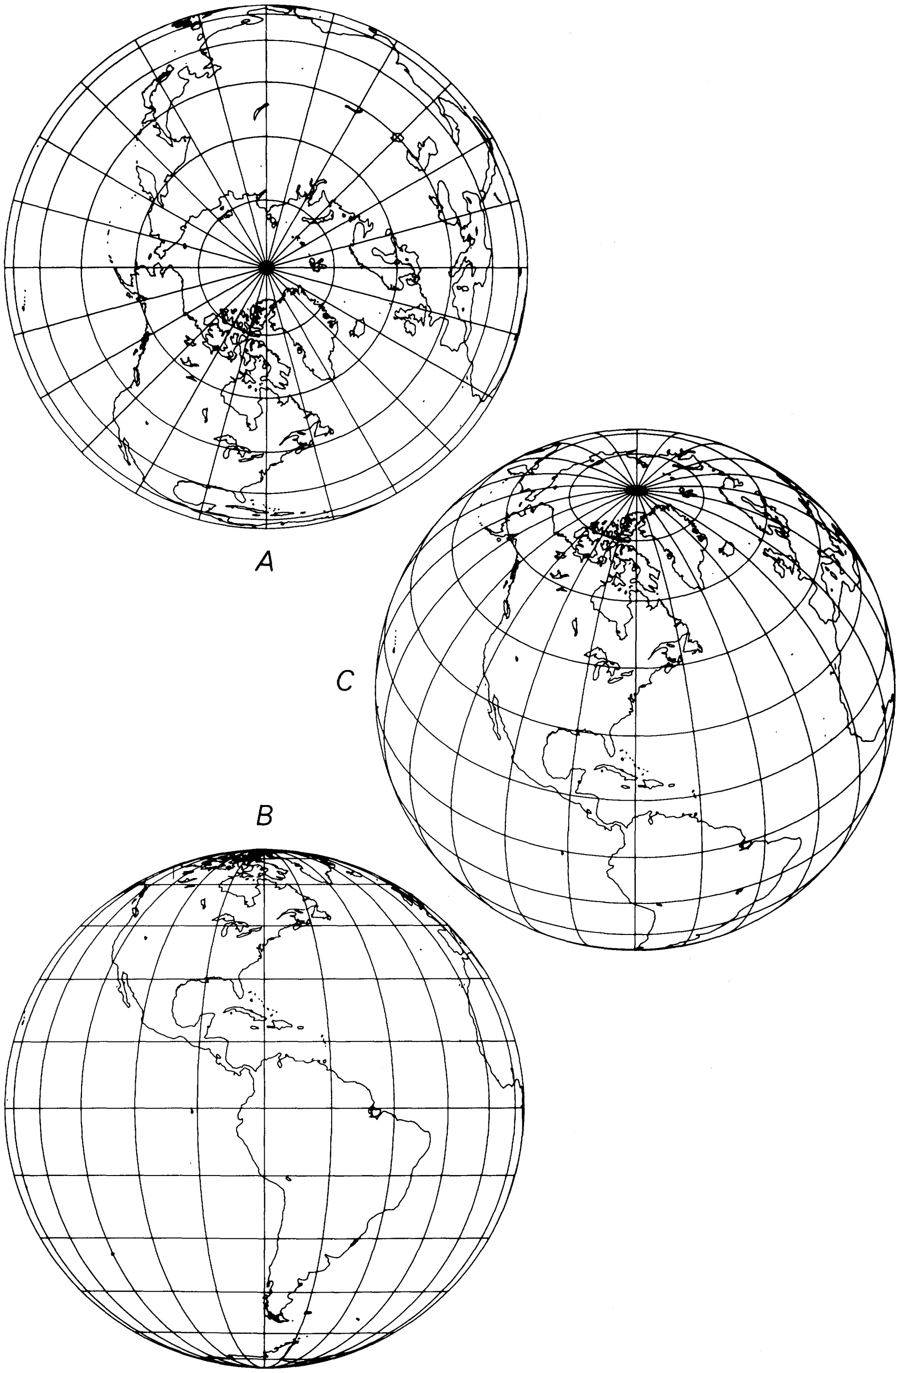

FIG. 5. Orthographic projection. (A) Polar aspect. (B) Equatorial aspect, approximately the view of the Moon, Mars, and other outer planets as seen from the Earth. (C) Oblique aspect, centered at lat. 40° N., giving the classic globelike view.

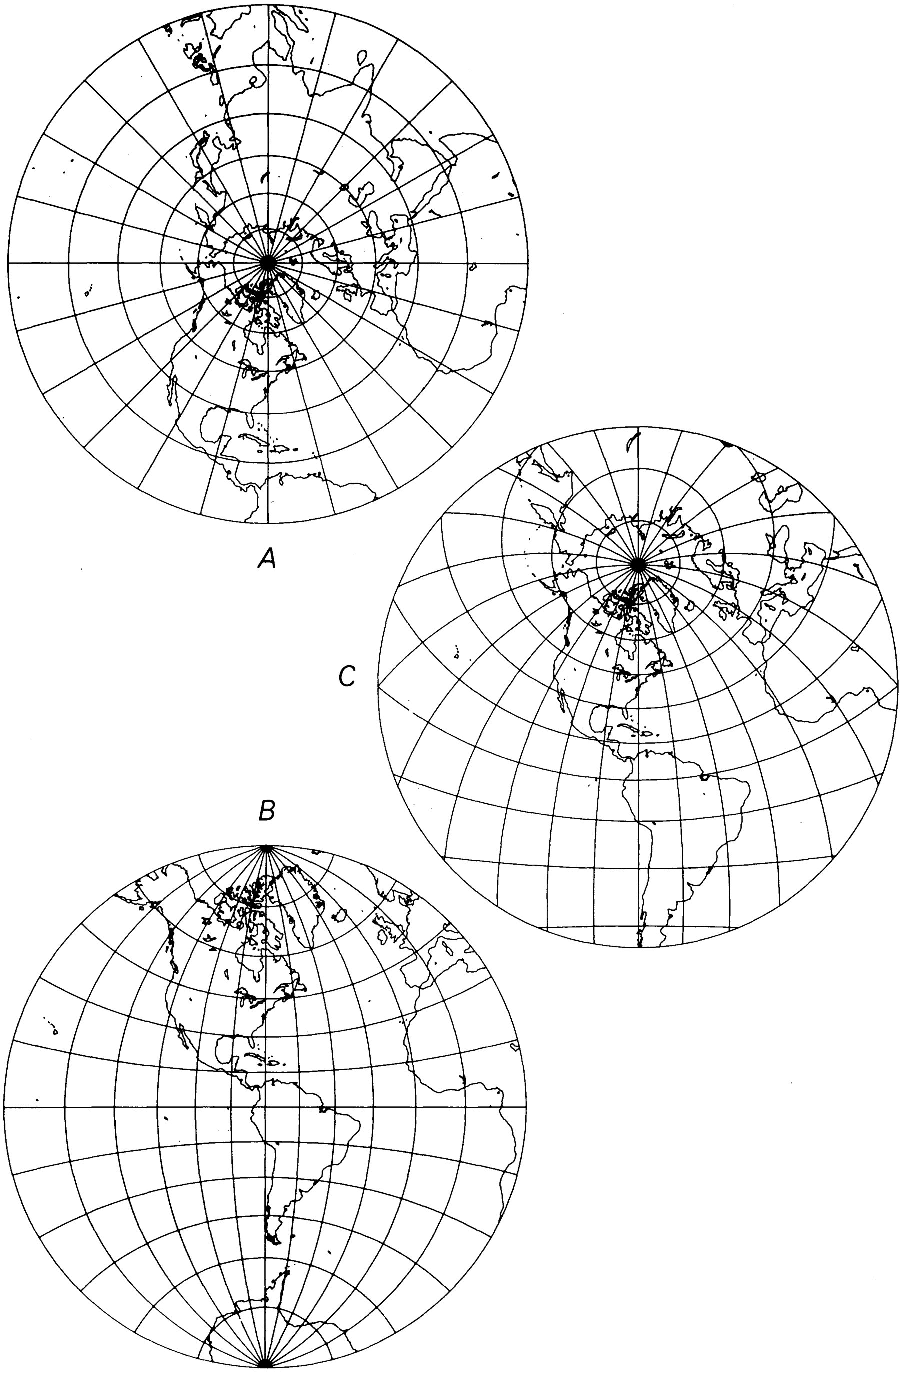

FIG. 6. Stereographic projection. (A) Polar aspect; the most common scientific projection for polar areas of Earth, Moon, and the planets, since it is conformal. (B) Equatorial aspect; often used in the 16th and 17th centuries for maps of hemispheres. (C) Oblique aspect, centered on lat. 40° N. The stereographic is the only geometric projection of the sphere which is conformal.

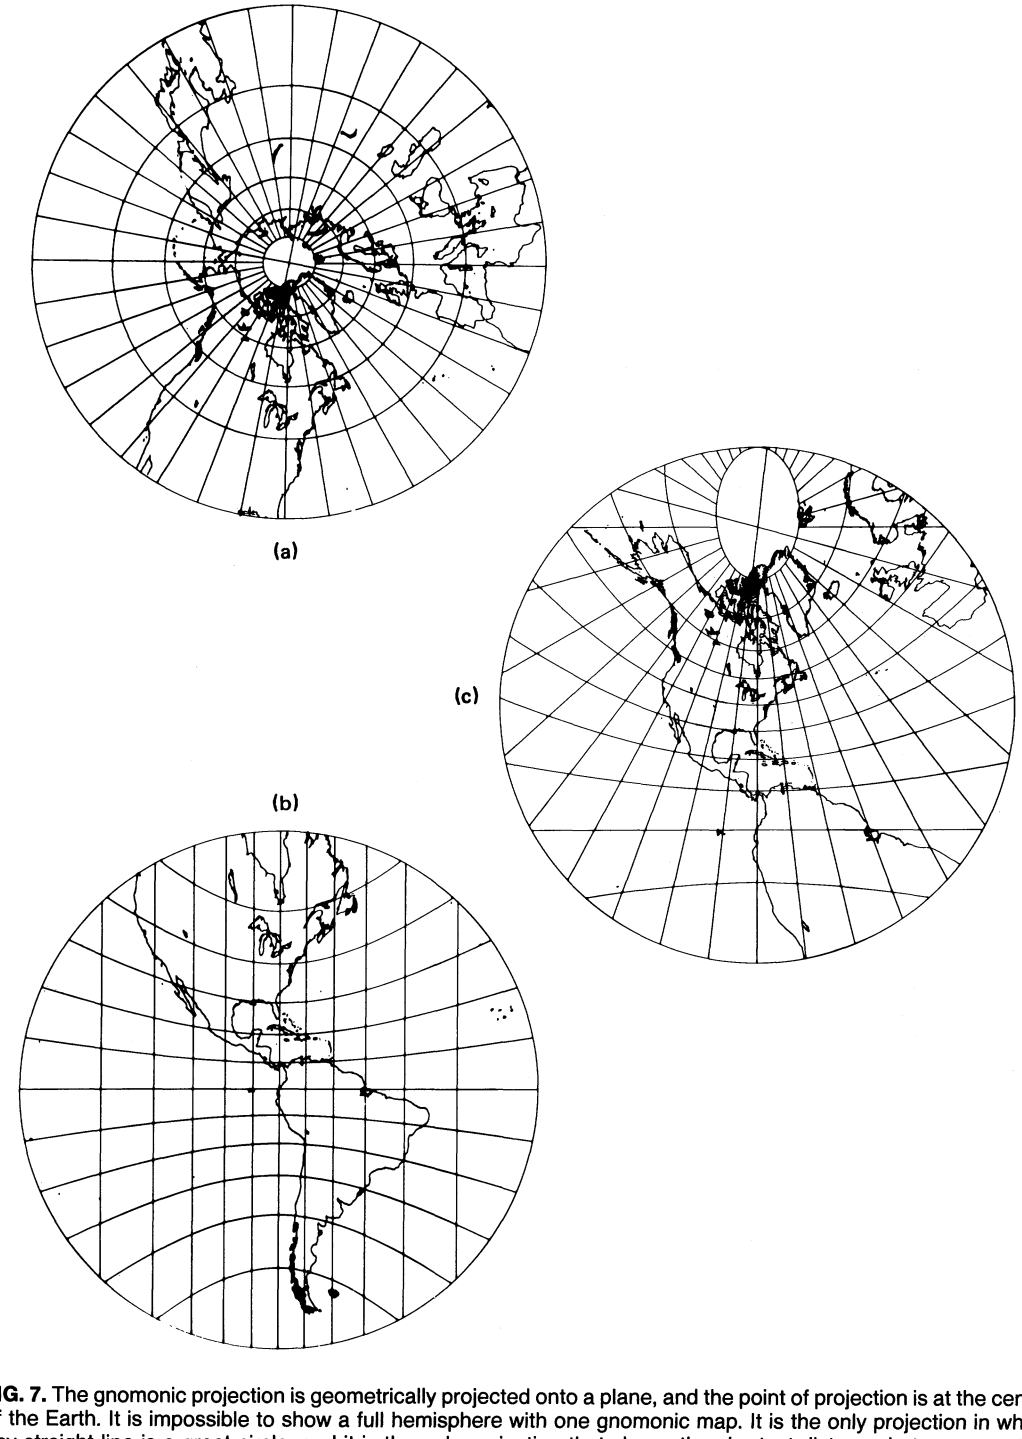

(a)

(c)

(b)

FIG. 7. The gnomonic projection is geometrically projected onto a plane, and the point of projection is at the center of the Earth. It is impossible to show a full hemisphere with one gnomonic map. It is the only projection in which any straight line is a great circle, and it is the only projection that shows the shortest distance between any two points as a straight line. Consequently, it is used in seismic work because seismic waves travel approximately great circles. The gnomonic projection is used with the Mercator projection for navigation.

imated, since the latitude could easily be converted to ground distance to the pole and scaled to the radial distance from the center of the projection (Fig. 8). An *azimuthal equal-area* projection would be slightly more complicated, since the radii must be scaled so that the areas of interlatitude bands on the map are proportional to the areas of those bands on the globe (Fig. 9).

Cylindrical projections are normally constructed with the cylinder tangent to the sphere at the equator, and are plotted with the equator extending horizontally across the centers. The most famous of these is Mercator's projection, which Gerhardus Mercator first published in 1569, and which is conformal. Mercator's projection is unique in that lines of constant compass bearing (sometimes termed "rhumb lines" or "loxodromes") are straight lines on the map (see Fig. 10). Recall that lines of longitude converge on the globe, but they appear as parallel straight lines on a cylindrical projection tangent to the equator. Thus the east-west scale necessarily increases from the equator toward the poles. The conformal property is achieved by increasing the north-south scale (i.e., by increasing the spacing of lines of latitude) at the same rate that the straightening of the meridians increases the east-west scale. A navigator could draw a straight line between origin and destination on a map using the Mercator projection, measure the bearing on the map, and then reach the destination by traveling on that bearing (barring intervening barriers, and after making appropriate magnetic corrections). Transverse Mercator projections result when some great circle other than the equator is used as the point of tangency. The universal transverse Mercator (UTM) divides the earth into 60 north-south bands (and two polar circles), and constructs a transverse Mercator projection centered on the central meridian of each 6° zone. UTM coordinates are an important standard coordinate system for topographic mapping (especially by the military) and for integrating data from disparate sources into a geographic information system.

Conic projections involve a developable surface in the form of a cone. In their simplest forms, the cone is tangent to the sphere along some small circle (often a line of latitude). In an important variation, the cone intersects the sphere along two circles. Perhaps the best known of these projections is *Lambert's conformal conic*, which is the *de facto* standard map projection for maps of the 48 contiguous United States. With the two standard parallels at 33° N and 45° N latitude, Lambert's conformal conic projection distorts areas and distances by less than ½% over the 48 contiguous states, while perfectly preserving angles because of its conformal nature (Fig. 11). Other projections in the conic family include polyconic projections, which in effect combine several conic segments, either piecewise or through a continuous change in the apex angle of the cone.

Finally, there are many important projections that cannot be cast in the traditional form of a projection onto a developable surface. These are called *mathematical* or, occasionally, *"conventional" projections*, and include such popular projections as the sinusoidal projection, the homolographic (or Mollweide's), the homolosine (Goode's), and others. Goode's projection is interrupted, meaning that continents are mapped onto components of the projection while oceans are divided, and the resulting world maps are important in atlases when land-based data are presented.

For further readings and information on map projections, see Snyder (1982).

1.3 Reference Maps

One of the basic functions of maps is to provide locational information within recognizable frames of reference. Maps that are produced primarily to serve such a function are often called *reference maps*. Possible synonyms include "general maps," and the entire class has occasionally been named after one of its more prominent members, the topographic map. What these have in common is an attempt to represent to a great extent physical features of the world, such as roads, rivers and lakes, shore lines, railways, towns and villages, parks, etc. Name labels for such features also are fundamental, since they are almost always essential in the process of relating map features to the real-world objects they represent.

1.3.1 Topographic Maps. The term "topographic" map is often used as a synonym for "contour map," and although contours are not absolutely required on a topographic map,

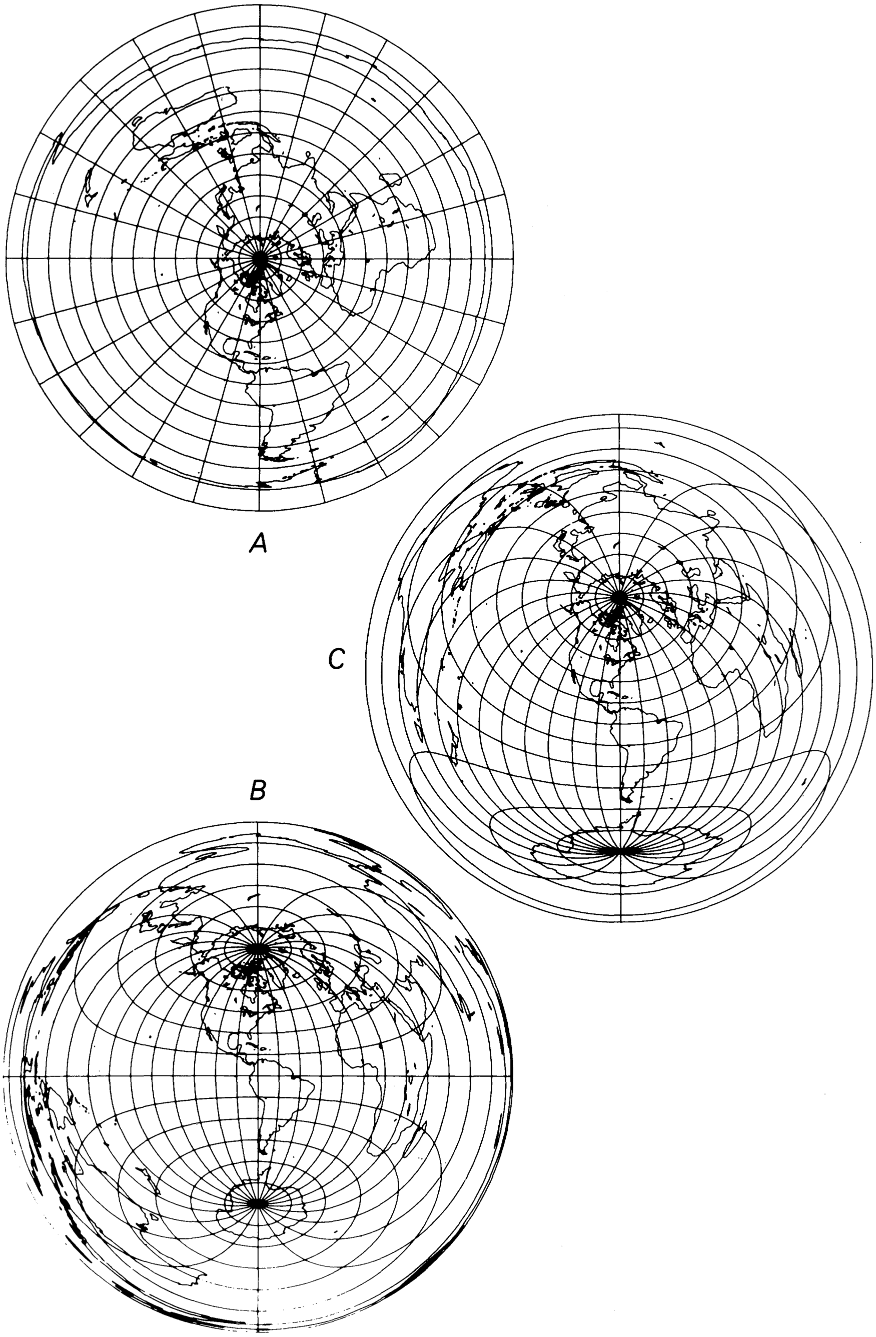

FIG. 8. Azimuthal equidistant projection. (A) Polar aspect extending to the South Pole; commonly used in atlases for polar maps. (B) Equatorial aspect. (C) Oblique aspect centered on lat. 40° N. Distance from the center is true to scale.

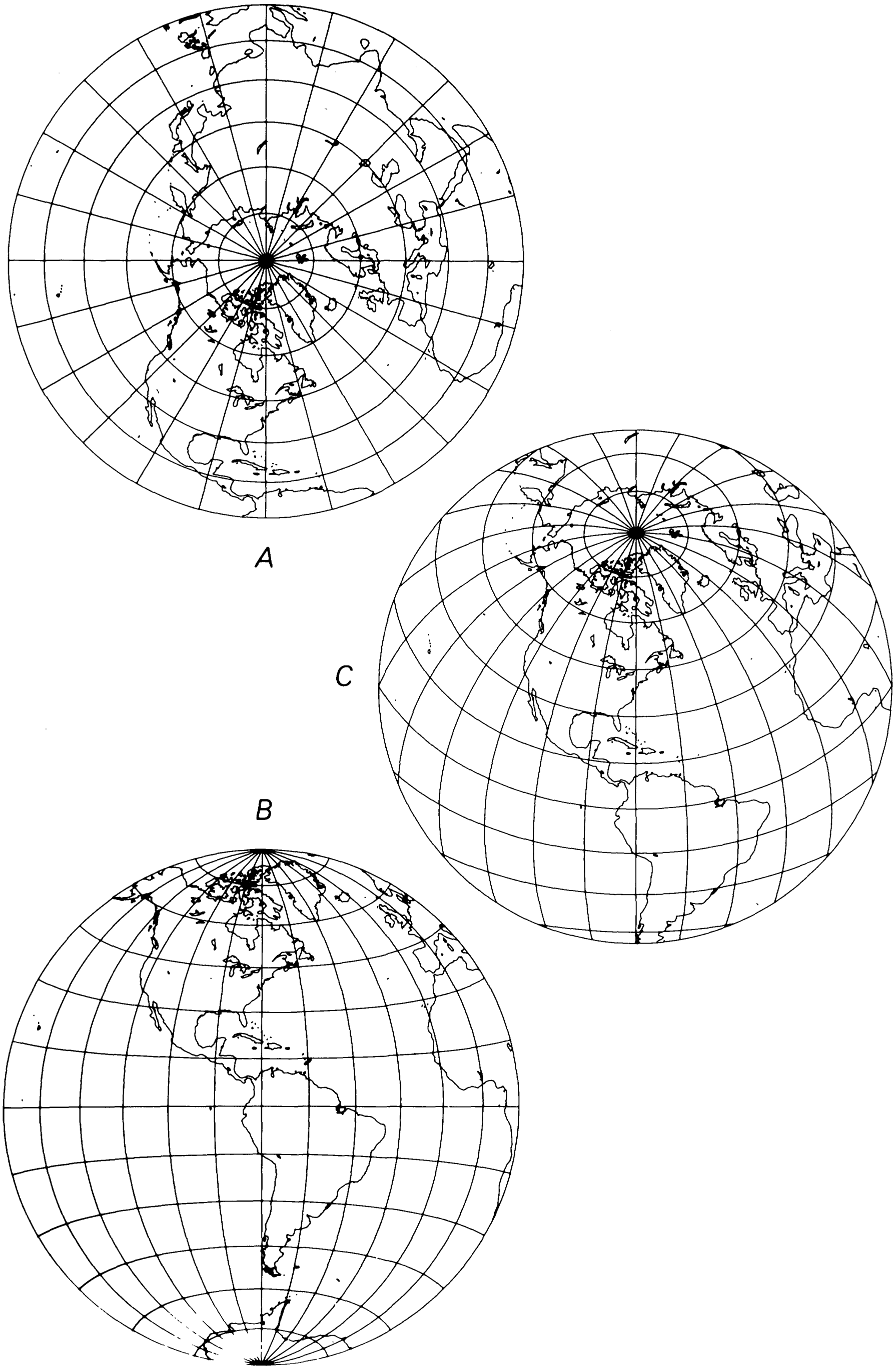

FIG. 9. Lambert azimuthal equal-area projection. (A) Polar aspect showing one hemisphere; the entire globe may be included in a circle of 1.41 times the diameter of the equator. (B) Equatorial aspect; frequently used in atlases for maps of the Eastern and Western hemispheres. (C) Oblique aspect; centered on lat. 40° N.

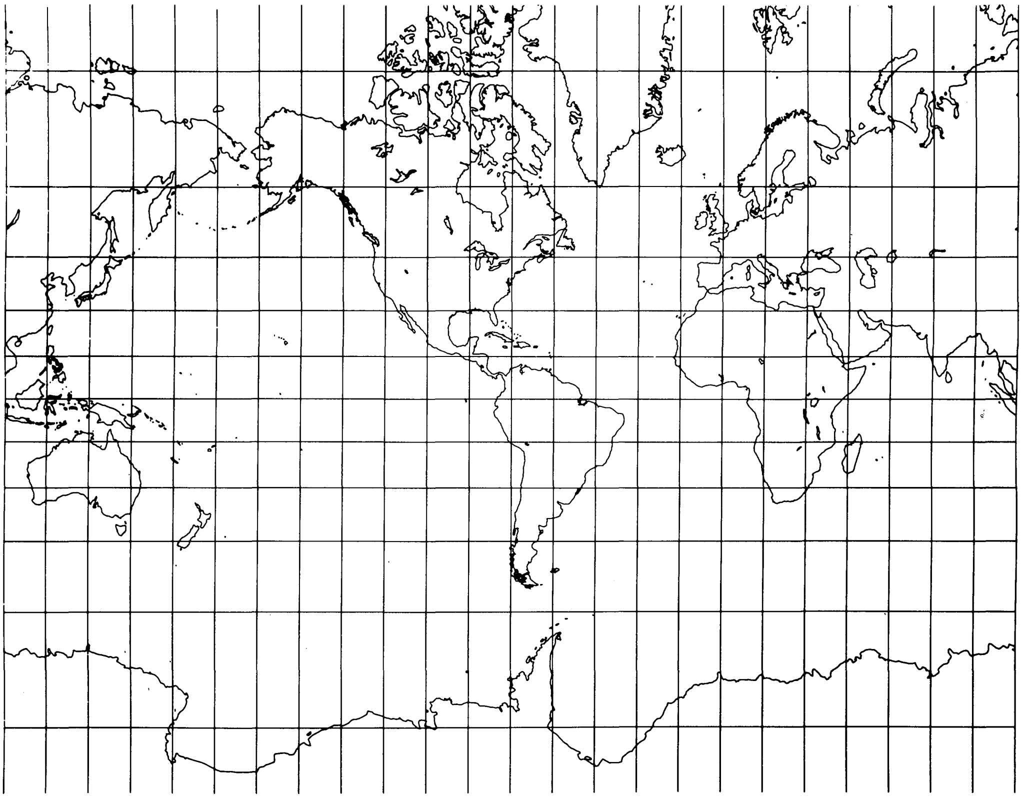

FIG. 10. The Mercator projection. All angles are shown correctly; therefore small shapes are true, and it is called conformal. Since rhumb lines are shown straight on this projection, it is very useful in navigation. It is commonly used to show equatorial regions of the Earth and other bodies.

they usually are a predominant theme. Contours are lines joining places of equal elevation above some datum, and have been the standard way of depicting elevation information on maps for almost 300 years. Topographic maps usually are dominated by cartographic features that represent visible entities on the Earth's surface: streams, lakes, and other hydrographic features; transportation features such as roads, railways, power lines, etc.; buildings and built-up areas; and political and institutional boundaries (see Fig. 12). Topographic maps are commonly produced by governmental agencies, either civilian or military, and most countries have a standard series of scales. In the U.S., the most detailed standard scale published by the U.S. Geological Survey (USGS, the civilian agency responsible for topographic mapping) is 1:24 000. At this scale, 1 in. on the map represents 2000 ft on the ground; 1 km on the ground would occupy about 4.2 cm on the map. In Canada, 1:25 000 scale mapping is conducted only in the most heavily settled southern regions, while for the rest of the country, the most detailed scale is 1:50 000. In Australia, 1:100 000 scale represents the most detailed national coverage, whereas in most European countries, maps at scales of 1:10 000 or larger often are available.

Topographic maps are used in forest management, military planning, engineering, and earth science applications. They are also used by hikers and to support a variety of outdoor activities. The digital equivalent of the elevation data depicted on such a map is called a *digital elevation model* (DEM), and occasionally is referred to as a "digital *terrain* model" (DTM). The USGS distributes 30-m-resolution grids for areas equivalent to their 1:24 000 scale map series. Digital cartographic data equivalent to other information on the topographic maps, such as hydrography and transportation, are distributed as "digital line

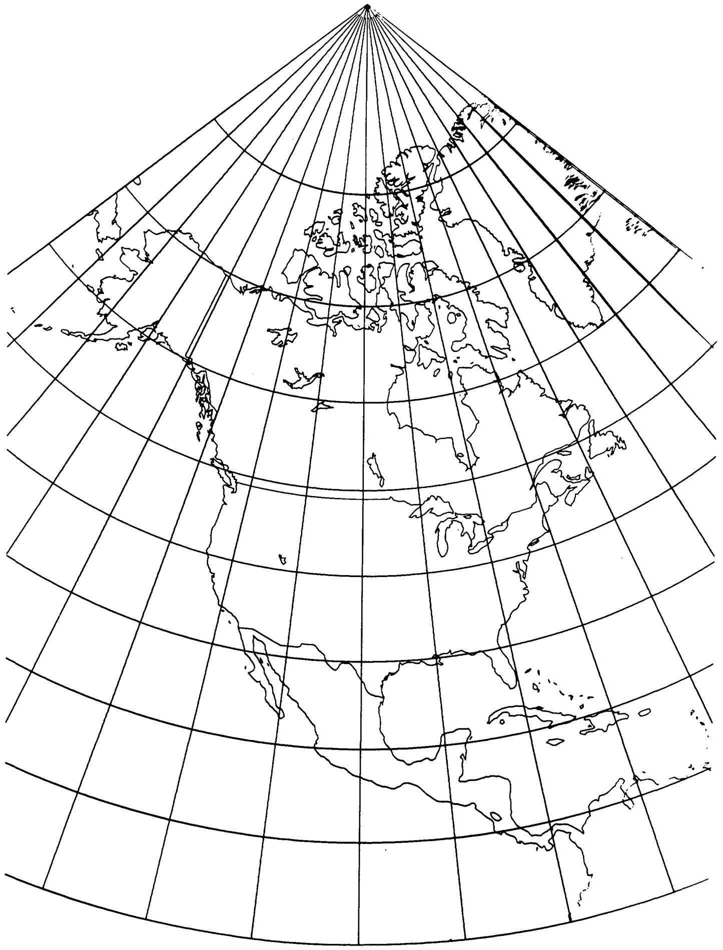

FIG. 11. Lambert conformal conic projection, with standard parallels 20° and 60° N. North America is illustrated here to show the change in spacing of the parallels. When used for maps of the coterminous United States or individual states, standard parallels are 33° and 45° N.

graphs" (DLGs). Similar digital topographic data are now available in many countries.

1.3.2 Road Maps. Road maps are perhaps the most familiar and most widely distributed maps in North America and Europe. They are an almost essential accessory in an automobile, and annual sales are very great. Unlike topographic maps, most road maps are produced by private-sector firms, and most are sold directly to the public. Exceptions are automobile clubs that provide maps to their members. Some state (provincial) and local governments provide free road maps, but this is much less common than it was 10 or 20 years ago.

Although road maps serve many purposes, their main function is to provide navigation assistance to drivers. Roads are obviously among the most important features on these maps. For city road maps (sometimes called "town plans" in British English), the roads and road names predominate, whereas for nonurban areas, names of populated places share the design spotlight with the roads. Other information is provided to serve as landmarks and to indicate potential trip destinations (parks, airports, shopping centers, etc.). Since the map cannot perform its primary function if the destination cannot be located on the map, a premium is placed on

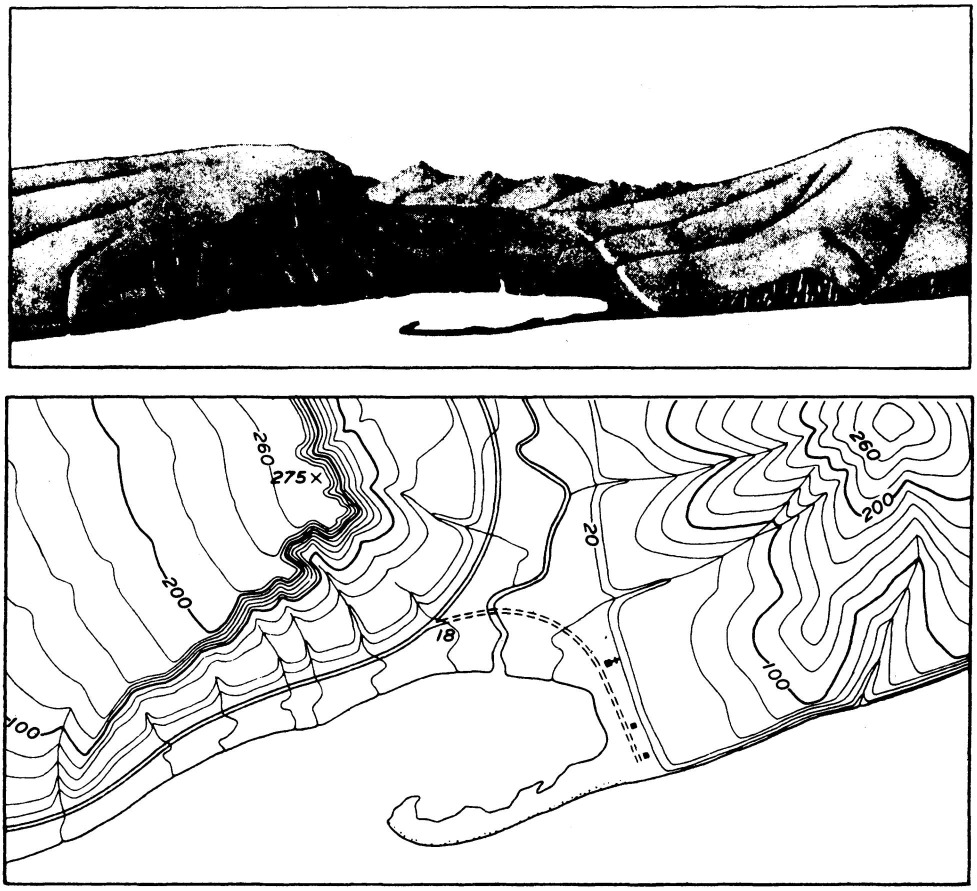

FIG. 12. In the early twentieth century the U.S. Geological Survey used this pair of oblique (above) and plan (below) views on the back of its topographic maps to explain to users the representation of terrain by contour lines (in the plan view). Plan view is also a planimetric map.

fitting as many name labels on the map as possible while retaining clarity.

In the late 1980s, several computer-based in-car vehicle navigation aid (VNA) systems were tested, and some reached the market. Such systems might eventually replace printed road maps for many situations, and can potentially be linked to traffic computers to advise motorists of construction zones, accidents, and other kinds of traffic congestion, even routing vehicles along roads to avoid such difficulties.

1.3.3 Charts. Although "chart" is an archaic synonym for any kind of map, the word is commonly used in modern English to refer to specialized maps designed to support navigation by ships and aircraft. (Note, however, that the cognate words in some other languages, such as *carte* in French and *Karte* in German, are the general words for "map" in those languages.) Ship and aircraft navigation problems are similar to each other, and distinct from road navigation, in that travel is much less restricted, and often involves physically unrestricted movement in almost any direction through or on a fluid medium containing occasional obstacles or other vehicles. Although charts are distinguished from other reference maps by purpose and have specialized information for maritime (e.g., water depths, buoys) and airborne (e.g., towers, radio beacons) navigators, they otherwise are very similar to other kinds of reference maps.

1.3.4 "Base" Maps. The term base map is used to refer to a reference map which serves as a background or reference frame for thematic information. A thematic map (see Sec. 1.4) of, say, mean January temperatures for Australia will mean very little to most map users if it is simply plotted over a latitude-longitude graticule. Most users would find it much easier to interpret the pattern if it were plotted on a base map showing the Australian coastline, the state boundaries, a few major cities, and perhaps some rivers. Base maps are designed according to principles similar to the ones that govern the production of other reference maps, except that information density is much lower to reduce interference with the thematic data. With the widespread availability of computer mapping systems, especially based on microcomputers, the use of preprinted base maps is not as important as it was a decade ago.

1.4 Thematic Maps

A thematic map portrays the geographic distribution of one or a small number of variables. Often, the phenomena shown are not directly visible in the real world, but rather are statistical in nature, determined by measurements, surveys, censuses, etc. Examples of topics for thematic maps include precipitation, gravity anomalies, crime rates, industrial production, and election results. Many atlases are collections of thematic maps.

Because many phenomena shown on thematic maps are not visible in the real world, the cartographer has a much greater range of possibilities in the way the data are represented. For example, election results, gravity anomalies, and travel times do not have color, and so in principle any color-coding system could be used on maps of these phenomena.

There is a wide range of techniques available for thematic mapping, again perhaps because the phenomena being mapped are often abstract in their geographical expression, and thus have no "natural" visual expression. In the remainder of this section, three important techniques for presenting *quantitative* information on thematic maps are presented: *isoline maps, choropleth maps,* and *proportional area symbols.* Other techniques, such as area cartograms, dot maps, and various mapping techniques for nominal data, can be found in standard cartographic and map-reading texts (e.g., Robinson, Sale, Morrison, and Muehrcke, 1984; Muehrcke, 1986; Campbell, 1984).

1.4.1 Isoline Maps. Isolines are commonly used to portray phenomena which can be represented as single-valued functions of location in geographic space. (The term *isoline* is used here in preference to the more etymologically sound *isopleth* and *isarithm,* because many cartographers use isopleth and isarithm to refer to different types of data—there is no accepted classical-root–based term that includes both.) Such data are sometimes referred to as *fields.* An isoline map is composed of a set of lines, along which the phenomenon in question has a constant value. An example is shown in Fig. 13. Although the lines are often described as *joining* points (places) of equal value, it probably is more useful to think of the isoline as *dividing* areas below some value from areas above that value. A contour map (see above) is a familiar example, and "contour" is sometimes (incorrectly) used as a synonym for isoline. The earliest known isoline map, portraying lines of equal magnetic compass declination, was included in a report by Edmund Halley, published in 1701 (Thrower, 1972, pp. 67–68). Thus, isoline maps are among the oldest forms of thematic maps.

Isoline maps can now be produced efficiently and objectively by computer programs running on microcomputers, workstations, and larger computers. Often, the programs offer the user a choice from among several interpolation methods. Isolines are often named for the phenomenon represented: iso*bars* for pressure, iso*therms* for temperature, iso*pachs* for thickness, iso*chrones* for time, etc. The name "contour" is not considered to be a synonym for "isoline," but should be considered to be the name for isolines depicting topographic elevations.

1.4.2 Choropleth Maps. The choropleth method shows quantitative data for statistical units by filling each unit with a uniform color or pattern (see Fig. 14). The term choropleth should only be used when quantitative data are collected for a set of mutually exclusive and collectively exhaustive zones, such as countries, states, counties, or census districts. Then a scheme is developed for determining a color or pattern to represent the value of the statistic for each zone. Usually, this involves the classification of the zone values into about 5–7 categories, although "unclassed" choropleth maps, in which each zone's color or

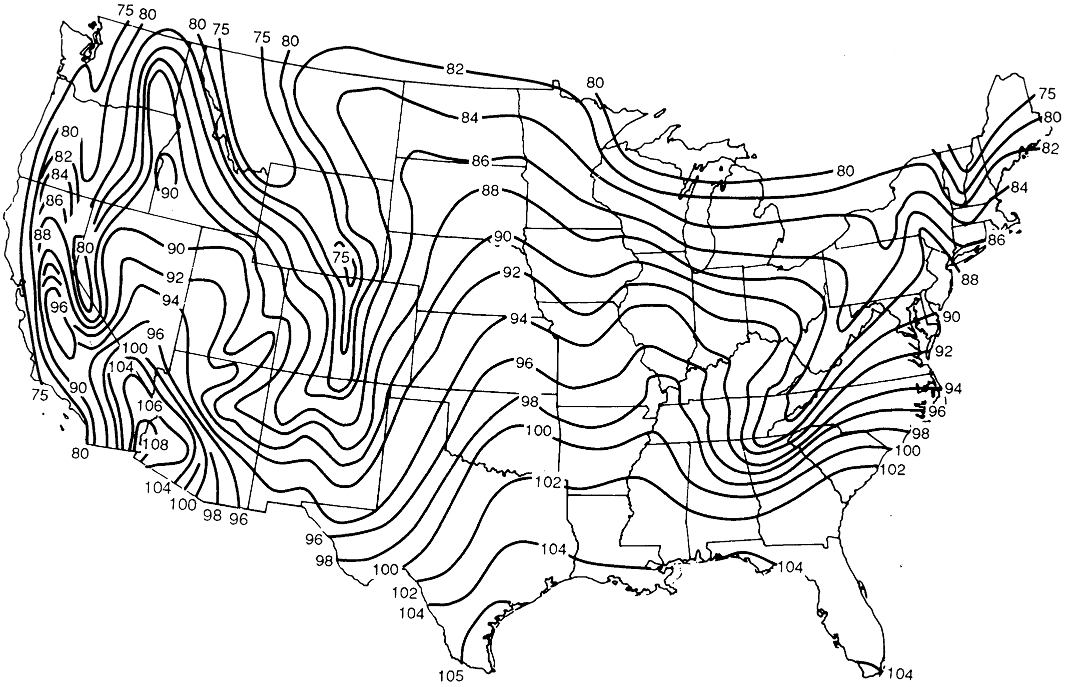

FIG. 13. Example of an isoline map. Average mid-summer noon apparent temperatures in the U.S. adjusted for relative humidity, wind, and isolation. [After R. G. Steadman, "The Assessment of Sultriness," *Journal of Applied Meteorology*, **18**, no. 7, 861–884 (1979), with supplemental data added by the National Climatic Center; U.S. Department of Commerce, National Oceanic and Atmospheric Administration, Environmental Data and Information Service, *Heat Stress*, Environmental Information Summaries C-19 (Asheville, NC: National Climatic Center, 1980), p. 4.]

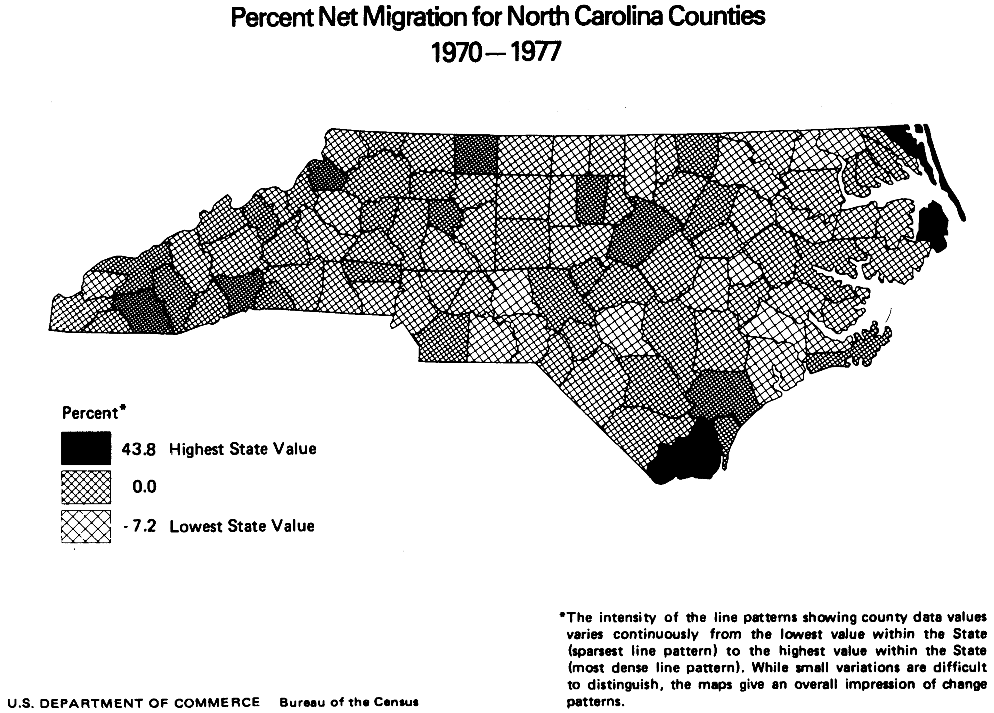
pattern is a function of the zone's exact value, have also been constructed. (Such unclassed maps only became a practical possibility with the advent of computer-driven plotters in the 1960s; conventional cartographic wisdom still prefers "classed" choropleth maps.)

It is important in choropleth mapping that the quantity being mapped have the property of being ***intensive***. For physical objects, properties such as color or density are intensive, and would apply to parts if the object were cut apart; this is in contrast to an extensive property such as weight, where the value of the whole is divided among the parts. If an extensive geographic statistic, such as number of people, number of crimes, or number of cases of a disease, is plotted using the choropleth technique, then the resulting map would be more a function of the zones than of the phenomenon. A cynical police administrator could reduce the mapped intensity in a district merely by dividing it into two parts, and thus such extensive data should never be mapped by choropleth. Instead, the data should be transformed into intensive data by dividing by land area, base population, or some other appropriate item. If per capita crime rates are mapped, then splitting a district will either leave both halves in the same category as the original, or will result in the rate rising in one subzone and declining in the other. Unfortunately, no mapping program known to the author keeps such "data-type" distinctions, or is capable of detecting and eliminating such misuse; thus, if users are not aware of this, invalid and perhaps misleading maps will result.

1.4.3 Proportional Point Symbols. Often, quantitative data are available for features which are essentially points. Examples might be industrial production by plant or city, population figures by populated place, or mineral production by mine or well. If the data are of ratio type (real numbers, with "0" actually designating the absence of the at-



Percent Net Migration for North Carolina Counties 1970–1977

*The intensity of the line patterns showing county data values varies continuously from the lowest value within the State (sparsest line pattern) to the highest value within the State (most dense line pattern). While small variations are difficult to distinguish, the maps give an overall impression of change patterns.

U.S. DEPARTMENT OF COMMERCE Bureau of the Census

FIG. 14. Continuous-tone, nonclassed choropleth map showing percent net migration, by county. North Carolina, 1970–1977. (From U.S. Bureau of the Census, *Current Population Reports*, Series P-26, No. 77-33, September 1978, p. 9).

tribute being considered), *proportional point symbols* can be a powerful and effective component of a thematic map.

One of the most commonly used forms of proportional point symbols is the proportional circle. Geometrically, it would appear that the area of the circle should be scaled to the quantity being represented, and a circle with 3 times the radius would represent a quantity 9 times as large (3^2). However, psychophysical research conducted in the 1960s by Flannery showed that people systematically underestimate the "sizes" of larger circles compared to smaller ones. Empirically, Flannery found that scaling radii to the 0.57 power of size to be represented (rather than the 0.5, as suggested by the area principle), leads to circles whose "sizes" are perceived "correctly" by typical users. Such an adjustment for "perceptual biases" is now firmly entrenched in cartographic practice (cf. Robinson *et al.*, 1984, pp. 292–294; Campbell, 1984, pp. 300–302). This is a good example of the application of a "communication" theory of mapping: The most important thing is placing an image of geography in the mind of the map user; thus any biases introduced during map reading should be anticipated by building their inverses into map construction procedures.

Many other symbols besides circles have been used. In addition to other regular geometric forms, it is possible to use pictorial symbols, such as trees (for forestry), people (for personnel numbers), or ships (for naval strength), scaling their area according to the quantities to be represented. However, these symbols have not been investigated for perceptual "biases" similar to those discussed above for circles. It is perhaps more common for these symbols to choose a constant symbol size and then to reproduce it several to many times to indicate different quantities. And of course type size itself is often used to indicate city size; the label can be considered to be a special sort of graded proportional symbol.

1.5 Computers and Cartography

As recently as 1980, an article or section in computer-assisted cartography would have had to begin by making the case for the computer's role in map-making. However, during the 1980s, computers became so pervasive that it is hardly necessary to provide such a justification. Computers are essential to much of cartography today.

Much of computer mapping in the 1960s and 1970s used the computer as "electronic paper"; effort was almost entirely directed toward producing by computer the sorts of hard-copy graphics that had been developed and perfected in manual cartography. But even though Craig Fields challenged researchers at a 1977 Harvard conference to look "beyond electronic paper," techniques possible on the computer but impossible or impractical on a static print medium have yet to receive much attention from cartographers. Interactive maps (connected to GIS or similar databases) can be designed quite differently, placing only essential information on the graphic, and allowing the user to request additional information by commands or pointing. Similarly, animation and related techniques have great potential to show time-varying spatial data, such as atmospheric phenomena, earthquake activity, land-use change, etc. Such techniques, associated with the newly named field of *scientific visualization* (see next section), will almost certainly gain in importance in the cartography of the future.

1.6 Visualization in Geographic Computing

During the 1980s, the scientific research community "discovered" the power of graphic representation of data (see COMPUTER GRAPHICS). Whereas geography, geology, and many natural sciences have routinely used maps and graphics as tools for data exploration for many years, this is not true of all disciplines. In many areas, especially physics, simulations using supercomputers produced data at unprecedented rates and volumes, such that it was essentially impossible for human minds to comprehend them in numerical form. Similarly, space-borne earth observation platforms also were recording observations at unprecedented rates. In response to this situation, the U.S. National Science Foundation and the computer science community developed the "Visualization in Scientific Computing" (ViSC) report and initiative; see McCormick *et al.* (1987) for the report. Earth science applications figure prominently in that report.

1.7 Summary

Cartography is the science, art, and craft of making, evaluating, and using maps. Maps have been a very important part of culture for a very long time, and remain important today. Reference maps are used to represent locations of concrete objects on the Earth's surface, and thematic maps show more abstract or statistical data. Many techniques are available for thematic mapping, and not all can be applied to any data. Computers are becoming more and more important in mapping, and continue to provide challenges for cartographers to take full advantage of new technologies.

2. GEOGRAPHIC INFORMATION SYSTEMS

In their glossary, Star and Estes define a *geographic information system* as "the complete sequence of components for acquiring, processing, storing, and managing spatial data" (Star and Estes, 1990, p. 267). Often, the ability to overlay two data layers, in a procedure analogous to overlaying two paper maps on a light table, is viewed as the quintessential GIS function. Critical issues for GISs include data models, data structures, and algorithms; geographic analysis and spatial statistics; user interfaces and human factors; and social, economic, institutional, and legal issues. These will be reviewed in the following sections.

2.1 Data Models, Data Structures, and Algorithms

2.1.1 Data Models. A geographic information system may be thought of as a computerized model of some aspects of the geographical world (cf. COMPUTER DATABASES). The term *data model* is used to refer to a model of relevant aspects of the real world, which has been abstracted from that world in such a way as to retain those properties which are relevant to the current problem domain, and yet which can be implemented on a computer. Data modeling for GISs is thus an exercise in geography, plus forestry, earth science, or whatever domain the GIS is to be applied to. To some extent, a generic GIS thus is unlikely, unless it is an implementation of the union of all possible application-domain data models. However, different application domains have enough in common that generic commercial GISs are possible and useful. Nevertheless, any particular commercial GIS is better for some classes of applications than for others.

2.1.2 Data Structures. The term *data structure* is usually used to refer to the details of how the data model is implemented on a computer. One dichotomy is between raster and vector GISs. In the *raster* family of geographic information systems, geographic space is partitioned into a large number of small cells, usually of a uniform size and shape; then, for each cell, geographic attributes are recorded. In most such systems, cells are square, and often are referred to as *pixels*, a contraction of "picture elements"; in image processing, a single complete row of the image is referred to as a raster, from which this family of data structures gets its name. Raster data structures dominate in remote sensing. The essence of the raster approach is a data model based on "spatial occupancy": space is partitioned into cells, independently of theme, attributes, or objects, and then theme, attributes, or objects are observed and recorded for each cell. One problem with the raster approach is that often there is a great deal of redundancy, with many neighboring cells having identical values. Specialized methods such as quadtrees have been developed to make raster data handling more space efficient, or to give quicker response time to spatial search queries. A quadtree is a data model that divides an image into quadrants, and recursively divides each of these into subquadrants as long as they contain variation.

An alternative data modeling approach is to observe the themes, attributes, objects, or phenomena in geographic space, and then to include location as part of their representation on the computer. This defines the family of data structures commonly referred to as *vector* data structures, which often represent objects as digital versions of lines on maps (hence, "vector"). Most commercial GISs use this approach to represent geographic information. Some systems take an explicit map-like approach, conceptualizing all data as "layers," conceptually equivalent to digital maps. In other systems, the emphasis is on the representation of individual geographic objects, which can be constructed from spatial primitives that may be shared among compound objects. Of course, layers and objects can often be supported as different user views of the same database. Ideally, the system should support whatever view of the data corresponds to the way the user conceptualizes the data.

2.1.3 Algorithms. An algorithm is a sequence of steps which, when carried out in order, lead to the solution. A recipe for baking a cake is a good example of an everyday algorithm. Algorithms are essential to computing. Some of the more important algorithms correspond to basic GIS procedures. Map overlay (Boolean or logical combination of two layers) is one of the most basic GIS procedures. Another is "point-in-polygon"; the object is to determine in which of a set of plane polygons some specified coordinate pair falls—point-in-polygon would be used in a vector GIS to determine the attribute at a specified point, by first determining the geometric polygon that the point falls in, and then looking up the attribute in a database. Other basic GIS procedures include windowing (retrieving all objects within a user-defined subarea or "window") and various display procedures.

Algorithms are intimately intertwined with data structures. Algorithms for overlaying two layers are extremely simple for raster data sets using identical pixels, somewhat more complicated for specialized raster structures such as quadtrees, and very different and much more involved for vector data structures. Even within the same data structure, several different algorithms may be available to solve the same problem. One may be easiest to program, another fastest for average or typical data but occasionally very slow, and another fastest in a worst-case situation. In commercial GISs, algorithms are sometimes proprietary, making it difficult for users to know how answers to their commands or queries are being achieved.

2.2 Geographic Analysis and Spatial Statistics

Up to now, GISs have been used mainly in an inventory or archival role or in conceptually simple Boolean overlay analyses. However, much of the potential of GIS lies in combining the ability to handle large and complex data sets with sophisticated modeling and analysis techniques. Many analytical procedures were developed by geographers and other spatial analysts in the 1960s and 1970s, but were never widely applied because of problems with data availability and with applying the methods to very large data sets.

Geographic information systems offer the potential to bring these spatial analysis methods to users. Commercial GISs now often have "macrolanguages" or "tool boxes" that allow users to build and apply their own models. Soon, it is expected, vendors will begin to supply ready-made macros for common or user-requested analytical procedures. Network analysis methods can be applied to find minimum paths through networks of links and nodes, and can be incorporated into location–allocation models. Spatial decision support systems represent an important class of spatial analysis procedures that have much in common with GISs, but differ from typical GISs in the high capacity for user interaction, testing, and comparing of various scenarios, and ease of user-defined analytical models.

Spatial statistics are critical in at least two ways. In one case, they can be used to remove spatial effects in statistical models and to determine correlations and regressions that have had such spatial effects removed. [Otherwise, two autocorrelated or coherent spatial distributions will often have an apparently significant yet spurious positive (if peaks by chance coincide) or negative (if peaks are far apart) correlations.] Controlling for spatial autocorrelation effects is difficult in standard statistical packages and impractical in current GISs, but might be easier to incorporate into a GIS framework in the future. [See Griffith (1987) for an overview.]

Spatial statistics are of current practical importance in the area of error modeling and assessment (see ERROR ANALYSIS). Error in digital geographic data has often been ignored, but it has an obvious and important impact on the use of such data in decision making and in scientific research. Furthermore, GIS modeling may amplify errors or damp them out; sensitivity of GIS procedures to error, and error propagation through GISs, are important research topics. Recently, a book edited by Goodchild and Gopal (1989) has surveyed some of the critical issues.

2.3 User Interfaces and Human Factors

Any computer system is only as useful as its user interface, since that is the only way that the users can use it. In fact, Matthew McGranaghan of the University of Hawaii recently claimed in a conference presentation that, for the end user, the user interface *is* the system, since that is the only part that the user "sees." The interface must allow the user to pose commands and queries, and to get results of those commands and queries in a form consistent with what they had in mind when they asked. This requires that the user interface and the user be employing similar concepts of the problem and of the objects and operators involved.

Human-computer interaction (HCI) is the term used for a subfield of "human factors," which is concerned with evaluating how well people can use computers. It is part of engineering. *Computer-human interaction* (CHI) is the term most often used in computer science for a very similar subdiscipline. CHI represents the applied side of "cognitive science," a field which studies how humans conceptualize and reason about phenomena.

2.3.1 Forms of Human-Computer Interaction. The early days of computing required users to enter programs and data through the medium of paper tape. Many people in the GIS field began their computing experience with the next medium, punch cards (or "Hollerith cards"). Almost all computing in the late 1960s and early 1970s was "batch mode." Punch cards are almost obsolete, at least in North America and Europe, and at present and in the near future, five forms of human-computer interaction are important:

- **Command line interpreter.** This is the familiar method in which the user types commands at some prompt, and the computer then executes the command. If required parameters or arguments for the command are missing, the computer may prompt the user for them, or may give the user an error message. Almost always, each command is executed when complete (or when the user hits "return" or "enter"), and then the computer "forgets" it, requiring complete specification of the next command, even if many of the parameters or arguments are the same. Most systems require a "verb-object" syntax similar to commands or queries in English.

- **Form fill-in.** In this approach, the computer specifically prompts the user for each parameter or argument needed for the current command or query.
- **Menu selection.** Menus can be permanent on-screen features, or the now well-known "pull-down" menus of the Macintosh and many other systems. Either the cursor keys or a pointing device (such as a "mouse") is used to select from a menu of possible commands or actions. This method, and especially the pull-down form, has a certain element of direct manipulation, and often is combined with that method.
- **Direct manipulation.** In the direct manipulation approach, the user employs a pointing device (usually a mouse) to select, "grasp," and "move" objects on the screen. Such movements may rearrange directory structures, select files, execute procedures, redesign screen layouts, or create and edit images or text. Direct manipulation and menu selection also more easily lend themselves to "object-verb" syntax. (For example, on a Macintosh the user can first select a file icon, and then choose some command or operation to apply to it, such as "open.")
- **Natural language.** "Natural language" is a term used to refer to human languages such as Spanish, English, Hopi, Japanese, etc. (The modifier "natural" is inserted to distinguish them from computer languages such as Pascal, FORTRAN, C, etc.) Typed natural language is not a very practical method for HCI; however, with the advent of real-time speech-understanding systems, spoken natural language is likely to become a very important form of system interaction for GIS. Ideally, users will be able to express their needs through a combination of speech and gestures (pointing at items on CRTs, using a mouse, track ball, or touch-screen technology).

2.3.2 Who Are the "Users"? A final set of questions that are an important part of the research agenda for GIS involves the differences among current and potential users of GISs. What level of geographic knowledge and training should be assumed for the users? A system designed for "spatially aware professionals," such as geologists, urban planners, or foresters, could borrow concepts from cartography and from those disciplines. An ideal system for such users would probably be too complicated for a "citizen-scientist" to walk up to in a public library and use to enquire about an environmental or planning issue. But the "walk-up-and-use" system would probably be tedious for the professional to use. Furthermore, some of the simplification needed for the hypothetical walk-up-and-use system would be compensating for low computer knowledge and skills. How should level of computer knowledge and related skills interact with level of geographic knowledge in order to create an ideal user interface? And how does frequency of use influence the design? A person who uses a system 30–40 h per week as a GIS technician or operator would soon learn even the most cryptic commands; on the other hand, a person with high geographic and computer skills might still need a simple system, if he or she only used it for half an hour at a time, twice a month. Finally, a programmer's interface might be quite different from the interface for "end users."

This section presents more questions than answers. That reflects the author's opinion of the state of user interface research in GISs late in 1990. In the next decade, we can expect dramatic improvements in this area. Specialists in related disciplines will play an important role in tailoring the interface design to their field's view of the geographic world.

2.4 Social, Economic, Institutional, and Legal Issues

The introduction of any new technology raises a number of social, economic, institutional, and legal issues. Geographic information systems are no exception. The ability to use home addresses as a method for combining disparate databases leads to new potentials for modeling and planning on the one hand, and invasion of privacy on the other. GISs are being used to transfer census data to postal delivery zones, improving potential for targeted commercial mailings, often considered "junk mail" by recipients. GIS-related technology in redistricting can bring "gerrymandering" (manipulation of electoral districts to maximize the chances for selected candidates) to a whole new level of sophistication, but low-cost solutions can give the same power to manipulate to all political factions and special interests.

Much effort is currently being expended in attempts to determine how people actually use geographic information in decision making, and how the availability of computerized systems (GISs) changes that use. Then, it would be very useful to know the value that the information has in promoting better decisions, or in reducing risk associated with "wrong" decisions. One difficulty in using a cost-benefit analysis approach is that benefits often are unanticipated, and may even fall outside the organization's mandate.

Another set of concerns reflects the conceptual and technical issues of institutions sharing information. If two organizations or departments are not competitors, they might both gain from a sharing of information. However, neither organization may be willing to rely on the other for information critical to its own mission, and thus they might duplicate the data collection in order to remain in control. The situation is further complicated by the fact that organizations might develop different data models for what are essentially the same phenomenon. Thus, roads may be viewed as networks of links with capacities by a garbage-collection entity or a delivery fleet, but as polygonal regions with pavement types and ages by the road maintenance department. Lastly, different proprietary GISs often use different data structures, and exchange of data between different systems may be complicated.

In the area of legal issues, decision making always involves some risk of litigation if a "wrong" decision is reached. If a GIS is used together with commercial market research data to decide where to locate a retail outlet, and if the outlet then fails because the number of potential customers was much less than predicted, who would be liable—the GIS vendor, the data vendor, or the consulting firm that used both to come up with the recommendation? On the other hand, it may be more important in a trial to be able to document the decision-making procedures than to justify the result *per se*, and GISs may be extremely helpful in documenting how the decision was reached.

3. SUMMARY AND PROSPECTS

Maps will continue to play an essential role in the analysis of spatial data in the earth sciences, biology, the social sciences, and other areas. As computer systems such as GISs take over the data-storage function that maps have traditionally performed, graphic maps will remain important as visualization tools. Paper maps will continue to be important, but real-time mapping, involving animation, three-dimensional effects, and intense human-computer interaction, will gain in importance.

Geographic information systems (GISs) have much in common with maps and mapping, and indeed have cartography as a chief conceptual technical ancestor. However, as GIS matures, analytical capabilities will continue to grow, and mere storage, retrieval, and display of map data will receive less emphasis. Remote sensing and other advanced data acquisition techniques will, combined with GISs, computer mapping, and geographical visualization, lead to powerful tools for decision makers, planners, and scientists alike.

GLOSSARY

Chart: In modern English, a specialized map designed to support navigation by ships and aircraft.

Choropleth Map: A map which shows quantitative data for statistical units by filling each unit with a uniform color or pattern.

Conformal Projection: A map projection in which all angles on the Earth's surface are preserved on the map.

Data Model: A model of relevant aspects of the real world, which has been abstracted from that world in such a way as to retain those properties which are relevant to the current problem domain, and yet which can be implemented on a computer.

Data Structure: A detailed description of how a data model is implemented on a computer.

Developable Surface: A term in map projections for a surface that can be flattened without distortion; includes cones, planes, and cylinders.

Digital Elevation Model (DEM): A digital representation of topographic elevation, usually as a regularly spaced grid of heights, but also represented in other ways.

Equal-Area Map Projection: A map projection such that regions of equal area on the Earth's surface always have equal areas on the map projection, regardless of their shapes or locations.

Geographic Information System (GIS): A computer program or system of programs used for acquiring, storing, retrieving, analyzing, managing, and displaying geographic data and associated processes.

Isoline Map: A map which shows a phenomenon that can be considered to be a single-valued function of location in geographic space, using lines connecting points of equal value for the phenomenon. A contour is a special case of the isoline.

Map Projection: A formula or geometric construction procedure for transferring locational information from the spheroid which approximates the Earth's surface to a plane.

Pixel: In image-processing and raster GISs, a single element or cell in a digital image. It is a contraction of "picture element."

Quadtree: A spatial data model that divides an image into quadrants, and recursively divides each of these into subquadrants, keeping the structure either as a recursive tree of out-degree four, or through index numbers for subquadrants. Typically, in image analysis, the stopping criterion for recursive subdivision is uniformity of image values.

Raster Data Structure: In GISs, a data structure which represents geographic information as images composed of large numbers of small cells (pixels), usually of a uniform size and shape, and records geographic attributes for each cell. A "raster GIS" is one which employs this data structure.

Reference Map: A map which attempts to portray concrete, measurable features of the Earth's surface as accurately as possible for general purposes of locational reference and measurement.

Scientific Visualization: Techniques for the visual communication of scientific information to researchers, using computer graphics, animation, etc.

Thematic Map: A map which portrays the geographic distribution of one or a small number of variables to allow people to comprehend geographic patterns and distributions.

Vector Data Structure: In GISs, a data structure which represents geographic objects as digital versions of lines on maps, using sequences of coordinate pairs along boundaries and other lines. A "vector GIS" is one which employs this data structure.

Vehicle Navigation Aid (VNA): An in-car system that keeps track of the location of a vehicle and provides navigation assistance to the driver, either through maps or other means.

INTRODUCTION

A *catalyst* is a substance that increases the rate of a chemical reaction but is not consumed or permanently altered by the reaction. It will be obvious that increasing the rate of desired chemical reactions will have economic benefits for society. While it is not easy to quantify these precisely, it has been estimated that between 25% and 30% of all manufactured goods in the U.S.A. involve a catalyzed step, which suggests that the economic impact on our daily lives is very large indeed. Industrially, catalyzed reactions are very much dominated by heterogeneous catalysts: catalysts that are in a phase different from that of the reactants, most commonly a solid catalyst acting on fluid (gas or liquid) reactants. Heterogeneous catalysts have several advantages over other kinds of catalysts which are usually classified as either enzyme or homogeneous. Let us briefly discuss each kind before we return to our main topic which is heterogeneous catalysis.

1. KINDS OF CATALYSIS

1.1 Homogeneous Catalysis

As can be divined from the name, we expect that a homogeneous catalyst will be uniformly distributed in the reactant phase. There are many examples of gas-phase catalyzed reactions which are nearly uniform on a macroscale (meters to hundreds of meters) in stratospheric chemistry. Consider one that is relevant to the discussion of destruction of ozone in the stratosphere. Ozone is formed by UV radiation, which photolyzes molecular O_2 into atoms that then react with molecular O_2 to form the triatomic molecule O_3. In the absence of catalysis, the main reaction that converts O_3 back into molecular O_2 is the direct reaction with oxygen atoms:

$$O+O_3 \rightarrow 2O_2. \tag{1}$$

The formation and destruction of O_3 would establish some steady-state concentration which would only change if either the formation or destruction rates were changed. Such a steady state is established, but it results in a much lower concentration than would result from the two reactions so far mentioned, O_2 photolysis and reaction of oxygen atoms with O_3. This is the result of homogeneous catalysis of the latter reaction by oxides of nitrogen. Nitrous oxide, N_2O, is formed at ground level by natural biological activity. Because this molecule is rather inert in the troposphere, it diffuses into the stratosphere where it can be converted by UV radiation into nitric oxide, NO, a more active form which acts as a homogeneous catalyst for reaction (1) above:

$$NO+O_3 \rightarrow NO_2+O_2, \tag{2}$$

$$NO_2+O \rightarrow NO+O_2. \tag{3}$$

What should be noted here is that at steady state the rate of NO consumed in reaction (2) will be equal to the rate of NO production in reaction (3), and a similar statement can be made about NO_2. Thus NO (or NO_2) can be viewed as the catalyst here. However, there is a net consumption of both types of odd oxygen, i.e., atoms and O_3. Also, it should be appreciated that the rate of O_3 destruction by the set of reactions (2) and (3) is much faster than the direct reaction (1). This is a common fact of catalysis, i.e., more reaction steps which represent a more complex set than the uncatalyzed reaction can still be faster than the uncatalyzed reaction.

As an example of a commercial homogeneously catalyzed reaction, we can consider the Monsanto process for methanol carbonylation to acetic acid. Acetic acid is produced continuously by reacting methanol and CO in a liquid-phase homogeneous catalytic reactor using $[Rh(CO)_2I_2]^-$ as a catalyst. In the Monsanto process acetic acid is separated from the catalyst by distillation. The Monsanto process operates at low temperatures and pressures relative to earlier commercial processes.

1.2 Enzyme Catalysis

Enzymes are biological catalysts and might also be considered homogeneous since they are often uniformly distributed at least on the cellular level. However, their size (on the order of microns) puts them somewhere between homogeneous and heterogeneous catalysts. Also, the fact that they are biologically active proteins (amino acid polymers) which are sensitive to *p*H, temperature, solvent, etc., as is true of almost all biological material, distinguishes them from most heterogeneous catalysts, but less so from homogeneous catalysts, which are often metal organic complexes which might have similar thermal stability to that of enzymes.

An important commercial application of enzymes is as additives to synthetic detergents. This additive is protease or another hydrolase (an enzyme that catalyzes hydrolysis of various kinds) which breaks down a variety of fabric stains and aids in the solubilization of soil.

1.3 Heterogeneous Catalysis

Heterogeneous catalysts will be our main topic of discussion, but are introduced here primarily to allow a quick comparison of properties with homogeneous and enzyme catalysts. These catalysts are almost always solids and usually metals (e.g., Pt) or inorganic oxides (e.g., alumina). They are often combined, e.g., very small particles (of order of 10 Å) of Pt on high-area (of order of 100 m^2/g) alumina. The largest dollar use of heterogeneous catalysts at the present time is for the application to pollutant control of automobile exhaust. These catalysts are a combination of Pt, Pd, and Rh supported on a ceramic matrix (and often have other important components, e.g., ceria, BaO, etc.). These catalysts can effectively convert a wide variety of unburned hydrocarbons and CO to CO_2 and H_2O while also converting NO to molecular N_2. This application can be used to illustrate the advantages of heterogeneous catalysts over their homogeneous counterparts. First among these is the cost of separation of the reactants from the catalyst, which can be minimal for heterogeneous catalysts since the gas passes over the solid catalyst, reacts, and is displaced by incoming reactant (exhaust gas). Second is the fact that reactors can be designed to process huge flows. This is usually quantified in terms of a space velocity, defined as the volume of gas in units of the reactor volume that can be processed in a given time. Typically an auto exhaust catalyst has a hourly space velocity of 100 000, meaning that a volume of gas 100 000 times the size of the reactor is processed each hour, something that would not be possible for most homogeneous catalysts, which normally are dispersed in a liquid. Third, there is the harsh environment in which the catalyst must be stable. Typical exhaust catalysts experience temperature excursions that can reach 1000 °C and, by law, have to last 50 000 miles (soon to be increased to 100 000 miles). Most enzymes would have long been reduced to a char by the time the exhaust catalyst reaches its steady-state operating temperature of a few hundred degrees Celsius.

Finally, we should dispel the mistaken conception that enzymes catalyze reactions at rates that man-made heterogeneous catalysts cannot attain. The origin of this presumption is that we ask heterogeneous catalysts to operate at the same temperature at which enzyme action will be optimized, which is around ambient or somewhat above. But this is not a fair comparison because we should allow both catalysts to operate where they are near their optimum. Consider CO oxidation. For a stoichiometric mixture of CO and O_2, this will be about 600 K for Pd, when more than a quarter of all CO molecules that strike the Pd surface react. If we use a foil or gauze, the rate at which the CO molecules reach the Pd surface is limited primarily by molecular velocities over which we have not too much control. There are enzymes that catalyze this reaction, but they will be at a triple disadvantage if operated at their optimum conditions for a high rate. This will be a lower temperature, but the activation energies are comparable; thus the rate will be lower for reasons of thermal activation. Next, the enzyme will have to operate in some solvent through which the diffusion to the surface will be slower than in the gas phase. Finally, because of the large size of the enzyme, the number of active sites per unit area (defined later) will be small relative to that of the Pd surface where it appears that most atoms are active. However, the ground on which heterogeneous catalysts cannot compete with enzymes is specificity or selectivity, e.g., to hydrogenate a given double bond among many in a complex molecule.

2. HISTORY

Catalysts have been called the philosophers' stone of the alchemist, and perhaps for this reason the mysterious nature of catalysis was retained long after physical chemists began to study it (Burwell, 1983). In 1835 Berzelius surveyed several different kinds of chemical reactions—homogeneously catalyzed hydrolysis, heterogeneously catalyzed oxidation, and both homogeneously and heterogeneously catalyzed decomposition of H_2O_2—and designated the common agent in these reactions a catalyst. Unfortunately, he attributed the actions of these agents to a "catalytic force," an idea that did not disappear until the beginning of the twentieth century.

The oldest technological use of catalysis is surely related to the enzymatic catalysis involved in the fermentation for wine making and beer brewing. Even homogeneous catalysis, as practiced in the acid-catalyzed hydrolyses needed for the manufacture of soaps, predates industrial applications of heterogeneous catalysis since, apparently, the first technological application of a heterogeneous catalyst was as a spontaneous igniter of H_2 in the Döbereiner's Tinder Box, an early version of the modern flint lighter that was commercialized in the early part of the nineteenth century. Other industrial applications of heterogeneous catalysis for chemicals production were introduced in the second half of the nineteenth century with the oxidation of HCl to Cl_2 on $CuCl_2$ (the Deacon process) and the Pt-catalyzed oxidation of SO_2 to SO_3 in the manufacture of sulfuric acid.

The development of heterogeneous catalysis both scientifically and for industrial applications remained largely a European activity at the beginning of the twentieth century. Ostwald and Sabatier received Nobel Prizes for work on catalysis in 1909 and 1912, respectively, and Sabatier's work on catalytic hydrogenation had wide industrial applications. Haber's and Bosch's Nobel Prizes derived from the discovery and development, respectively, of the technical basis for the synthesis of ammonia from its elements, a process commercialized in 1913. It would be possible to outline almost all of the modern catalytic concepts by reviewing work on this catalytic reaction alone. One would not wish to discontinue the name dropping of Nobel Prizes for catalysis without mention of Langmuir, for several reasons. It is worth noting that Langmuir, while making very significant contributions to industrial catalysis, must be given primary credit for advancing new concepts and techniques in catalysis, e.g., the Langmuir isotherm and Langmuir kinetics, and that he did this work in an industrial laboratory while trying to make a better light bulb for General Electric.

Important modern applications of heterogeneous catalysis have occurred in the petroleum and petrochemical industry, and these were largely to be developed in the U.S. Since this brief historical sketch is necessarily very selective, we will focus on one class of catalysts, solid acids. Such catalysts are used for polymerization, alkylation, cracking, isomerization, and other important refinery reactions. Solid acid catalysts were the first kind of catalysts to be introduced into petroleum refining. Polymerization was the first commercial catalytic process introduced to the petroleum industry and initially utilized solid phosphoric acid formed by heating H_3PO_4 on kieselguhr (siliceous earth, SiO_2), a catalyst developed by V. N. Ipatieff at Universal Oil Products. However, catalytic cracking (the conversion of heavier petroleum hydrocarbons into lighter fragments, particularly in the gasoline boiling range) is the most important acid-catalyzed reaction and remains the largest volume use of heterogeneous catalysts yet today. Early but limited use of an $AlCl_3$ catalyst occurred in 1915. However, the modern process was developed and commercialized by the Houdry Process Corp. (with Socony-Vacuum, now Mobil, and Sun Oil Co.) in the decade of the 1930s with 1936 usually taken as the year of commercialization. The initial commercial catalysts were clays rich in silica and alumina and low in Na, Fe, Ca, and Mg impurities. By 1940 these were replaced by synthetic silica-alumina cracking catalysts that eliminated the variability in clay properties and produced less coke. A major discontinuity in technology resulted from the commercialization of zeolite cracking catalysts by Socony-Mobil Oil Corp. based on the work of Plank and Rosinsky. A zeolite is a crystalline silica-alumina with micropores and an ion-exchange capacity associated with each Al^{3+} in the tetrahedral framework. Plank and Rosinsky stabilized the zeolite (a faujasite structure called *Y*) by ion exchange of rare-earth metals and by distributing the zeolite crystallites in a matrix of silica-alumina. Such catalysts were commercialized in 1961.

Finally, let us return to the fact that catalysis is by definition a kinetic phenomenon in order to mention some names passed over up to this point. Bodenstein, a student of Ostwald, must be mentioned here, although his interpretation of the kinetics, i.e., the mechanism of catalysis involving multilayers that inhibited reaction, was discarded by Langmuir in favor of partial monolayers of chemisorbed molecules. We also must mention E. K. Rideal and H. S. Taylor, who published in 1919 the first comprehensive book on catalysis, *Catalysis in Theory and Practice* (1919). Finally, we cannot close without recognizing P. H. Emmett's work on the kinetics of ammonia synthesis and the BET (Brunauer, Emmett and Teller; see below) method for determining surface area.

3. ADSORPTION OF GASES ON SOLID SURFACES

For heterogeneous catalysis the term *adsorption* describes the accumulation of any particular substance on the surface of a solid, without penetration into the bulk, in a concentration which is higher than that in the bulk. In the particular case of adsorption on solid surfaces from the gas phase, the term refers to the process of a gas molecule (adsorbate) sticking on the solid surface (adsorbent) as a consequence of a collision. The term *desorption* describes the reverse process, i.e., the transfer of adsorbed molecules from the surface to the gas phase.

From a thermodynamic point of view, adsorption is almost always an exothermic process. This can be rationalized considering that the thermodynamic criterion for a spontaneous process requires that the free energy (ΔG) be negative. For most adsorption processes the entropy change (ΔS) is negative as the molecule proceeds from a disordered state in the gas phase to a more ordered state on the surface. Because $\Delta G = \Delta H - T\Delta S$, it follows that ΔH must be negative and its absolute value must be greater than $T\Delta S$.

3.1 Types of Adsorption

The magnitude of ΔH reflects the strength of adsorption and can be used to distinguish two different types of adsorption phenomena. These types are *physisorption*, or physical adsorption, and *chemisorption*, or chemical adsorption.

Physisorption can be considered as a condensation process. The ΔH values for this type of adsorption are about 2–5 kcal/mol, which is in the range of the heats of liquefaction. Physisorption is nearly independent of the nature of the solid surface, and because it is nonspecific, multilayers can form. The forces involved in the physisorption process are of the van der Waals type. The physisorbed molecule is not associated with any particular site on the surface. Thus, the physisorption can be used as a measure of the overall surface area of any solid. On the other hand, the values of ΔH for chemisorption processes are much higher and usually exhibit a much broader range than physisorption. Typical ΔH values for chemisorption range from 15 to 50 kcal/mol, which are of the same order of chemical bond energies. This indicates that chemisorption indeed involves the formation of surface chemical bonds. Consequently, adsorbates on the surface are generally considered to occupy localized *adsorption sites*. The nature of these sites can vary greatly and, in many cases, their exact identity and structure are unknown. An unoccupied site is symbolized by an asterisk (*), while an occupied site is symbolized by A^*, where A is the adsorbed molecule or molecular fragment.

3.2 Adsorption Isotherms

An adsorption isotherm is the constitutive relation which gives the amount of adsorbate on the surface in equilibrium with the pressure of the particular gas being adsorbed, at constant temperature.

The adsorption equilibrium is represented by

$$A + {*} \Leftrightarrow A^* \tag{4}$$

with an equilibrium constant $K_A = [A^*]/[\mathrm{A}][*]$, where the brackets imply concentration. If it is assumed that the rate of adsorption is proportional to the number of gas molecules colliding on vacant sites, then it can be written

$$r_{\mathrm{ads}} = k_{\mathrm{ads}} P_A (1 - \theta_A), \tag{5}$$

where r_{ads} is the adsorption rate, k_{ads} the adsorption rate constant, P_A the partial pressure of the adsorbing gas, and θ_A the fraction of occupied sites, or fractional coverage. Similarly, it can be assumed that the rate of desorption should be proportional to the fractional coverage. Thus,

$$r_{\mathrm{des}} = k_{\mathrm{des}} \theta_A. \tag{6}$$

At equilibrium, the two rates must be equal. Thus,

$$k_{\mathrm{ads}} P_A (1 - \theta_A) = k_{\mathrm{des}} \theta_A. \tag{7}$$

Consequently,

$$K_A = \theta_A / P_A (1 - \theta_A) \tag{8}$$

or

$$\theta_A = K_A P_A / (1 + K_A P_A). \tag{9}$$

This equation is the well-known Langmuir isotherm. Typical adsorption isotherms which have the Langmuir form are illustrated in Fig. 1.

When two different molecules, A and B, adsorb simultaneously on the surface and compete for the same adsorption sites, Eq. (9) changes. The corresponding isotherm becomes

$$\theta_A = K_A P_A / (1 + K_A P_A + K_B P_B). \tag{10}$$

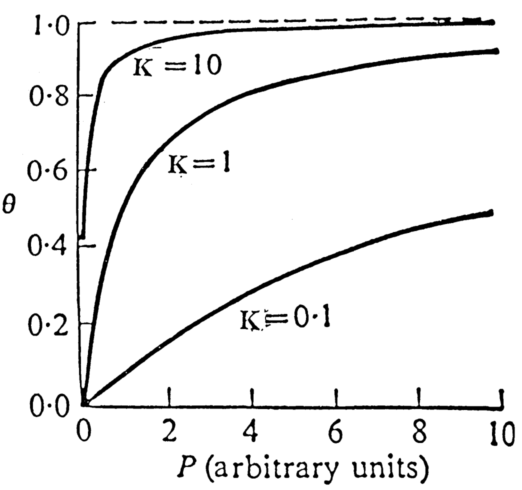

FIG. 1. Langmuir-type adsorption isotherms for different values of the equilibrium adsorption constant, *K* (Bond, 1987).

3.3 Dissociative Adsorption

Dissociative adsorption refers to the process by which the gas molecule dissociates on the surface during the adsorption. The chemisorption of hydrogen on metals is an example of dissociative adsorption. This process can be represented by

$$H_2 + 2^* \Leftrightarrow 2H^*. \qquad (11)$$

Figure 2 illustrates potential-energy curves as a function of distance from a metal surface for H_2 molecules and H atoms. A H_2 molecule, far from the surface, is taken as a reference for the zero potential energy. Both curves exhibit minima at particular distances from the surface, r_P and r_C. The depths of these minima reflect the strength of the adsorption processes. On the basis of the great differences typically observed for these depths, the adsorption of H_2 can be called physisorption while the adsorption of H can be called chemisorption. Accordingly, the values ΔH_P and ΔH_C, indicated in the figure, represent the heats of physisorption and chemisorption, respectively.

3.4 Thermal Desorption

The rate of desorption can be written in terms of an Arrhenius expression:

$$-d\theta/dt = \nu\theta^n \exp(-E_d/RT), \qquad (12)$$

where ν is the frequency factor, θ the surface coverage, n the kinetic order, and E_d the activation energy for desorption. By increasing the temperature of the sample with a linear heating program and monitoring the variation of θ with time it is possible to evaluate E_d and n.

It can be shown that when the sample chamber is evacuated at a pumping rate much higher than the desorption rate, the variation in surface coverage with time is proportional to the pressure inside the chamber. As the temperature varies linearly with time, plots of desorption rates (pressure) as a function of temperature (time) can be readily obtained. From the analysis of the variation in positions and shapes of the peaks in those plots, the kinetic parameters can be determined. Figure 3 illustrates temperature-programmed desorption (TPD) profiles for the desorption of hydrogen from tungsten. Four different peaks are clearly distinguished corresponding to different binding states, each one having different kinetic parameters. For example, β_1 corresponds to a first-order desorption and the position of the peak does not change with varying coverage. On the other hand, β_2 corresponds to a second-order desorption in which the peak shifts to lower temperatures as the coverage increases. Decomposition of the TPD curves into peaks requires appropriate assump-

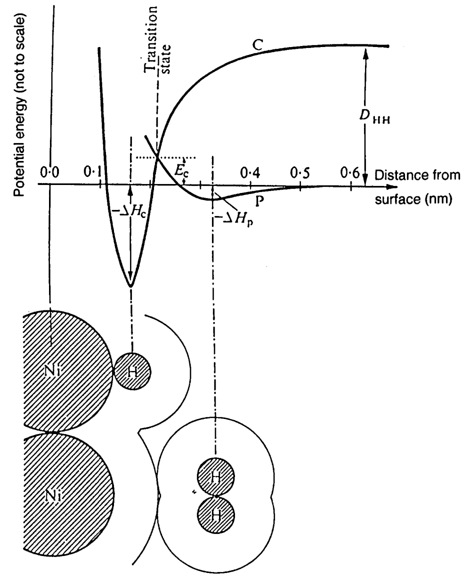

FIG. 2. Potential-energy curves for the adsorption of hydrogen on a metal surface (Bond, 1987).

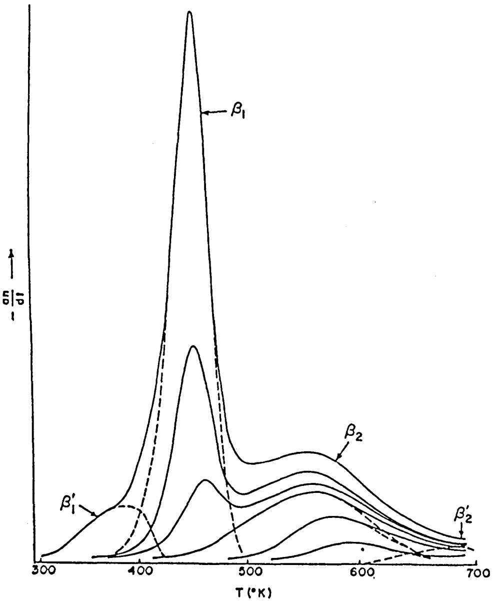

FIG. 3. A TPD sequence for successively larger amounts (curves from bottom to top) of H_2 adsorbed at 300 K on W (100) (Tamm and Schmidt, 1969).

tions. However, if both the coverage and rate of temperature change are varied over a wide range, the whole curve can be modeled and the frequency factor, kinetic order, and activation energy can be extracted without *a priori* assumptions.

4. TYPES OF CATALYTIC MATERIALS

Heterogeneous catalysts may adopt various forms. In many cases, such as in most petrochemical industrial processes, the catalytically active material is stabilized on a high–surface-area *support*. In other cases, unsupported and massive catalysts are used. For fundamental research purposes, catalytic chemists and surface physicists often use well-characterized, single crystals as models of catalysts.

4.1 Supported and High-Area Catalysts

When the catalytic reaction is not limited by mass transport to or from the surface, the rate of reaction is proportional to the surface area of the active phase. This can be maximized by making the particles of the active material as small as possible. To stabilize this small size it is very advantageous to support them on a high–surface-area material.

There is a wide range of materials which can be used as catalyst supports. The most commonly used are

- high-area amorphous silica (SiO_2), such as silica gels;
- alumina (Al_2O_3) in any of several metastable crystalline forms (γ, η, θ);
- titania (TiO_2) in its two most common crystalline forms, rutile and anatase;
- mixed oxides such as SiO_2-Al_2O_3;
- zeolites and natural clays;
- carbon;
- low-area monolithic supports made from metals or ceramic materials (cordierite, mullite, etc.)

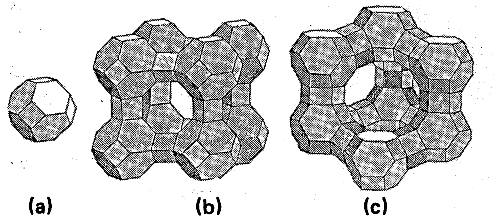
In some cases, the high–surface-area materials (zeolites, aluminas, etc.) may themselves be catalytically active. These are called high-area catalysts. In other cases, both the supported active material and the support participate in the catalytic reaction. This type of catalyst is called "bifunctional."

4.1.1 Supported Metal Catalysts. A large number of catalytic reactions use a metal as the active material. In general, *d* orbitals are involved in the adsorbate–metal bonding. Consequently, most catalytically active metals belong to the *d* transition series. Transition metals are used in oxidation, hydrogenation/dehydrogenation, reforming, hydrocracking, and synthesis reactions.

4.1.2 Supported Nonmetal Catalysts. Supported nonmetal catalysts have found a large number of industrial applications. Among them, transition-metal oxides, sulfides, and chlorides have been the most widely used. Transition-metal oxides are used in a number of chemical processes, such as selective and total oxidation, oxidative dehydrogenation, ammoxidation, and water-gas shift. Sulfides are used in hydrodesulfurization of petroleum. Among other reasons, the sulfur commonly present in crude oils has to be removed before entering the reforming processes because the catalysts used in that process are metallic and are poisoned by sulfur.

4.1.3 Amorphous Oxide Catalysts. Single oxides generally exhibit a degree of acidity which is too low for catalytic purposes. But binary oxide compounds may drastically increase the acidity and make the material catalytically active. This is the case of the silica-alumina system. The origin of the acidity is the bridging hydroxyl between Si and Al which is formed for charge balance. One can picture the formation of this site as the removal of tetrahedral Si, which is formally +4, and replacement by Al in the same tetrahedral position, but the Al is formally +3. There is a wide distribution of acidity of these sites in amorphous silica-alumina, and it has been shown that the acidity is affected by both the bond angles of the Si-OH-Al linkage and the distribution of ligands in the coordination spheres of Si and Al.

4.1.4 Zeolites. Zeolites are highly crystalline aluminosilicate materials of high surface area and well-defined structure. Some of these materials can be found as natural minerals. Examples of these natural zeolites are the faujasites and mordenite. In the last few decades, a great variety of synthetic zeolites have been prepared and used as adsorbents and catalysts. The basic unit of a faujasite is the sodalite cage tetrahedral units. This cubo-octahedral unit, shown in Fig. 4(a), is composed of SiO_4^{4-} and AlO_4^{5-}. The -4 charge on SiO_4^{4-} is balanced by bonding to four other tetrahedral Si or Al ions. The extra negative charge in the AlO_4^{5-} unit is balanced by positive ions, such as Na^+,K^+,Ca^{2+}, etc. From the sodalite unit different zeolites can be obtained. When the sodalite units are connected by their square faces they form a highly porous and regular array. This is called *A*-zeolite [Fig. 4(b)]. The size of the opening depends on the cations balancing the negative charge, i.e., 0.3 nm for K^+, 0.4 nm for Na^+, 0.5 nm for Ca^{2+}. On the other hand, when the sodalite units are connected by their hexagonal faces, a structure containing large cages joined by smaller openings results. Depending on the silica/alumina ratio in the material, the resulting zeolites are called *X* (silica/alumina 1.5) or *Y* (silica/alumina 1.5 to 3).



(a) (b) (c)

FIG. 4. Zeolite structure (Bond, 1987): (a) Cubo-octahedral unit of faujasite zeolites; (b) *A*-zeolite structure; (c) *X*- and *Y*-zeolite structures.

Zeolites exhibit a great variety of possibilities as catalytic materials. They can be designed with precise control of acidity and structure. The density and strength of acid sites can be varied by exchanging the zeolites with different cations. The dimensions of the pore openings are of the same order as molecular sizes, and so shape and size selectivity can also be readily affected by proper cation exchange.

4.2 Unsupported Catalysts

Although in most cases, it is more convenient to have the active species of a catalyst supported on a high–surface-area material, sometimes unsupported catalysts can be used. For example, the Raney nickel catalysts are unsupported Ni prepared from Ni-Al alloys by leaching the Al out with NaOH to make a porous metal. This catalyst is used to hydrogenate vegetable oil and in the production of fine chemicals.

Also, unsupported colloidal platinum of relatively uniform size (about 1.5 nm) has found interesting applications, particularly as a model catalyst. However, the most widely used unsupported metal catalyst is not in the form of particles, but metallic gauzes. This type of catalyst is used, for example, in nitric acid plants for the oxidation of ammonia. In this and most similar applications, the reaction temperature is very high, and essentially every molecule that strikes the catalyst surface reacts. Thus, high area, which is always accomplished by porosity, will not improve the conversion because the transport into the pores would limit the rate for such fast reactions.

4.3 Single-Crystal Catalysts

In many fundamental studies, single-crystal model catalysts have been used. The advantage of these catalysts is that the composition and structure of the surface can be readily determined and controlled. They can be analyzed under ultrahigh-vacuum conditions, minimizing the presence of impurities or undesired adsorbates. In addition, they can be studied by physical characterization techniques such as x-ray photoelectron spectroscopy (XPS), Auger-electron spectroscopy (AES), low-energy electron diffraction (LEED), or electron energy-loss spectroscopy (EELS), which can determine surface composition, symmetry, and molecular vibrations. Single-crystal surfaces are identified in terms of the Miller indices of the exposed planes. Figure 5(a) shows the arrangement of atoms on the surfaces of a face-centered-cubic metal for the particular indices (100), (110), and (111). In other cases the surface exhibits defects such as those illustrated in Fig. 5(b): steps, kinks, ledges, vacancies, etc.

5. PREPARATION AND CHARACTERIZATION OF HETEROGENEOUS CATALYSTS

5.1 Preparation

In the preparation of supported catalysts the following sequence of steps is usually followed: (a) incorporation of the active components on the support, (b) drying, and (c) thermal activation.

5.1.1 Incorporation of the Active Components on the Support. There exist several practical methods for incorporating the precursors. The most widely used are the following.

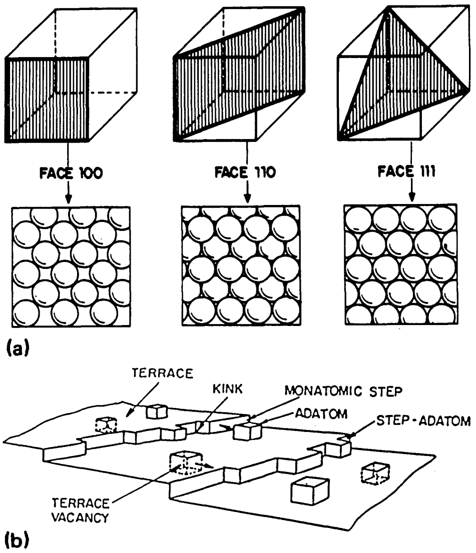


FIG. 5. (a) Ideal fcc metal surfaces for (100), (110), and (111) planes (Le Page, 1987). (b) Typical defects commonly present on metal surfaces (Boudart and Djega-Mariadassou, 1984).

5.1.1.1 Impregnation. The support is impregnated with a solution (usually aqueous) containing the ions of the active species. The solvent is evaporated, and the precursors deposited. After the proper thermal treatments, small particles are formed. The size of these particles strongly depends on the concentration of the impregnating solution. When the volume of the solution used does not exceed the pore volume, the method is called "incipient wetness impregnation."

5.1.1.2 Adsorption from Solution. The oxide supports usually have a relatively high surface density of hydroxyl groups. Depending on the nature of the oxide and the solution in which it is immersed, these hydroxyl groups can be exchanged with charged species from the solution. In this way, cation adsorption takes place when surface H^+ are exchanged with cationic species, e.g.,

$$\mathrm{MOH}+C^+\rightleftarrows\mathrm{MO}C+\mathrm{H}^+. \tag{13}$$

The analogous anion exchange involves the adsorption of H^+ and the anionic species. This process can be described as

$$\mathrm{MOH}+H^+ +A^-\rightleftarrows\mathrm{MOH}_2A. \tag{14}$$

In either case, the precursors are incorporated in a highly dispersed state. After the thermal treatment, the resultant particles deposited on the support are very small.

5.1.1.3 Precipitation. The solution containing the active species, usually in the form of nitrate, chloride, or sulfate, is contacted with an alkali solution to cause precipitation of the active species in the form of a metal oxide or carbonate on the support.

5.1.2 Drying and Calcination. During the drying step the precursors crystallize on the surface of the support. The rate of drying must be carefully controlled. When drying is too fast nonuniform distribution of the active phase may occur. During the calcination the crystallized salt is decomposed and dispersed oxide particles are formed which tend to wet or bind to the support surface.

5.1.3 Thermal Activation. The thermal activation is the final step in producing the active species on the support surface. Depending on the nature of the catalyst being prepared, the thermal activation can be an oxidation in O_2 (oxide catalysts), a reduction in H_2 (metal catalysts), a treatment in mixtures of H_2S/H_2 (sulfided catalysts), HCl/O_2 (oxychloride catalysts), etc.

5.2 Characterization

The importance of catalyst characterization can be analyzed from several points of view. In the first place, to understand the microscopic processes and reaction mechanisms taking place on the surface of heterogeneous catalysts, a detailed knowledge of their structure, composition, and properties is absolutely necessary. Also, from the practical point of view, in the development of effective and reproducible catalyst preparation methods, structure and composition of the catalysts during the different stages of the process must be known. Some of the most commonly used characterization techniques are listed in Table 1.

Bulk composition can be determined by dissolution and analysis of the solution by atomic absorption (AA) spectroscopy. But the determination of surface composition is less straightforward since it strongly depends on the surface sensitivity of the particular analytical technique being used. Two of the most widely used techniques for surface analysis are x-ray photoelectron spectroscopy (XPS) and Auger-electron spectroscopy (AES). In both techniques electrons are ejected from the sample after being excited by a photon or an electron source, respectively. In the case of XPS the kinetic energy of primary photoelectrons is measured, while for AES, that of secondary Auger electrons is measured. From the intensities of the observed peaks and with differences in excitation cross-sectional values for each element taken into account, a surface composition can be derived by both techniques. Because of the variation of the elastic mean free path of electrons in solids as a function of kinetic energy, the surface sensitivity of XPS is significantly lower than that of AES.

In the case of supported metal catalysts, the fraction of exposed metal atoms is a very important parameter that can be determined by selective chemisorption. Hydrogen, CO, and oxygen selectively chemisorb on most

Table 1. Most common techniques employed in catalyst characterization.

Technique	Information Provided
Gas adsorption	Surface area Exposed metal area
Mercury porosimeter	Pore size distribution
Temperature–programmed reduction (TPR)	Reducibility of metal particles Metal-support interactions Metal-metal interactions
Differential thermal analysis (DTA)	Heats of adsorption
Infrared spectroscopy (IR)	Nature of adsorbed species and reaction intermediates
X-ray diffraction (XRD)	Crystallinity Phases present Particle size
Electron microscopy (TEM, SEM, STEM)	Particle sizes and shapes Texture
Electron spectroscopies (XPS, AES)	Surface composition Electronic interactions Oxidation states
X-ray absorption (EXAFS, XANES)	Coordination number Oxidation states Electronic interactions
Atomic absorption (AA)	Bulk composition

metals at room temperature. As chemisorption occurs into a monolayer, the exposed metal fractions can be immediately determined after the measurement of saturation uptakes, provided that the metal content and the adsorption stoichiometry are known. In most metals, hydrogen adsorbs with a stoichiometry H/M of about 1/1. On the other hand, CO frequently exhibits a range of stoichiometries. For example, Fig. 6 illustrates an IR spectra of CO adsorbed on Rh. The band at 2070 cm^{-1} corresponds to linearly adsorbed CO (stoichiometry 1/1), the doublets at 2101 and 2031 cm^{-1} are due to gem dicarbonyl species (stoichiometry 2/1 with Rh oxidized to Rh^+), while the broad band at about 1870 cm^{-1} corresponds to multiply bonded bridge form (stoichiometry 1/2, 1/3, or even 1/4).

On the other hand, physisorption of an inert gas, such as N_2, Ar, or Kr, at low temperatures can be used to determine the total surface area of the catalysts. Physisorption is a nonselective process and therefore takes place over the entire solid surface. The BET method (Brunauer-Emmett-Teller model for the relation between amount adsorbed and pressure) provides reproducible values of overall surface areas and is universally used.

Direct observation of metal particles can be achieved by transmission electron microscopy (TEM). A typical TEM micrograph is shown in Fig. 7, for a Pt-Sn/Al_2O_3 reforming catalyst. The metal particles appear as dark spots over a light background. This technique allows one to obtain not only an average particle size, but also particle size distributions. Particles of the order of 0.5–1 nm in size can be observed.

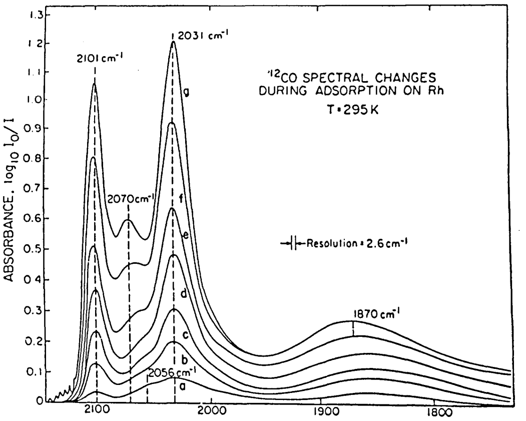

FIG. 6. IR spectra for CO adsorbed on Rh at increasing surface coverages (Yates *et al.*, 1979).

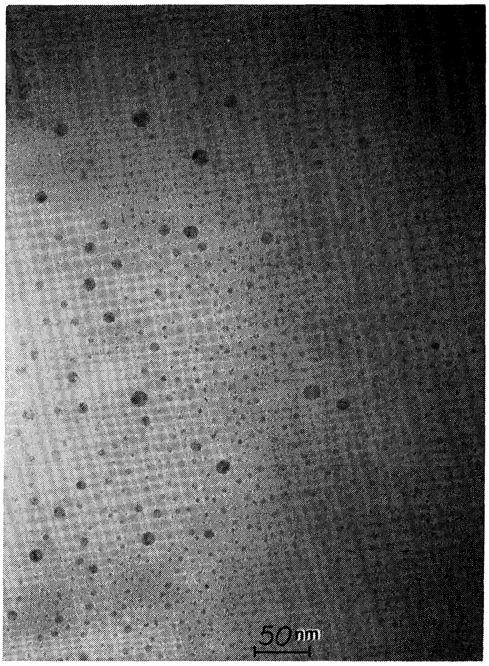

FIG. 7. Electron micrograph of a supported bimetallic Pt-Sn reforming catalyst. The metallic particles appear as well-defined dark spots, contrasting with the light background of the oxide support (Srinivasan *et al.*, 1991).

6. KINETICS OF HETEROGENEOUS CATALYTIC REACTIONS

6.1 Elementary Steps

The catalytic reactions on solid surfaces generally comprise the following sequence of steps:

1. diffusion of reactants to the surface,
2. adsorption,
3. surface reaction,
4. desorption,
5. diffusion of products from the surface.

Any one of these steps may be slow enough to become rate limiting. If steps 1 or 5 limits the rate, the reaction is said to be transport limited. If any of the other steps involving chemistry limit the rate, this chemical step would be called the rate-determining step (RDT; Boudart and Djega-Mariadassou, 1984).

6.1.1 Unimolecular Reactions on Surfaces. If a reactant A adsorbs and reacts on a catalytic site (*), the following set of elementary steps can be written:

1. adsorption; $A + * \rightarrow A*$
2. desorption; $A* \rightarrow A + *$
3. surface reaction; $A* \rightarrow$ Products.

If the surface reaction is much more rapid than the rates of adsorption and desorption, the reaction rate will be determined by the rate of adsorption. On the other hand, if the surface reaction is slow compared with adsorption-desorption, then steps 1 and 2 can be considered in quasiequilibrium and the reaction rate will be determined by step 3. Thus,

$$r = k_S \theta_A, \tag{15}$$

where k_S is the surface reaction coefficient and θ_A is the fractional coverage in equilibrium with the concentration of A in the gas phase. Then

$$r = k_S K_A P_A / (1 + K_A P_A). \tag{16}$$

At low concentrations of A in the gas phase, $1 \gg K_A P_A$. Then Eq. (16) becomes

$$r = k_S K_A P_A \tag{17}$$

and the reaction order is one.

The surface reaction coefficient, k_S, can be written in an Arrhenius form as

$$k_S = A_0 \exp(-E_S/RT), \tag{18}$$

A_0 being the preexponential factor and E_S the activation energy for the surface reaction, and K_A as

$$K_A = \exp(-\Delta G/RT)$$
$$= \exp(\Delta S/R) \exp(-\Delta H_A/RT), \tag{19}$$

where ΔG_A, ΔS_A, and ΔH_A are, respectively, the changes in free energy, entropy, and enthalpy for the adsorption of A. Then Eq. (17) can be written as

$$r = A_0 P_A \exp(-E_S/RT) \exp(\Delta S/R)$$
$$\times \exp(-\Delta H_A/RT), \tag{20}$$

which can be rearranged to give

$$r = A' \exp[-(E_S + \Delta H_A)/RT]. \tag{21}$$

Then, the activation energy determined experimentally would not be the true activation energy, E_S, but rather an apparent activation energy,

$$E_{\text{app}} = E_S + \Delta H_A. \tag{22}$$

As described in Sec. 3, in most cases $\Delta H_A < 0$. Then, E_{app} can be expressed in terms of the absolute value of the heat of adsorption, λ_A:

$$E_{\text{app}} = E_S - \lambda_A. \tag{23}$$

On the other hand, at high concentrations of A, $1 \ll K_A P_A$. Then

$$r = k_S. \tag{24}$$

In this case, the reaction order is zero and $E_{\text{app}} = E_S$. Table 2 summarizes rate expressions and apparent activation energies for bimolecular reactions for different heats of adsorption of reactants.

7. MECHANISMS OF HETEROGENEOUS CATALYSIS

There are different levels of sophistication with regard to description of mechanisms of heterogeneous catalysis (Haller and Delgass,

Table 2. Rate expressions and apparent activation energies for bimolecular reactions.

$\Delta H_{\text{ads}}(A)$	$\Delta H_{\text{ads}}(B)$	r	E_{app}
Moderate	Moderate	$\dfrac{k_{SA}k_{SB}K_AK_BP_AP_B}{(1+K_AP_A+K_BP_B)^2}$	
High	Low	$\dfrac{k_{SA}k_{SB}K_BP_B}{K_AP_A}$	$E_S-\lambda_B+\lambda_A$
Low	Low	$k_{SA}k_{SB}K_AK_BP_AP_B$	$E_S-\lambda_B-\lambda_A$
Low	Low (inhibitor X strongly absorbed)	$\dfrac{k_{SA}k_{SB}K_BP_BP_AP_B}{(K_XP_X)^2}$	$E_S-\lambda_B-\lambda_A+2\lambda_X$

1986). The most elementary mechanism is a sequence of elementary steps that accomplishes the overall reaction. As an example, we can consider the oxidation of CO catalyzed by noble metals,

$$CO+{*}\leftrightarrow{*}CO, \tag{25}$$

$$O_2+2{*}\rightarrow 2{*}O, \tag{26}$$

$${*}CO+{*}O\rightarrow CO_2+2{*}. \tag{27}$$

Here, we have assumed that CO is *associatively* and *reversibly* absorbed and O_2 is *dissociatively* and *irreversibly* adsorbed at the reaction temperature. Irreversibility implies a negligible rate of desorption at the given temperature; there will always be a finite probability of desorption which will become rapid with sufficient increase in temperature. It is likely that the second step in this mechanism is more complicated than indicated since there is good evidence that O_2 initially adsorbs as a molecular *precursor* to dissociative chemisorption. This is an elementary mechanism, i.e., a hypothesis of how the reaction occurs, but it leaves out a lot that we know or would like to know. At the next level we would like to know something about the details of the bonding of the intermediates to the surface and the energetics of this bonding. For example, from infrared experiments we know that the predominant chemisorbed species is a linear bonded CO on small Pt particles, e.g., Pt–CO, bonded through carbon, but that on Pd particles CO is likely to be bridge bonded, e.g., Pd_2CO. Note that we are suggesting the beginning of structure about the site where CO is chemisorbed, but it is not very definite, and at temperatures where this reaction occurs at maximum rate, this detail might not be important since the rate of diffusion is rapid and there may not be a particular bonding structure of the CO intermediate. This may be one reason why this reaction appears to be *structure insensitive,* i.e., occurs at the same rate on different crystal planes of Pt, Pd, Rh, etc., or different metal particle sizes. Not all reactions are so structure insensitive. For example, CH_3–CH_3 hydrogenolysis to CH_4 is *structure sensitive,* i.e., it occurs at different rates on different metal crystal planes or on different particle sizes. It should also be appreciated that in the above elementary mechanism the sites for CO and for oxygen-atom chemisorption, while both are represented by *, are not the same. On the high-density Pt surfaces, we know from LEED that the oxygen atom sits in a threefold hollow of Pt atoms.

Perhaps the most sophisticated mechanism description that we can aspire to is one in which not only do we know the structure of intermediates and the sites to which they are bonded as well as the bond energies, but we also have comparable information about the activated complex. If we have such detailed information about the motion of the atoms as they form the activated complex from reactants and decompose into the products, along with the potential energies between the activated complex and the surface, we can say that we understand the *dynamics* of the reaction. This implies that we know how the energy between the top of the barrier to reaction (the activated complex) and the ground state of the product (in the gas phase if it is not chemisorbed, the case for the CO_2 product for the above reaction) is distributed between the surface and the product; that we know how that energy carried away by the product molecule is distributed between translation, rotation, vibration, and electronic excitation; that we know the angular dependence of the desorption trajectories, etc. Such a complete mechanism is not known for any reaction, but considerable progress toward this goal has been made for chemisorption of some simple molecules, e.g., CH_4 on metals, and for the CO oxidation on Pt that we have been discussing.

8. CHEMICAL ENHANCEMENT/ POISONING OF CATALYTIC ACTIVITY

8.1 Catalyst Promoters

A catalyst promoter is any substance which, although it has no catalytic activity by itself, when added to a catalyst improves the activity, selectivity, or stability. The nature of promoter action can vary widely. Some examples of catalyst promoters are given in Table 3. The improvement of catalytic properties by the addition of a promoter may be due to

- increase in activity of the catalyst by modification of the electronic or geometric structure of the active site;

Table 3. Some catalyst promoters and their functions.

Promoter	Function
Re	Decreases catalyst coking in reforming processes
S	Decreases hydrogenolysis in reforming processes
HCl	Increases acidity of the support in reforming catalysts
K	Increases selectivity towards longer-chain hydrocarbons in CO hydrogenation reactions
K_2O	Increases rate of N_2 dissociation in ammonia synthesis on Fe
KCl	Increases reaction rate and stability of $CuCl_2$ catalysts in oxychlorination reactions
Al_2O_3	Prevents sintering of Fe in ammonia synthesis catalysts and stabilizes activity
Cl_2	Increases selectivity in ethylene oxidation on Ag catalysts

- increase in catalytic activity by creation of new sites;
- increase in selectivity towards desired products by selective deactivation of undesired paths;
- interaction of the promoter with the reaction intermediates modifying their energetics;
- stabilization of particular surface species.

8.2 Catalyst Poisons

A catalyst poison is any substance which makes the catalyst lose activity (Butt and Petersen, 1988). In general, a poison is an adsorbate which reacts permanently with the active site (strong adsorption). A poison can be introduced in the catalyst itself or in the reactant feed. Metal catalysts are very sensitive to poisons. Metal poisons can be metallic or nonmetallic. In both cases, the degree of toxicity depends on the ability of the *d* orbitals of the catalyst to interact with those of the poison. For example, the presence of small quantities of sulfur may rapidly deactivate a catalyst by formation of surface sulfides. Also, oxygenated compounds (air, water, carbon dioxide) may act as poisons for metal catalysts. Poisoning of acid catalysts can be explained in terms of the basicity of the poison. For example, a strongly basic organic molecule, such as quinoline, has a much higher toxicity for acid catalysts than aniline, a weaker basic molecule.

A special type of poisoning which is very frequently encountered in catalytic reactions is called self-poisoning. In this case, the poisoning is caused by the reaction itself. The reactants, the products, or the reaction intermediates may act as precursors of poisoning. The most common type of self-poisoning is known as *coking*. This is a general term which describes the deposition of carbonaceous deposits onto the catalyst surface, causing a decrease in activity. However, not all of the carbonaceous deposits have the same deactivating effects. Some authors distinguish between "soft coke" (high H/C ratio) and "hard coke" (low H/C ratio). The former can be considered as a strongly dehydrogenated hydrocarbon deposit while the latter has a pseudographitic structure.

In continuous operation, the activity loss due to coke formation has to be overcome by an increase in the operating temperature. When this temperature is too high, the catalyst must be regenerated by burning off the coke. Coke may not only affect the activity of a catalyst, but it may also affect selectivity. In general, structure-insensitive reactions, e.g., dehydrogenation, hydrogenation, are less affected by coke than structure-sensitive reactions, e.g., hydrogenolysis.

9. HETEROGENEOUS CATALYTIC REACTORS

There exist several criteria by which we classify reactors. For example, according to the mode of operation they can be classified as batch, semibatch, or continuous. According to the flow pattern used, they can be of the plug flow type, perfect mixing type, or intermediate. Plug flow (characterized by the fact that the flow of fluid is so ordered that no element of fluid mixes with another element ahead or behind it) or perfect mixing (mixing of elements of fluid on the molecular level) flow patterns are called "ideal" in the sense that the flow can be completely described on a molecular level. Although they cannot exactly describe the behavior of real reactors, they make possible a simple and relatively accurate mathematical treatment that approximates many real reactors.

A large number of heterogeneous catalytic reactors have flow patterns which can be described as plug flow. Among them we can find fixed-bed and moving-bed reactors. Fixed-bed reactors are the catalytic reactors most commonly found in industrial operations. They cover a large variety from packed-bed reactors, such as those used for naphtha reforming, to catalytic wall reactors, such as the catalytic converters used for controlling automobile exhausts. Among the fixed-bed type, we can also mention the metal gauze reactors, such as those used for the oxidation of ammonia in nitric acid plants. Another type of fixed-bed reactor is the trickle bed. As opposed to the previously mentioned reactors, in this case the reactants are in both the liquid and the gas phase, e.g., a liquid olefin being hydrogenated on a solid catalyst.

Moving-bed reactors find many applications in those cases in which the catalyst loses activity very rapidly and has to be continuously reactivated. In moving-bed reactors, the catalyst is continuously drawn off, regenerated, and reinjected. An example of these reactors is the Thermofor (bead moving bed) catalytic cracking process in petroleum refining.

Fluidized-bed reactors have a very complicated flow pattern and cannot be described as plug-flow reactors. They are frequently used to improve heat or mass transfer and also when the catalyst has to be continuously regenerated. Examples of these type of reactors are found in oxidation, oxychlorination, ammoxidation, and catalytic cracking processes.

10. INDUSTRIAL CATALYTIC PROCESSES

Catalysts play an essential role in many chemical, petrochemical, and petroleum refining processes. Some industrially important catalytic processes are summarized in Table 4.

10.1 Pollution Control

The abatement of nitrogen oxides (NO_x), carbon monoxide (CO), and unburned hydrocarbons is carried out on catalytic converters. These catalytic devices are used for both industrial operations (stationary sources) and automobile exhausts (mobile sources). The conditions to be met by these catalytic devices are indeed rigorous. They should be able to remove carbon monoxide, hydrocarbons, and NO_x at very high spatial velocities, reaching conversions close to 100%. They should resist cyclic variations in temperature and gas composition, maintaining their activity for at least 50 000 miles or five years, without regeneration. Since emissions are higher when the engine is cold, the catalyst should be effective at the lowest possible temperature.

10.2 Selective Oxidation

Catalytic reactions involving hydrocarbons and oxygen are frequently found in industrial processes. They can be classified into total oxidation, selective (partial) oxidation, ammoxidation, oxychlorination, oxidative coupling, and oxidative dehydrogenation. Among the numerous selective oxidation reactions found in the petrochemical industry, we can mention the production of (a) ethylene oxide by oxidation of ethylene over promoted silver catalysts at temperatures below 250 °C, (b) acrolein by oxidation of propylene over bismuth molybdate catalysts, (c) maleic anhydride by oxidation of butadiene over vanadium oxide catalysts, etc.

10.3 Cracking

The conversion of large molecules present in crude oil into smaller hydrocarbons in the gasoline range is called cracking. Cracking processes were originally noncatalytic, but after the development of highly efficient catalysts, most of them were rapidly switched to the catalytic alternative. The cracking reac-

Table 4. Some industrially important catalytic processes.

Process	Main reactions	Catalysts used
Air pollution control	Oxidation of CO, unburned hydrocarbons NO_x reduction	Pt-Pd-Rh/monolithic supports
Ammonia synthesis	$1/2N_2+3/2H_2 \rightarrow NH_3$	Fe promoted with alkali, alumina, etc.
Cracking	Cracking of larger paraffins, naphthenes, or olefins to smaller olefins Dealkylation of alkylaromatics Isomerization of olefins Condensation of alkylaromatics	Solid acids (zeolite crystals in silica-alumina matrix)
Oxidation	Total oxidation Selective (partial) oxidation Ammoxidation, oxychlorination Oxidative coupling Oxidative dehydrogenation	Platinum, bismuth molybdate, vanadium oxide, copper chloride, multicomponent oxides, chromia-alumina
Polymerization	Small olefins to polymers (polyethylene, polypropylene, etc.)	Transition-metal salts (Ti, V, Cr, Mg, etc.) and metal alkyls of Al
Reforming	Dehydrogenation of cyclohexane Isomerization of *n*-alkanes Dehydroisomerization of alkylcyclopentanes Dehydrocyclization of alkyls Hydrogenolysis of alkanes	Pt promoted with Re, or Ir, supported on chlorided alumina

tions involve the rupture of C–C bonds and mainly proceed through surface carbenium-ion intermediates on acid sites. The improvement of the activity of the catalysts over the years, as a consequence of intense research work in the field, has helped to reduce the size of the cracking reactors. The cracking process is carried out at temperatures about 550 °C in a riser-tube reactor. In that tube, the feed contacts the catalyst for a short time (about 5 s). During that time, high conversions are reached while the catalyst rapidly loses its activity through coke formation. Subsequently, the catalyst is separated and regenerated in a fluidized-bed reactor where the coke is burned off. The cracking process does not produce gasoline with a sufficiently high octane number to meet the market demands. To obtain a higher octane number the concentration of aromatics and branched alkanes must be increased. This is accomplished in a catalytic process known as naphtha reforming.

10.4 Reforming

The reforming catalysts contain small amounts of platinum, or a combination of platinum with rhenium, tin, or iridium, supported on an acidic alumina carrier. In these catalysts, the support plays a decisive role since it participates in the reactions, providing the acid sites on which some of the reactions occur. The hydrogenation/dehydrogenation reactions occur on the metallic sites, while the molecular rearrangement takes place on the acid sites. The catalysts are therefore called *bifunctional.* The reforming process is carried out in a series of fixed-bed reactors at temperatures about 450–500 °C and pressures between 10 and 35 atm.

11. SUMMARY

Heterogeneous catalysis is an interdisciplinary field involving the efforts of chemical engineers, material scientists, chemists, physicists, etc. This is so because it is an applied science which is advanced by an understanding of chemical reactions at the molecular level on well-defined surfaces (e.g., single crystals) and which is practiced in reactors that are from fractions of a meter to tens of meters in length, e.g., a refinery. We have briefly surveyed some of the fundamentals and outlined a sampling of applications, mostly related to petroleum processing.

It should be repeated that catalysis is by definition a chemical kinetic phenomenon and, as such, must be considered in any chemical reaction. It is very likely that catalysis will have been introduced either in a Darwinian way in nature or by empirical optimization by man. In either case, it will be the goal of the catalytic scientist both to try to understand the fundamental chemistry and to improve on the existing catalyst. It is generally agreed that these two goals are strongly coupled, i.e., if we understand a catalytic reaction on a molecular mechanistic level, we will then have the basis for designing an improved catalyst.

GLOSSARY

Adsorption: Accumulation of any particular substance on the surface of a material without penetration into the bulk of the material, in a concentration which is higher than that in the bulk fluid. The term associative adsorption indicates that the molecule adsorbs without undergoing decomposition. Dissociative adsorption indicates that the molecule dissociates on the surface upon adsorption.

Adsorption Site: A particular location on the solid surface where the adsorption is more probable to occur.

Bifunctional Catalysis: Catalysis that involves different functions on different sites which are physically separated: a metallic function such as hydrogenation/dehydrogenation, and an acid function such as olefin structural isomerization.

Catalyst: A substance which accelerates a chemical reaction but is not consumed or permanently changed during the process.

Chemisorption: Adsorption process involving enthalpy changes of the order of chemical bond energies.

Coke: A carbon-rich deposit formed on the surface of a catalyst by hydrocarbon reactants/products. It does not have a well-defined stoichiometry or molecular weight.

Desorption: Evolution of an adsorbate from the surface to the gas phase.

Elementary Step: A reaction step written as it takes place at the molecular level.

Physisorption: Adsorption process involving enthalpy changes of the order of liquefaction heats.

Plug Flow: Ordered flow characterized by the fact that for any given element of fluid, no element ahead of or behind it becomes mixed with it.

Precursor State: Intermediate state in the adsorption process in which the adsorbing molecule has lost one degree of freedom compared to the gas phase but does not yet occupy a localized adsorption site.

Reversible or Irreversible Adsorption: These terms distinguish adsorption processes in which the adsorbate desorbs (reversibly) or stays on the surface (irreversibly) upon lowering of the gas partial pressure over the solid surface.

Support: A generally inert material of high surface area used to stabilize high dispersions (small particle size) of the active phase. In some cases it may participate in the reaction (see bifunctional catalysts).

Structure Sensitivity: Effect of particle size or crystallographic plane of the catalyst on the turnover number (TON) of a particular reaction.

Turnover Number (TON): Specific rate of a catalytic reaction expressed as the number of molecules reacted per active site in unit time.

INTRODUCTION

Push on something. It will move. Push just a little bit harder and it will move just a little bit more. This incremental response to incremental stresses is very typical. But under rare conditions a small increase in the level of stress will produce a large and dramatic response. Such a response is called a "catastrophe." This kind of behavior has been summarized succinctly in the phrase "the straw that broke the camel's back."

Although this phenomenon occurs under rare conditions, it is also "typical." That is, although it is unlikely that any *particular* straw will break the camel's back, it is certain that after enough straw has been loaded, *some* straw *will* break the camel's back.

Situations in which gradually increasing stress leads to gradually increasing response, followed by a sudden catastrophic jump to a qualitatively different response state, are all too common. Many examples can be given:

1. Under gradually increased loading a bridge sags to a greater degree, followed by a sudden collapse under the last bit of stress (Zeeman, 1977; Poston and Stewart, 1978; Gilmore, 1981).
2. As temperature is gradually decreased at

constant pressure, a gas gradually contracts until a certain temperature is reached, at which it condenses to its liquid (or solid) state, with a sudden and very large change in its volume (Zeeman, 1977; Poston and Stewart, 1978; Gilmore, 1981).

3. Slow variation of the aileron trim settings (wing flaps) of an airplane leads to slow change in the attitude of the plane, until a certain threshold value is passed, at which point there occurs a large change in aircraft attitude (Gilmore, 1981).
4. When a glass tube filled with a helium–neon or carbon dioxide–neon mixture is set inside a cavity formed by two highly reflecting mirrors and a gradually increasing current is passed through it, the amount of incoherent light emitted gradually increases. After a current threshold is passed, the light which is emitted increases rapidly in intensity and coherence: the laser has turned "on" (Poston and Stewart, 1978; Gilmore, 1981).
5. The amount of sunlight falling on the Earth varies gradually over about 1000 years due to variation of the Earth's orbital parameters. Sudden dramatic changes leading to the occurrence and disappearance of the Ice Ages occur during this period and seem to be precipitated only by this gradual variation of the Earth's orbital parameters (Gilmore, 1981).
6. It is even possible to conceive of small causes producing big effects in biological, economic, social, and political systems (Thom, 1975; Zeeman, 1977; Poston and Stewart, 1978).

Catastrophes are widespread, occurring throughout all fields in the scientific and engineering disciplines, and even beyond. Moreover, the mathematical description of a catastrophe follows the same procedure and draws from the same restricted set of functions, independent of whether the catastrophe occurs in the area of physics, chemistry, structural engineering, aircraft dynamics, climate dynamics, etc. The mathematical description of catastrophes, involving mathematical functions called elementary catastrophes, provides a language in terms of which discontinuous phenomena can adequately be described.

It is easy to imagine how to describe systems in which a small push gives rise to a small response. One expects the mathematics of continuity, the calculus of Newton, to be applicable. One also expects that linearization about the local state (linear response function) will give a quantitative estimate of how much the system will respond to a small push.

But what of the mathematics of discontinuity? How does one describe catastrophes? Is it necessary to give up the ideas of continuity?

Roughly speaking, the state of a system is an equilibrium—in fact, a stable equilibrium. By changing some external parameters called control parameters (stress, loading), the equilibrium is displaced. A small change in these parameters usually results in a small displacement of the equilibrium. Sometimes small parameter changes result in the appearance of new equilibria or the disappearance of old equilibria. It is the latter instance in particular that can lead to a catastrophic sudden jump. A systematic study of catastrophes is closely related to a systematic study of equilibria, and especially the appearance and disappearance of equilibria.

Families of functions depending on (control) parameters are called catastrophes when the number of equilibria they possess changes as the parameters are varied. There are only a small number of catastrophes. A very small number have been used to model sudden jumps in physical systems. We will study the mathematics of catastrophes in two steps:

1. We first study functions representing situations in which the number of equilibria is about to change. This occurs when two or more equilibria occur at the same point (become degenerate).
2. We then study the effects of perturbations on the degenerate equilibria. In fact, we identify the simplest perturbation which can reproduce the effects of the most general perturbation.

That both these programs can be carried out successfully is remarkable.

A major obstacle in applying the mathematics of catastrophe theory to physical systems is in identifying the underlying catastrophe. A multiplicity of phenomena occur in the presence of a catastrophe (catastrophe flags). The occurrence of any one of these is an indication that others are present and can be found, and that a catastrophe is ultimately responsible for all. The catastrophe flags are easy to recognize and provide an inordinate amount of information about the underlying catastrophe. This information includes the type of catastrophe, a rough indication of where the sudden jump may occur, and—most important—how to avoid it if that is a desirable objective.

This article is organized into three parts. Section 1 describes what catastrophe theory is, Sec. 2 describes how the catastrophe functions are constructed, and Sec. 3 describes how catastrophe theory is applied to the description of phenomena that occur in the science and engineering disciplines.

In Sec. 1 we describe a progression of three theorems of elementary calculus. These theorems describe local standard forms for functions in the neighborhood of a point. The first, the implicit function theorem, tells us that a function can be replaced by its linear approximation when its slope is nonzero at a point. The second theorem, the Morse lemma, tells us that under suitable conditions a function can be well approximated by a quadratic form in the neighborhood of an equilibrium. The third result, the Thom splitting lemma, describes what happens when the "suitable conditions" required above are not satisfied. In this case two or more equilibria occur very close together (are degenerate), making it possible for a small perturbation either to split or annihilate the equilibria. This change in the number of equilibria is a "catastrophe." Tables containing Thom's list of elementary catastrophes and a complete list of all elementary catastrophes are provided. This is followed by a discussion of the geometric properties of the very simplest catastrophe functions. This section provides a clear answer to one of the questions posed above: it is possible to describe discontinuous phenomena without giving up the ideas of continuity. In fact, this mathematics of discontinuity is an essential part of the calculus of Newton.

In Sec. 2 we compute some explicit catastrophe functions. The first example starts with a family of functions depending on one state variable and two control parameters. Following an algorithmic procedure, we reduce this to a standard form in the neighborhood of its most degenerate equilibrium. This degenerate equilibrium is then perturbed in order to determine how these critical points can be created and annihilated as a function of the control parameters. The algorithm developed to effect this reduction to normal form is then summarized and applied to a more complicated family of functions.

In Sec. 3 we address the question of how to apply the mathematics of catastrophe theory to real world processes that exhibit discontinuous phenomena. Two widely adopted conventions are first described. These are assumptions about the mathematical characterization of the equilibrium state of a physical system: whether it is determined by a local minimum or the global minimum of a potential, and the conditions under which a jump from one minimum to another occurs. The mathematics tells us only where, how many, and what type of equilibria a catastrophe function possesses; the convention isolates the physically important equilibria. When a physical system exhibits a catastrophe, a multiplicity of phenomena occur. It is useful to be able to recognize them—particularly if one wants to avoid the physical catastrophe (e.g., bridge collapse). These phenomena are called catastrophe flags. The presence of any one is an indication that the others are present. Their recognition provides a great deal of information about the underlying catastrophe. The use of catastrophe conventions and catastrophe flags is illustrated in the context of an important example in Sec. 3.3. This illustrates unexpected dangers which may arise in the design of structures following standard optimization criteria employed to reduce costs. In Sec. 3.4 we indicate how the elementary catastrophes may make their appearance within the broader program of catastrophe theory, in the field of dynamical systems theory. That is, the fold catastrophe appears in the guise of saddle-node bifurcations while the cusp catastrophe appears in the guise of pitchfork and Hopf bifurcations.

In a short Appendix we outline the early turbulent and confusing history of catastrophe theory, which was at one point heralded as the greatest advance in mathematics since the development of the calculus by Newton.

1. WHAT IT IS

In Sec. 1 of this article we describe the enormous mathematical program called catastrophe theory and the much smaller and more manageable mathematical program called elementary catastrophe theory (Sec.

1.1). This latter program is not only the starting point for the study of the larger program, but also a continuation of a very important and rather simple program in elementary calculus. This is the program of determining and classifying the standard, or canonical, forms that functions can assume in any of their neighborhoods.

The first two stages in this program are well known at an intuitive level (Sec. 1.2). These are the implicit function theorem and the Morse lemma, which are the mathematical justifications underlying the approximation of a function by a linear function at a point where its slope is nonzero, or by a quadratic form at an equilibrium (where the slope is zero). The third stage, the Thom splitting lemma, describes what happens when two or more equilibria become degenerate. Under this condition a perturbation can either split the equilibria or annihilate them. Change in the number of equilibria is closely related to the occurrence of sudden jumps in physical systems.

Functions that describe sudden jumps, or changes in the number of equilibria of a system, are called catastrophes. There is a small number of elementary catastrophes. They are classified in Sec. 1.3 and presented in Tables 1 and 2 (Sec. 1.4). Since the number of catastrophes is small, the properties of each can be studied in detail (Sec. 1.5); the results are then directly applicable to any physical system described by that mathematical function. The geometric properties of the two simplest of the elementary catastrophes are studied in detail in Sec. 1.6. In Sec. 1.7 we make quantitative the statement that a small push will displace an equilibrium by just a little bit by computing the linear response function for a large class of physical systems, and showing that this function diverges precisely when a sudden jump is imminent.

1.1 The Program of Catastrophe Theory

Catastrophe theory is a program. The purpose of the program is to determine how the qualitative properties of solutions of equations change as the parameters that appear in the equations change (Gilmore, 1981).

It often happens that small changes in the values of parameters that appear in equations produce only small quantitative changes in the solutions of the equations. However, there may be parameter values for which a small change, either in parameter values, initial conditions, or boundary conditions, produces a large quantitative change in the solutions to these equations. Large quantitative changes in solutions describe qualitative changes in the behavior of the system. Catastrophe theory is concerned with determining the parameter values at which qualitative changes occur in solutions of equations described by parameters (Thom, 1975; Zeeman, 1977; Poston and Stewart, 1978; Gilmore, 1981).

This is an ambitious and difficult program. For example, for systems of equations of the form

$$F_\alpha(x,x',t;c)=0, \tag{1}$$

where F_α is a set of functions; x is an n-vector, $x=(x_1, x_2,...,x_n)\in R^n$, called a state vector; c is a k-vector, $c=(c_1, c_2,...,c_k)\in R^k$, called control parameters; and $'=d/dt$, there are no general results. When the set of equations is restricted to the simpler form of coupled nonlinear first-order ordinary differential equations (also called dynamical systems) of the form

$$x_i'=f_i(x,t;c), \tag{2}$$

very little can be said in general. Many results are known when $n=2$ and f is independent of t. A few results are known when $n=2$ and the forcing term is periodic, $f(x,t;c)=f(x,t+T;c)$. Much less is known when $n=2$ and f is not periodic. The case $n>2$ invites a lifetime of work.

When the forcing function in the dynamical system equations (2) is independent of time and can be written as the gradient of some potential,

$$f_i=-\partial V(x;c)/\partial x_i, \tag{3}$$

then the system

$$x_i'=-\partial V(x;c)/\partial x_i \tag{4}$$

is called a gradient dynamical system. For such systems many results are available.

The qualitative properties of a gradient dynamical system can be constructed by investigating the phase-space portrait of its flow. This can be done by plotting the value of the potential as a function of the phase-space coordinates x_i. The phase-space flow is "downhill" on the potential function. It is easily determined in the neighborhood of each equilibrium, or critical point, independent of the stability of the equilibrium. The local flow portraits around each critical point can then be pasted together to determine a global phase portrait. The potential

$$V(x,y;a,b)=\tfrac{1}{4}x^4+\tfrac{1}{2}ax^2+bx+\tfrac{1}{2}y^2 \tag{5}$$

is illustrated in Fig. 1, together with the phase-space portrait in the state-variable space.

Small changes in the control-parameter values (a,b) typically produce small changes in the location of the critical points. In turn, this produces only small quantitative changes, and therefore no qualitative change, in the phase-space portrait. Qualitative changes will only occur when changes in the control-parameter values result in changes in the number of critical points. This number can change only when two or more critical points coalesce and annihilate or, viewed from the other direction, two or more critical points are created in phase space and then move apart from each other as the control parameters are varied.

Elementary catastrophe theory is the study of how the critical points of a potential, $V(x;c)$, move about, coalesce and annihilate each other, or are created and disperse from each other, in state space $x\in R^n$ as the control parameters $c\in R^k$ are varied.

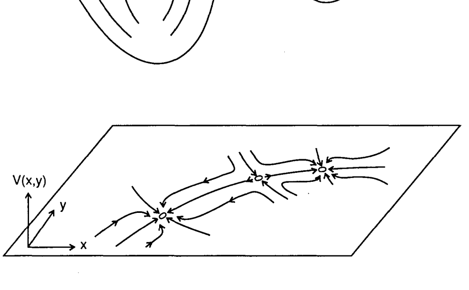

FIG. 1. The dynamics of a gradient system are governed by a potential. The potential of Eq. (5) is shown, together with the flows to and from the stable and unstable equilibria. These are projected down into the *x*-*y* plane.

1.2 Three Theorems from Elementary Calculus

Elementary catastrophe theory is found at the intersection of two lines of mathematical development, one old, one new. On the one hand, it is the latest development in the quest, in elementary calculus, for standard local forms for functions. On the other hand, it is the first result in the quest, in catastrophe theory, for canonical representations of functions that show qualitative changes when control parameters are varied.

Elementary catastrophe theory is the third in a series of reduction-to-standard-form theorems in elementary calculus. The three developments are the implicit function theorem, which depends on the first derivatives of a function; the Morse lemma, which depends on the second derivatives of a function; and the Thom splitting lemma, which depends on the third (and higher) derivatives of a function. Each of these results provides a standard, or canonical, form for a function in the neighborhood of a point.

We summarize these results now.

1.2.1 Implicit Function Theorem. The implicit function theorem tells us that if the slope of a function is nonzero at a point, the function can be represented locally by a linear approximation to that function. In a rough sense, it tells us that it is justified to linearize a function about a point at which its derivative is nonvanishing.

Implicit Function Theorem: Let $f(x)=f(x_1, x_2,\ldots,x_n)$ be a function with nonzero gradient at x_0:

$$\nabla f|_{x_0}\neq 0. \tag{6}$$

Then it is possible to find a new coordinate system, $y=(y_1,y_2,\ldots,y_n)$, $y=y(x)$, so that

$$f=y_1. \tag{7}$$

That is, f is equal, after a smooth change of coordinates, to y_1.

1.2.2 Morse Lemma. The Morse lemma takes over where the implicit function theorem leaves off. Suppose the gradient of a function does vanish at a point—what then? Such a point is called an equilibrium, or critical point. Provided that the function has enough "curvature" at the critical point, it can be represented locally by a quadratic form. In a rough sense, the Morse lemma tells us that it is justified to represent a function at an equilibrium by a quadratic form, provided none of the eigenvalues vanish.

Morse Lemma: Let $f(x)=f(x_1,x_2,\dots,x_n)$ be a function with equilibrium at x_0 and nonsingular stability matrix at x_0:

$$\begin{array}{ll} \nabla f|_{x_0}=0, & \text{equilibrium,} \\ \det[\partial^2 f/\partial x_i \partial x_j]|_{x_0}\neq 0, & \text{nonsingular.} \end{array} \qquad (8)$$

Then there is a smooth change of coordinates, $x'=x'(x)$, so that

$$f=\sum \lambda_i (x'_i)^2, \qquad (9)$$

where λ_i are the eigenvalues (all nonzero) of the stability matrix.

A critical point satisfying the conditions (8) is called variously a Morse critical point or an isolated critical point.

The quadratic form (9) can be put into a canonical form by rescaling the coordinates:

$$y_i=|\lambda_i|^{1/2} x'_i. \qquad (10)$$

Under this scale transformation the function at equilibrium assumes Morse canonical form:

$$\begin{array}{l} f=M_i^n, \\ M_i^n=-y_1^2-\cdots-y_i^2+y_{i+1}^2+\cdots+y_n^2. \end{array} \qquad (11)$$

The quadratic forms (11) are called Morse saddles. The Morse saddle M_0^n has a minimum at $y=0$, while M_n^n has a maximum at $y=0$. The remaining Morse saddles M_i^n, $i\neq 0,n$, have equilibria at $y=0$ that are neither maxima nor minima.

1.2.3 Thom Splitting Lemma. The Thom splitting lemma takes over where the Morse lemma leaves off. Suppose the stability matrix of a function is singular at an equilibrium. Then one or more eigenvalues (λ_i) vanish. What then? The Thom splitting lemma tells us that there is a smooth change of coordinates, $x'=x'(x)$, where $x'_1,\dots,x'_l$ are tangent to the eigenvectors with vanishing eigenvalues at the critical point, and $x'_{l+1},\dots,x'_n$ are tangent to the eigenvectors with nonvanishing eigenvalues at the critical point, so that the function can be broken down into two parts. One part, associated with the nonzero eigenvalues, is simple and can be put into Morse canonical form. The other part, associated with the vanishing eigenvalues, is interesting and has all its second derivatives equal to zero at the critical point. This non-Morse function is the principal object of study in elementary catastrophe theory.

Thom Splitting Lemma: Let $f(x)=f(x_1,x_2,\dots,x_n)$ be a function with equilibrium and singular stability matrix at x_0:

$$\begin{array}{ll} \nabla f|_{x_0}=0, & \text{equilibrium,} \\ \det[\partial^2 f/\partial x_i \partial x_j]|_{x_0}=0, & \text{singular.} \end{array} \qquad (12)$$

If the stability matrix has exactly l vanishing eigenvalues, then there is a smooth change of coordinates, $x'=x'(x)$, so that

$$\begin{array}{l} f(x)=f_{\mathrm{NM}}(x'_1,\dots,x'_l)+M_i^{n-l}(x'_{l+1},\dots,x'_n), \\ \partial^2 f_{\mathrm{NM}}/\partial x_i \partial x_j|_{x_0}=0, \quad 1\leqslant i,j\leqslant l. \end{array} \qquad (13)$$

The Thom splitting lemma can be proven by the methods of elementary calculus. It tells us that when the Morse lemma is not applicable, the function can be split into two functions, a "good" function in $n-l$ coordinates which can be put into Morse canonical form and a "bad," or non-Morse, function of l variables which bears further scrutiny. It tells us nothing about the non-Morse function except that its Taylor series expansion about the critical point begins with at least third-degree terms.

We emphasize here that the three results of elementary calculus, the implicit function theorem, the Morse lemma, and the Thom splitting lemma, depending on first, second, and third derivatives, are local in nature. The theorems do not provide an estimate for the size of the neighborhood for which the statement of the result is true.

1.3 Thom Classification Theorem

For a typical function, $f(x)$, the gradient at a random ("typical") point will be nonvanishing, so that the implicit function theorem is applicable. There are, however, typically isolated points at which the gradient vanishes. At such points the stability matrix is typically nonsingular, so that the Morse lemma is applicable. How, then, does it come about that the machinery of elementary catastrophe theory becomes useful?

When the function depends on control parameters c as well as state variables x, $f=f(x;c)$, then the eigenvalues of the stability matrix at a critical point, $x_0=x_0(c)$, depend on the control-parameter values: $\lambda_i=\lambda_i(c)$. As a result, there may be choices of the control-parameter values that annihilate one or more of the eigenvalues.

As a result, the structure of the non-Morse function in Eqs. (13) will depend on control parameters. The Thom classification theorem, which is outside the scope of calculus (elementary or otherwise), provides a further resolution of the non-Morse function into two functions. One of these, the catastrophe germ, depends only on the l state variables $y_1,y_2,\ldots,y_l$ and summarizes the nature of the singularity at the non-Morse critical point. The other function, the universal perturbation, is a function of both the l state variables and k control parameters. This function summarizes what can happen to the singularity, or degenerate critical point, under the most general possible ("universal") perturbation.

Thom Classification Theorem: Let $f_{\mathrm{NM}}(y;c)=f(y_1,\ldots,y_l;c_1,\ldots,c_k)$ be a non-Morse function of l state variables and k control parameters. Then there is a smooth change of coordinates so that

$$f_{\mathrm{NM}}(y;c)=\mathrm{Cat}(l,k). \tag{14}$$

The elementary catastrophe function, $\mathrm{Cat}(l,k)$, is the sum of two terms:

$$\mathrm{Cat}(l,k)=\mathrm{CG}(l)+\mathrm{Pert}(l,k). \tag{15}$$

The catastrophe germ, $\mathrm{CG}(l)$, depends only on the l state variables. All its second partial derivatives vanish at the critical point. The universal perturbation depends on the k control parameters as well as the l state variables. The dependence of $\mathrm{Pert}(l,k)$ on the control-parameter values is linear. For "most" choices of control-parameter values (all but a set of measure zero) the function $\mathrm{Cat}(l,k)$ has isolated critical points.

The Thom classification theorem, like the three results of elementary calculus described in the previous section, is local in nature. The theorem does not provide an estimate of the size of the neighborhood for which the statement of the theorem is true.

1.4 Thom's List of Elementary Catastrophes

Thom's original classification theorem provided a list of the elementary catastrophes (Thom, 1975). A slightly expanded version of this list is provided in Table 1 (Arnol'd, 1981, 1986). This list contains the canonical catastrophe functions for $k<6$ and therefore (cf. Sec. 2.3) $l<3$. This list consists of the classification of the function following the beautiful convention introduced by Arnol'd (1981), the original descriptive name, when it exists (Thom, 1975; Zeeman, 1977; Poston and Stewart, 1978), values for k and l, the catastrophe germ, $\mathrm{CG}(l)$, and the universal perturbation, $\mathrm{Pert}(l,k)$. Thom's original list contained only the seven members with $k \leqslant 4$ (dimension of spacetime) for unsupportable historical reasons.

The catastrophe functions listed in Table 1 are elementary in the sense that all coefficients in the catastrophe germ can be assigned canonical values. There are no free parameters; every coefficient in the catastrophe germ can be given canonical numerical values such as $\pm 1,0$ by a coordinate change. For example, a term of the form $-3x^4$ in the A_{-3} catastrophe could be transformed to the canonical

Table 1. All catastrophes up to control-parameter dimension five are elementary and are listed below by dimension of control-parameter space.

k	l	Classification	Name	$\mathrm{CG}(l)$	$\mathrm{Pert}(l,k)$
1	1	A_2	Fold	x^3	a_1x^3
2	1	$A_{\pm 3}$	Cusp	$\pm x^4$	$a_1x^2+a_2x^2$
3	1	A_4	Swallowtail	x^5	$a_1x^2+a_2x^2+a_3x^3$
3	2	D_{-4}	Elliptic umbilic	x^2y-y^3	$a_1x+a_2y+a_3x^2$
3	2	D_{+4}	Hyperbolic umbilic	x^2y+y^3	$a_1x+a_2y+a_3x^2$
4	1	$A_{\pm 5}$	Butterfly	$\pm x^6$	$a_1x+a_2x^2+a_3x^3+a_4x^4$
4	2	D_5	Parabolic umbilic	$\pm(x^2y+y^4)$	$a_1x+a_2y+a_3x^2+a_4y^2$
5	1	A_6	Wigwam	x^7	$a_1x+a_2x^2+a_3x^3+a_4x^4+a_5x^5$
5	2	D_{-6}	Second elliptic umbilic	x^2y-y^5	$a_1x+a_2y+a_3x^2+a_4y^2+a_5y^3$
5	2	D_{+6}	Second hyperbolic umbilic	x^2y+y^5	$a_1x+a_2y+a_3x^2+a_4y^2+a_5y^3$
5	2	$E_{\pm 6}$	Symbolic umbilic	$\pm(x^3+y^4)$	$a_1x+a_2y+a_3xy+a_4y^2+a_5xy^2$

form $-x'^4$ (or $-\frac{1}{4}x'^4$) by an appropriate scale change $x'=\lambda x$.

Thom's list of elementary catastrophes is not a complete list. The complete list is provided in Table 2. There are two infinite series of elementary catastrophes and one finite series. One infinite series, the cuspoids $A_{\pm k}$, depends on only one state variable. The other infinite series, the umbilics $D_{\pm k}$, depends on two state variables. The exceptional elementary catastrophes, $E_{\pm 6}$, E_7, E_8, depend on two state variables (Arnol'd, 1981, 1986; Poston and Stewart, 1978; Gilmore, 1981).

There is a remarkable correspondence between the classification theory of elementary catastrophes and the classification theory for Lie algebras all of whose roots (in the root space diagram) have the same length (Arnol'd, 1981, 1986; Gilmore, 1981). The correspondence is as follows. The phase-space portraits of the elementary catastrophes with maximum number of isolated critical points can be summarized by drawing the flow from each equilibrium to any of the others to which a flow is possible. The phase-space portraits so obtained are exactly the Dynkin diagrams which classify all the simple Lie algebras whose roots have equal length; these are A_{n-1}, D_n, and the exceptional simple Lie algebras E_6, E_7, and E_8. This nomenclature for simple Lie algebras has accordingly been adapted to the classification of elementary catastrophes. For Lie algebras the subscript (e.g., 8 for E_8) denotes its rank; for elementary catastrophes the subscript denotes the number of isolated (complex) critical points generated by an arbitrary perturbation of the function. This is the maximum number of real critical points into which the non-Morse critical point splits under a general perturbation.

Tables 1 and 2 differ in a subtle way, indicating that they are responses to somewhat different questions. The question to which Table 1 responds is: "Up to what control-parameter dimension are all catastrophes elementary, and what are they?" The question to which Table 2 responds is: "For each control dimension $k=1,2,\ldots$, what are the elementary catastrophes?"

The difference between the two tables indicates that for control dimension $k\geqslant 6$ there are catastrophes that are elementary and those that are not, while for $k<6$ all catastrophes are elementary. We will explore what happens at $k=6$ to generate nonelementary (modal) catastrophes as well as elementary catastrophes in Sec. 2.3. Briefly, the result is as follows. To annihilate l eigenvalues of the stability matrix requires $k\geqslant l(l+1)/2$ control parameters. A linear transformation can be used in an attempt to provide canonical values for cubic terms in the Taylor series expansion

Table 2. There are three series of elementary catastrophes. The cuspoids A_k depend on one state variable while the umbilics D_k and the exceptional catastrophes E_k, $k=6,7,8$, depend on two state variables. The subscript k indicates the maximum number of real Morse critical points the catastrophe splits into under an arbitrary perturbation. The number of control parameters required in the universal perturbation is $k-1$.

Symbol	Catastrophe germ	Universal perturbation
$A_{\pm k}{}^{a}$	$\pm x^{k+1}$	$\sum_{j=1}^{k-1} a_j x^j$
$D_{\pm k}$	$x^2y \pm y^{k-1}$, k even $\pm(x^2y+y^{k-1})$, k odd	$\sum_{j=1}^{k-3} a_j y^j + \sum_{j=k-2}^{k-1} a_j x^{j-(k-3)}$
$E_{\pm 6}$	$\pm(x^3+y^4)$	$\sum_{j=1}^{2} a_j y^j + \sum_{j=3}^{5} a_j xy^{j-3}$
E_7	x^3+xy^4	$\sum_{j=1}^{4} a_j y^j + \sum_{j=5}^{6} a_j xy^{j-5}$
E_8	x^3+y^5	$\sum_{j=1}^{3} a_j y^j + \sum_{j=4}^{7} a_j xy^{j-4}$

[a] $A_{+k}=A_{-k}$ if k is even.

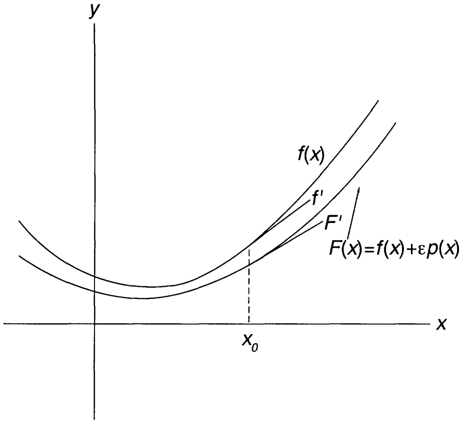

FIG. 2. At a point where the implicit function theorem is applicable, perturbation of a function does not produce a qualitative change in the function.

of the non-Morse function. When the number of cubic coefficients $[(l+3-1)!/(l-1)!3!]$ exceeds the number of degrees of freedom in the $l \times l$ linear transformation (l^2), then it is not possible to assign canonical values to all cubic terms in the Taylor series expansion of the non-Morse function, and the resulting catastrophe germ cannot be elementary. This first occurs for $l=3$ ($\Rightarrow k=6$). For $k \geqslant 6$ there are catastrophes that are elementary and those that are not. For $k<6$ all catastrophes are elementary.

1.5 Why a List of Perturbations is Required

The first two canonical form theorems of elementary calculus are clean and simple. If the function has certain properties at a point, then the canonical form in the neighborhood of the point is provided by the statement of the theorem (implicit function theorem, Morse lemma). By contrast, the third result is not nearly so clean cut. The Thom splitting lemma tells us that we can decompose a function at a non-Morse critical point into the sum of two functions, one Morse, the other interesting. The classification theorem provides a list of the interesting functions by number of state variables (l) and control parameters (k). Why is it that the classification theorem, in addition to providing a list of canonical forms for catastrophe germs, in the spirit of the implicit function theorem and the Morse lemma, also provides a list of canonical perturbations? The reason is that perturbation of the canonical linear form which is provided by the implicit function theorem does not change its qualitative properties. The same is true for the canonical quadratic form which is provided by the Morse lemma. However, perturbation of the canonical singularity CG(l) provided in Tables 1 and 2 produces dramatic changes in its qualitative properties. Different perturbations produce different qualitative changes. The canonical perturbation, Pert(l,k), of each catastrophe germ is the "smallest" function, in the sense of number of control parameters required, which incorporates all distinct qualitative changes produced by all possible perturbations of the catastrophe germ.

We illustrate these statements in Figs. 2–4. In Fig. 2 we show a function, $f(x)$, which satisfies the conditions of the implicit function theorem at x_0. Under a perturbation, $\varepsilon p(x)$, where $p(x)$ is a well-behaved function and ε is a small parameter, the new function, $F(x) = f(x) + \varepsilon p(x)$, also satisfies the conditions of the implicit function theorem at x_0 for ε sufficiently small. Therefore, perturbation of $f(x)$ at x_0 does not change its qualitative properties (perturbation "commutes" with the implicit function theorem).

In Fig. 3 we show a function, $f(x)$, which satisfies the conditions of the Morse lemma at x_0. Under a perturbation, $\varepsilon p(x)$, the new function, $F(x) = f(x) + \varepsilon p(x)$, no longer appears to satisfy the conditions of the Morse lemma at x_0, since typically $p'(x_0) \neq 0$. However, $F'(x_0) = \varepsilon p'(x_0)$ is small for small ε so

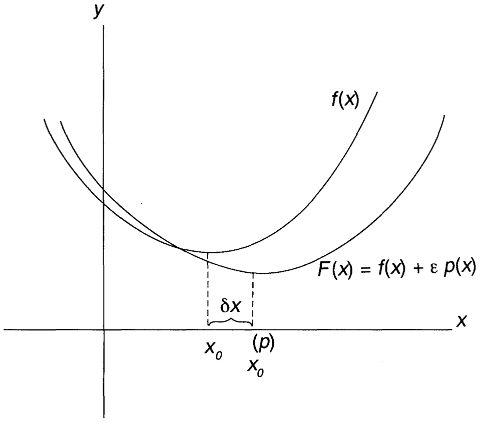

FIG. 3. At a point where the Morse lemma is applicable, perturbation of a function does not produce a qualitative change in the function.

that the implicit function theorem is on the verge of not being applicable. It is more useful to regard the perturbation as moving the location of the critical point to a nearby point, $x_0^{(p)} = x_0 + \delta x_0$. At this perturbed critical point the conditions for the Morse lemma are fulfilled. Thus, a small perturbation at an equilibrium produces only a small displacement of that equilibrium. Not only that, but the curvature or, more generally, the Morse saddle type of the canonical form remains unchanged. As a result, perturbation of a function that satisfies the conditions for the Morse lemma does not produce a qualitative change of the function in the neighborhood of the critical point.

The situation is quite different for a catastrophe germ. In Fig. 4 we plot the catastrophe function A_2: $f(x;a_1)=\frac{1}{3}x^3+a_1x$ for three values of the control parameter a_1. For $a_1=0$ the catastrophe germ $f(x;a_1=0)=x^3/3$ has a doubly degenerate critical point at $x=0$. The perturbation with $a_1<0$ splits this doubly degenerate critical point into two isolated critical points at $x_-=-(-a_1)^{1/2}$ and $x_+ =+(-a_1)^{1/2}$. The perturbation with $a_1>0$ removes the critical point altogether. These are the only two qualitatively distinct things that can occur to a doubly degenerate critical point under an arbitrary perturbation. These correspond to scattering of the solutions of $\nabla f(x;a_1)=0$ from the real axis to the imaginary axis as a_1 increases through zero, with the point of double degeneracy occurring at $a_1=0$. It is a remarkable result that the simple perturbation $P(1,1)=a_1x$ encapsulates all distinct possibilities under generic perturbations.

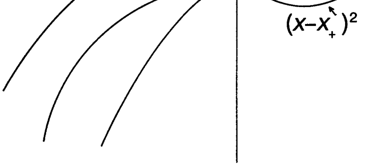

FIG. 4. At a point where a function has a degenerate critical point, so that neither the implicit function theorem nor the Morse lemma is applicable, perturbation of a function produces a qualitative change in the function. In the case shown, perturbation of the function x^3 either annihilates the critical points or splits them into two nondegenerate critical points.

It should now be clear why the catastrophe germs listed in the classification theorem must be accompanied by a list of universal perturbations while the implicit function theorem and the Morse lemma are not encumbered by such baggage. The canonical linear and quadratic forms are invariant under perturbation: perturbation produces no qualitative change. However, the catastrophe germs undergo a wide spectrum of distinct qualitative changes under perturbation. The perturbation functions listed are those of minimal control-parameter dimension which are capable of reproducing the entire spectrum of distinct qualitative changes induced by the most general perturbation.

It is a remarkable result that the control parameters appear linearly in these perturbations.

1.6 Geometry of the Fold and the Cusp

In this section we review the properties of the two simplest elementary catastrophes, the fold catastrophe A_2 and the cusp catastrophe $A_{\pm 3}$. Since the cusp catastrophe A_{+3} occurs more frequently in physical applications than A_{-3} (which is not bounded below), we study specifically the properties of A_{+3}. The properties of A_{-3} are related by appropriate sign changes. We also review a restricted set of properties of the co(ntrol)-dimension three catastrophes A_4, $D_{\pm 4}$.

For the fold and the cusp we study the following properties:

1. typical functions in the family of functions as well as the bifurcation set;
2. location of the critical points;
3. values of the function at the critical points;
4. curvature of the function at the critical points.

We present only the bifurcation set for the three catastrophes A_4, $D_{\pm 4}$.

1.6.1 Geometry of the Fold Catastrophe.

The fold catastrophe is

$$A_2:\ f(x;a)=\tfrac{1}{3}x^3+ax. \qquad (16)$$

The canonical properties of this function are shown in Fig. 5. In Fig. 5(a) we show members of this family with $a>0$, $a=0$, $a<0$. The bifurcation set is the set of points in the control parameter space at which there is a qualitative change in the nature of the function. This occurs when two or more critical points become degenerate. For the fold catastrophe this consists of the single point $a=0$, at which there is a doubly degenerate critical point at $x=0$.

The location of the critical points, the solution of $\nabla f(x;a)=0$, is shown in Fig. 5(b). The critical points, $x_\pm(a)=\pm(-a)^{1/2}$, have a standard 1/2 power-law dependence on the control parameter a. Note that the critical points $x_\pm(a)$ exist only for $a\leqslant 0$ and that the graph of $x_\pm(a)$ as a function of a is a smooth manifold embedded in the space R^1 (state space) $\times R^1$ (control parameter space). This is a general result. The fold catastrophe derives its name from the shape of its critical set $\nabla f(x;a)=0$, which looks like a curve folded over itself.

The value of the function at the critical points,

$$f_c(x_\pm(a);a)=\pm\tfrac{2}{3}(-a)^{3/2}, \tag{17}$$

is plotted in Fig. 5(c). This curve has a canonical 3/2 power-law dependence. This graph is not generally a manifold.

The curvature of the function,

$$f''(x_\pm(a);a)=\pm 2(-a)^{1/2}, \tag{18}$$

is shown in Fig. 5(d). Although the critical curvature happens to be a manifold in the present case, this is not generally true for the remaining catastrophes.

1.6.2 Geometry of the Cusp Catastrophe.

The cusp catastrophe is

$$A_{+3}\colon\ f(x;a,b)=\tfrac{1}{4}x^4+\tfrac{1}{2}ax^2+bx. \tag{19}$$

The canonical properties are shown in Fig. 6. In Fig. 6(a) we show the control-parameter plane $R^2=(a,b)$, various points in this plane, and the function $f(x;a,b)$ evaluated at these points. Within the cusp-shaped region the

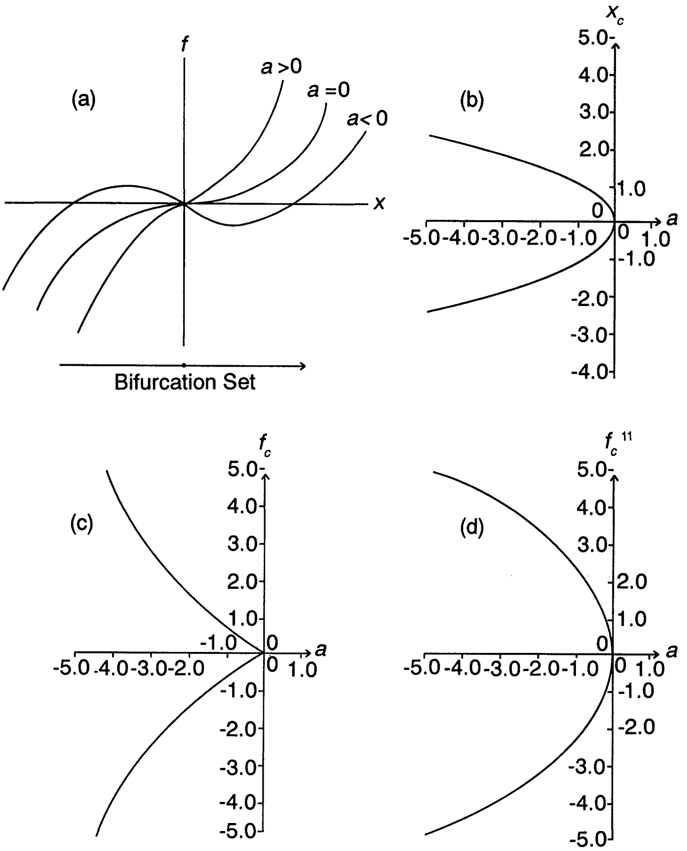

FIG. 5. (a) Members of the fold family of functions $f(x;a)=\frac{1}{3}x^3+ax$ for various values of the control parameter a. (b) Location of the critical points as a function of a. (c) Value of the function at its critical points. (d) Curvature of the function at its critical points.

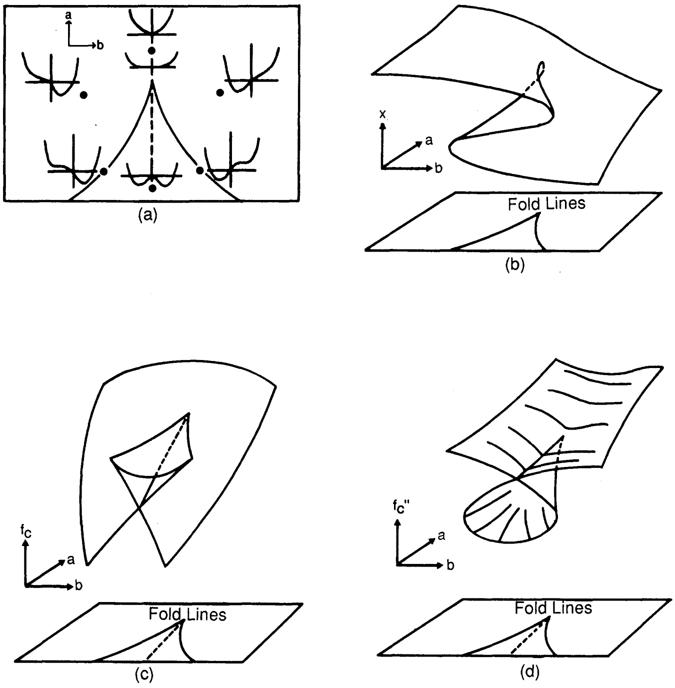

FIG. 6. (a) Members of the cusp family of functions $f(x;a,b)=\frac{1}{4}x^4+\frac{1}{2}ax^2+bx$ for various values of the control parameters *a,b*. (b) Location of the critical points as a function of position over the control parameter plane. (c) Value of the function at its critical points. (d) Curvature of the function at its critical points.

function has three isolated critical points, two minima separated by a local maximum. Outside the cusp-shaped region the function has only a single minimum. These two regions in the control plane parametrize two qualitatively distinct types of functions. Any path from one region to the other must pass through the cusp-shaped curve, along which there is a doubly degenerate critical point (triply degenerate at the tip of the cusp). This degeneracy occurs when the local maximum collides with one of the two minima. Entering the larger region complementary to the cusp-shaped region, the two degenerate critical points annihilate each other in a catastrophe which is of type A_2.

The cusp-shaped bifurcation set is determined by the condition that a critical point $[\nabla f(x;a,b)=0]$ is degenerate $[\nabla^2 f(x;a,b)=0]$:

$$\begin{aligned} &\text{critical point:} \quad f'(x;a,b)=x^3+ax+b=0,\\ &\text{degenerate:} \quad f''(x;a,b)=3x^2+a=0. \end{aligned} \tag{20}$$

From these two equations we compute the semicubical parabola

$$\begin{aligned} a&=-3x_c^2,\\ b&=2x_c^3, \end{aligned} \tag{21a}$$

along which a critical point is degenerate. The projection of this space curve into the control parameter plane is

$$(a/3)^3+(b/2)^2=0. \tag{21b}$$

This is the bifurcation set shown in Fig. 6(a).

In Fig. 6(b) we show the critical point(s), $x_c(a,b)$, as a function of the control parameters *a,b*. These points lie on the critical manifold or catastrophe manifold $\nabla f(x;a,b)=0$. Outside the cusp-shaped region there is a single critical point. Over the cusp-shaped region there are three. The middle critical point is the local maximum which separates the two minima. Moving toward the edge of the cusp-shaped region, two of the critical points move together. They collide on the bifurcation set and annihilate each other beyond the bifurcation set. The graph $x_c(a,b)$ in R^1 (state space) $\times R^2$ (control parameter space) is a smooth two-dimensional manifold. The locus of points on this manifold where the tangent is "vertical" is the semicubical parabola (21). From another point of view, the cusp-shaped bifurcation set in R^2 is the projection into R^2 of the fold in the manifold $x_c(a,b)$ in $R^1\times R^2$. The singularity in this catastrophe lies not in the catastrophe manifold itself, which is smooth, but in the projection of this two-dimensional manifold down into the two-dimensional control parameter space. In general, the graph of $\nabla f(x;c)=0$, with $x \in R^n$ and $c \in R^k$, is a smooth k-dimensional manifold embedded in $R^n \times R^k$. The only singularity occurs in the projection of this k-dimensional manifold into the k-dimensional space of control parameters.

In Fig. 6(c) we present the critical function, the value(s) of the function at the critical point(s). This graph is not a manifold because of the sharp corners and self-intersections. The two lower pieces of the graph are the values of the function at the two minima. Where these pieces intersect, the minima are equally deep (Maxwell set, $a<0$, $b=0$, Sec. 3.1). The remaining piece of this graph, which looks like the seat of an Art Moderne chair, is the value of the function at the local maximum. The creases at which the values at the local maximum and minimum join have canonical power-law dependence familiar from the behavior of the Gibbs free energy of a function exhibiting a second-order phase transition (Gilmore, 1981). This canonical power-law dependence is that of the fold catastrophe, namely, 3/2.

The critical curvature, $f''(x_c(a,b);a,b)$, or curvature of the function at its critical point(s), is shown in Fig. 6(d). The curvature is positive at the local minima and negative on the intermediate local maximum. Although there are no creases as in Fig. 6(d), this graph is not a manifold because of the self-intersection. Over the bifurcation set the critical curvature vanishes because the second derivatives vanish and the tangent is "vertical."

1.6.3 Bifurcation Sets for the Three-Dimensional Catastrophes. The geometry of the fold and the cusp was relatively easy to visualize because their graphs could be embedded in low-dimensional spaces: $R^1 \times R^1$ for the fold and $R^1 \times R^2$ for the cusp. Higher-dimensional catastrophes are more difficult to visualize. The catastrophe A_4 should be viewed in $R^1 \times R^3$ while the catastrophes $D_{\pm 4}$ should be viewed in $R^2 \times R^3$. However, the bifurcation sets for these three catastrophes are relatively simple to visualize, since they are embedded in the control-parameter space R^3. These three catastrophes are

$$A_4:\quad f(x;a,b;c)=\tfrac{1}{5}x^5+\tfrac{1}{3}ax^3+\tfrac{1}{2}bx^2+cx,$$

$$\begin{aligned} D_{+4}:\quad & f(x,y;a,b,c)=x^2y+\tfrac{1}{3}y^3+a(y^2-x^2)\\ &\qquad +bx+cy,\\ D_{-4}:\quad & f(x,y;a,b,c)=x^2y-\tfrac{1}{3}y^3+a(y^2+x^2)\\ &\qquad +bx+cy. \end{aligned} \tag{22}$$

In each instance the three-dimensional control-parameter space is partitioned into open regions by two-, one-, and zero-dimensional manifolds, components of the bifurcation set on which two, three, and all four of the critical points are degenerate. Within each open region the critical points are isolated; their number and type are unchanged by a sufficiently small perturbation. The number of critical points can change only when passing from one open region to another through the bifurcation set. The bifurcation sets for these three catastrophes are shown in Fig. 7. Shown in each figure is the number of critical points possessed by the catastrophe function in each of the open regions in its control parameter space. The catastrophes A_4, D_{+4} can each have zero, two, or four nondegenerate critical points while D_{-4} can have only two or four nondegenerate critical points.

1.7 Perturbations of Gradient Dynamical Systems

The qualitative properties of a gradient dynamical system are determined by the number, saddle type, and distribution of its critical points. If the critical points are isolated, then the dynamical system is structurally stable against perturbations. If one or more critical points are degenerate, the system is structurally unstable—a perturbation will produce a qualitative change in the properties of the system by splitting or annihilating the degenerate critical points.

As a result it is sufficient to use perturbation theory to describe the effect of a perturbation on a structurally stable system. In the case of a structurally unstable system it is useful to reduce the degenerate critical point to canonical form (a catastrophe) and then discuss the effect of a perturbation by using the catastrophe germ's universal perturbation.

To illustrate the effect of a perturbation in the structurally stable case, we consider a family of potentials, $V(x;c)$, depending on n state variables and k control parameters. As-

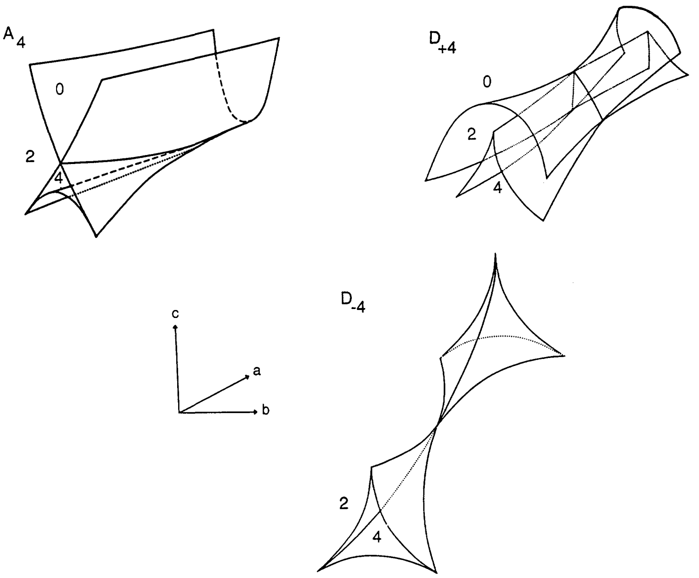

FIG. 7. Bifurcation sets for the three elementary catastrophes [Eq. (22)] of control dimension three as a function of the three control parameters *a,b,c*. The number of isolated critical points is shown in each of the open regions into which the control-parameter space is divided by the bifurcation set.

sume x_0 is a critical point for control-parameter value c_0. What happens under a perturbation $c_0 \to c' = c_0 + \delta c$? We expect that the critical point x_0 will move to a nearby point: $x_0 \to x' = x_0 + \delta x$. The displacement of the critical point as a function of the change in control-parameter value is determined by expanding $V(x_0+\delta x;c_0+\delta c)$ in a Taylor series about x_0, c_0:

$$
\begin{aligned}
V(x_0+\delta x;c_0+\delta c)& \\
&= V(x_0;c_0) + V_i\delta x_i + V_\alpha \delta c_\alpha + \tfrac{1}{2}V_{ij}\delta x_i \delta x_j \\
&\quad + V_{i\alpha}\delta x_i \delta c_\alpha + \tfrac{1}{2}V_{\alpha\beta}\delta c_\alpha \delta c_\beta \\
&\quad + \text{higher-order terms.}
\end{aligned} \tag{23}
$$

The coefficient $V_i(x_0;c_0)=0$, since x_0 is assumed to be a critical point for $c=c_0$. The value of δx is computed by solving $\nabla V(x_0+\delta x;c_0 + \delta c)=0$. To lowest order (linear), we find

$$V_{ij}\delta x_j + V_{i\alpha}\delta c_\alpha = 0. \tag{24}$$

If the stability matrix V_{ij} is nonsingular,

$$\partial x_i / \partial c_\alpha = -(V^{-1})_{ij} V_{j\alpha}, \tag{25}$$

where (V^{-1}) is the matrix inverse of the nonsingular stability matrix: $(V^{-1})_{ij}V_{jk} = \delta_{ik}$. That is, a small change in control-parameter value produces a small change in the location of the critical point, as long as the stability matrix is nonsingular. The matrix (25) is the linear response function for the potential at the equilibrium x_0: it describes how much the equilibrium is displaced by a small change in the control parameters.

To second order the value of the potential at the displaced critical point is

$$
\begin{aligned}
V(x_0+\delta x;c_0+\delta c)& \\
&= V(x_0;c_0) + V_\alpha \delta c_\alpha \\
&\quad + \tfrac{1}{2}[V_{\alpha\beta} - V_{\alpha i}(V^{-1})_{ij}V_{j\beta}]\delta c_\alpha \delta c_\beta.
\end{aligned} \tag{26}
$$

The stability matrix at the displaced critical point, $V_{ij}(x_0+\delta x;c_0+\delta c)$, is related to the stability matrix at the original critical point, $V_{ij}(x_0;c_0)$, by

$$
\begin{aligned}
&V_{ij}(x_0+\delta x;c_0+\delta c) = V_{ij}(x_0;c_0) + P_{ij\alpha}\delta c_\alpha, \\
&P_{ij\alpha} = V_{ij\alpha}(x_0;c_0) - V_{ijk}(V^{-1})_{kl}V_{l\alpha}.
\end{aligned} \tag{27}
$$

As a result, for sufficiently small perturbations the Morse saddle type cannot change if the stability matrix is nonsingular.

This application of perturbation theory, and the analytic results constructed in Eqs. (25)–(27), evaporate when the stability matrix V_{ij} becomes singular. Under these conditions the evolution of the dynamical system under change in the control-parameter values ("perestroika") is computed by expressing the potential, $V(x;c)$, in the neighborhood of a non-Morse critical point by an appropriate catastrophe, following the perturbation through the well-defined bifurcation sets, and then resuming the perturbation treatment sufficiently far from the critical point degeneracy.

2. WHY IT EXISTS

The reduction of a family of functions to the sum of a non-Morse function and a Morse *i*-saddle at a non-Morse critical point, which is guaranteed by the Thom splitting lemma, can be carried out by the methods of elementary calculus. It will therefore not be reviewed here.

The reduction of a non-Morse function in the neighborhood of a degenerate (non-Morse) critical point cannot be carried out by the methods of elementary calculus. It will therefore be discussed in Sec. 2 of this article. This reduction to canonical form can be accomplished following a simple algorithm. The algorithm is illustrated in Sec. 2.1 in the context of a simple example: the reduction of a two-parameter family of functions of a single state variable to canonical form in the neighborhood of its most degenerate critical point. The steps involved in this algorithm are summarized in Sec. 2.2, and applied in Sec. 2.3 to an important example in which the canonical form is not at all evident.

The algorithm involves two main procedures. The first is the determination of the most degenerate critical point, and the catastrophe germ at this point. This is accomplished by finding critical points, using the control parameter degrees of freedom to eliminate the leading terms in the Taylor series expansion of the function in the neighborhood of that critical point, and then using a nonlinear change of coordinates to eliminate the higher-degree terms in the Taylor series expansion. What is left over, between the eliminated terms of low and high degree, is the catastrophe germ, CG(l), describing the degenerate critical point.

The second procedure in this algorithm is the determination of a universal perturbation. This follows the steps described above in more or less reverse order. First, an arbitrary function (perturbation) is added to the catastrophe germ. Then the high-degree terms are eliminated by a nonlinear change of coordinates. Finally, as many as possible of the low-degree terms are eliminated by a rigid translation of the coordinate system. The small number of terms remaining from the original general perturbation form the universal perturbation, Pert(l,k), of the catastrophe germ CG(l).

The mathematics used in these examples appears naively simple. However, this simplicity should not hide the fact that the mathematical approach used here is correct in spirit and can be (has been) made rigorous with sufficient effort (Poston and Stewart, 1978; Arnol'd, 1981; Gilmore, 1981).

2.1 A Simple Example

We carry out the reduction of a family of functions with a triply degenerate critical point to the canonical form of the cusp catastrophe $A_{\pm 3}$. We begin by assuming $f(x;c_1,c_2)$ is a family of functions depending smoothly on one state variable, x, and two control parameters, c_1 and c_2. We wish to determine the qualitative properties of any member of this family and, in particular, to determine how these qualitative properties change as the control parameter values change.

To facilitate this study, we expand $f(x;c_1,c_2)$ about some point x_0:

$$f(x;c_1,c_2)=\sum_{n=0}^{\infty} f_n(x_0;c_1,c_2)(x-x_0)^n. \qquad (28)$$

The Taylor series expansion of this function is shown in line 1 of Fig. 8. The remainder of the discussion of this example will refer to subsequent lines of this figure. At points x_0 where $f_1 \neq 0$ the implicit function theorem is applicable and nothing qualitatively interesting will happen. We therefore search over the range of the state variables to find a critical point. At that critical point $f_1=0$. Since we are interested in the qualitative properties (shape) of the potential, we readjust our y axis so the function vanishes at the critical point. As a result of using these two degrees of freedom—choice of origin in both ordinate and coordinate—the first two terms in the Taylor series expansion of f vanish. The expansion is shown in line 2 of Fig. 8.

There remain the two degrees of freedom represented by the two control-parameter values c_1, c_2. It might be expected that we can use these two degrees of freedom to annihilate one, or at most two, of the remaining coefficients in the Taylor series expansion, but that

FIG. 8. The steps used to reduce a two-parameter family of functions to its canonical form at the most degenerate possible critical point are illustrated in lines 1–4. The steps used to determine the universal perturbation are shown in lines 5–7.

we cannot generically (some deep mathematics is required at this point: cf. Poston and Stewart, 1978; Arnol'd, 1981, 1986; Gilmore, 1981) annihilate more than two coefficients. If coefficients of some high powers (f_5 of x^5, f_7 of x^7) are annihilated, then the coefficient f_2 of x^2 remains nonzero, the Morse lemma is applicable, and nothing qualitatively interesting will happen. The most interesting things happen when the control parameter degrees of freedom are used to annihilate the leading nonzero terms in the Taylor series expansion. In the present case the following two interesting possibilities arise:

(i) $f_2=0,\ f_3\neq 0,$

(ii) $f_2=0,\ f_3=0.$

The second case is more interesting than the first, which can already be encountered in functions depending on one state variable and a single control parameter.

We assume therefore that the two control-parameter degrees of freedom can be used to annihilate the two leading nonzero terms in the Taylor series expansion given on line 2 of Fig. 8. The resulting Taylor series expansion shown on line 3 of Fig. 8 begins with a term of degree 4.

This is as far as we can go using the simple "linear" degrees of freedom represented by choice of origin in the ordinate and coordinate and the two control-parameter degrees of freedom. However, we have not yet exploited any "nonlinear" degrees of freedom. That is, there is the possibility to perform a smooth nonlinear change of coordinates to remove some of the higher-degree terms in the Taylor series expansion. To do this we seek a nonlinear change of variables,

$$x'=A_1x+A_2x^2+\cdots, \tag{29}$$

which will eliminate as many of the higher-degree terms as possible from the remaining Taylor series expansion (line 3, Fig. 8). It is possible to find a nonlinear change of variables that eliminates the Taylor tail, the tail of the Taylor series expansion (the term x^4 is determinate; more powerful mathematics is needed at this point also, cf. Poston and Stewart, 1978; Arnol'd, 1981, 1986; Gilmore, 1981). The first two coefficients in the nonlinear change of variables above are $A_1 = |f_4|^{1/4}$, $A_2 = \pm f_5/4|f_4|^{3/4}$. The expansion is analytic and the sum converges locally. In the new coordinate system the transformed function is $\pm x^4$. The Taylor series after this nonlinear change of variables is shown on line 4 of Fig. 8.

This procedure produces the catastrophe germ of the two-parameter family of functions $f(x;c_1,c_2)$:

$$f(x;c_1,c_2) = \pm x^4 \quad \text{(catastrophe germ)}. \tag{30}$$

The second step in the process of reducing a non-Morse function to canonical form is computation of the universal perturbation of minimum dimension. To do this, we repeat the procedure described above in almost the reverse order. We begin by adding an arbitrary perturbation

$$\epsilon(x) = \sum_{i=0}^{\infty} \epsilon_i x^i \tag{31}$$

to the catastrophe germ. The Taylor series expansion of the perturbed function is presented on line 5 of Fig. 8.

A nonlinear change of variables can once again be called upon to eliminate the Taylor tail. The nonlinear transformation (29) fails to converge unless the base term from which the elimination is made has a large coefficient. Thus, trying to eliminate the Taylor tail of terms above x, x^2, or x^3 will fail because the coefficients of these terms, ϵ_1, ϵ_2, ϵ_3, are small and not bounded away from zero. However, since the coefficient $(\pm 1 + \epsilon_4)$ of x^4 is large and bounded away from zero when ϵ_4 is small, all terms above x^4 may be eliminated by a nonlinear change of coordinates. To state this in another way: Any terms in the Taylor tail that may be eliminated in the initial construction of the catastrophe germ (line 3 to line 4) can be eliminated from the perturbation (line 5 to line 6). The result of this nonlinear change of variables is shown in line 6 of Fig. 8.

As a final step, we can choose a new origin of ordinates (rigid vertical shift) to eliminate ϵ_0 and of coordinates (rigid horizontal shift) to eliminate one of the three remaining terms. Since the linear and quadratic terms cannot always be eliminated but the cubic term can be, we choose to eliminate this term. The final result,

$$f(x;c_1,c_2) = \pm x^4 + \epsilon_1 x^1 + \epsilon_2 x^2, \tag{32}$$

is shown in line 7 of Fig. 8.

We summarize briefly the steps taken to answer the two equations implicit in the statement of the classification theorem presented at the beginning of this section:

1. How to construct the catastrophe germs:
   - (a) Locate a critical point and move the origin of coordinates to that critical point.
   - (b) Eliminate the leading Taylor series coefficients by using the control parameters.
   - (c) Remove the Taylor tail by a smooth nonlinear change of variables.
2. How to construct the universal perturbation:
   - (d) Add an arbitrary perturbation.
   - (e) Remove the Taylor tail by the same smooth nonlinear change of variables.
   - (f) Move the origin of coordinates to eliminate unnecessary terms.

2.2 General Procedure

The general procedure for reducing a non-Morse function to the sum of a catastrophe germ and a universal perturbation has been illustrated by example in the previous section. In some respect, the procedure followed in the reduction follows in spirit the procedure used in the study of electrodynamics. We often find that the near-field regime (low-degree Taylor series terms) is tractable, as is the far-field regime (Taylor tail). The really interesting part is between these two regimes (intermediate-field regime ~catastrophe germ).

We summarize the general procedure below and refer to Fig. 9. The following steps are taken to compute the catastrophe germ of a function $f(x;c)$ with $x \in R^n$ and $c \in R^k$:

1. Computation of the catastrophe germ CG(l):
   - (a) The function is expanded in a Taylor series. The origin of ordinates and coordinates is rigidly (linearly) shifted to a critical point. This eliminates the zeroth- and first-degree terms in the Taylor series expansion.
   - (b) The control parameter degrees of freedom are used to eliminate as many of the remaining low-degree Taylor series coefficients as possible. No more than k coefficients can typically be annihi-

lated (by transversality: cf. Poston and Stewart, 1978; Arnol'd, 1981, 1986; Gilmore, 1981).

(c) A smooth nonlinear change of variables is introduced to eliminate as many terms in the Taylor tail as possible. Whether all terms above some finite degree, or only most terms, can be eliminated is determined algorithmically (determinacy algorithm: cf. Poston and Stewart, 1978; Arnol'd, 1981, 1986; Gilmore, 1981).

After the catastrophe germ has been computed, the steps followed above are taken in reverse order to compute the universal perturbation of the catastrophe germ:

2. Computation of the universal perturbation $\mathrm{Pert}(l,k)$:
   (d) An arbitrary perturbation is added to the germ. The smooth transformation used to eliminate the Taylor tail in step (c) above is used again to eliminate the same terms of the perturbed germ and reduce the coefficients in the germ to the same canonical values.
   (e) A shift of ordinate and coordinate is introduced to eliminate the constant term in the perturbation and l (state space dimension of the germ) of the remaining terms of the perturbation.

This procedure reduces a family of functions to canonical form in the neighborhood of a degenerate critical point.

2.3 A More Complicated Example

In this closing section of Sec. 2 we tackle a more complicated example. This is done for two reasons:

1. to illustrate the methodology described in the previous section for a multidimensional state-variable space.
2. to illustrate exactly why the classification of elementary catastrophes terminates at control dimension $k=5$.

The particular example we consider is the reduction to standard form of the six-control-parameter family of functions defined on a three-dimensional state-variable space,

$$f(x;c)=f(x,y,z;c_1,c_2,c_3,c_4,c_5,c_6). \qquad (33)$$

To effect this reduction we follow the steps described in the previous two sections. The computation of the catastrophe germ is illustrated in Fig. 10(a). The computation of the universal perturbation is shown in Fig. 10(b). The steps 1–5 used to compute the germ below are indicated by the corresponding numbers over the arrows, which show the effect of these steps, in Fig. 10(a). Steps 6–9, used to compute the universal perturbation, are similarly keyed to the arrows in Fig. 10(b).

1. The Taylor series expansion for this function is

$$f(x;c)=\sum_{\substack{i\geqslant 0\\ j\geqslant 0\\ k\geqslant 0}} \frac{i!j!k!}{(i+j+k)!} f_{ijk}(x-x_0)^i \times (y-y_0)^j(z-z_0)^k. \qquad (34)$$

   This Taylor series is illustrated schematically in Fig. 10(a), where we have grouped together all terms of the same degree and suppressed factorials.
2. We search over state-variable space for a

critical point, then move the origin of coordinates to that point. This removes the constant and linear terms from the Taylor series expansion.

3. The six control-parameter degrees of freedom can be used to eliminate up to six of the remaining terms in the Taylor series expansion. If any of the quadratic terms remain, the catastrophe ultimately constructed appears in the list given in Table 2. However, if we use these six control-parameter degrees of freedom to eliminate all six second-degree terms from the Taylor series expansion, something new appears. Accordingly, we make this choice. The resulting expansion begins with the third-degree terms.
4. Using a homogeneous linear transformation we can attempt to put the cubic terms into some canonical form. Since a linear transformation on the state-variable space is a 3×3 matrix with 3^2 degrees of freedom and there are ten cubic coefficients, it is possible to give canonical values to only nine of these ten coefficients. Symmetry dictates the choice

$$\sum_{i+j+k\geqslant 3} f_{ijk}x^iy^jz^k = x^3+y^3+z^3+axyz \quad (+\text{ higher-degree terms}). \tag{35}$$

This linear transformation maps nth-degree terms ($n\geqslant 3$) into terms of the same degree. The parameter, a, which appears in this function cannot be given a canonical value, and is the reason why this catastrophe is not elementary.

5. We then search for a smooth nonlinear change of variables which will eliminate as much of the tail of the Taylor series expansion as possible. If

$$(a/3)^3+1\neq 0, \tag{36}$$

the cubic terms are determinate. This means that a smooth transformation exists which transforms away all terms in the Taylor series expansion of degree in excess of some finite value, in this case three. The resulting catastrophe germ is

$$f(x;c) = T_{3,3,3} = x^3+y^3+z^3+axyz. \tag{37}$$

This catastrophe germ is shown at the bottom of Fig. 10(a).

6. To compute the universal perturbation we add a general function of three state variables,

$$\epsilon(x,y,z) = \sum_{\substack{i\geq 0\\ j\geq 0\\ k\geq 0}} \epsilon_{ijk} x^i y^j z^k, \tag{38}$$

   to the catastrophe germ $T_{3,3,3}$. All coefficients ϵ_{ijk} are assumed to be small. The Taylor series of the resulting perturbed function is shown in Fig. 10(b).
7. Working backwards, we find a linear transformation which transforms the cubic terms to the form (37).
8. If the original function $T_{3,3,3}$ is determinate $[(a/3)^3+1\neq 0]$, the perturbed function must also be determinate $[(a'/3)^3+1\neq 0,\ a'=a+\epsilon_{111}]$ for a sufficiently small perturbation. This means that a smooth transformation exists which transforms away all terms in the Taylor series expansion of the perturbed germ of degree greater than 3.
9. Finally, we make a rigid displacement of coordinate system to eliminate the constant term ϵ_{000} in the perturbation and three of the remaining nine linear and quadratic terms. Since it is always possible to eliminate the three terms x^2, y^2, z^2, the universal perturbation is

$$\begin{aligned}\mathrm{Pert}(l=3,k=6) = {} & \epsilon_{100}x+\epsilon_{010}y+\epsilon_{001}z\\ & +\epsilon_{110}xy+\epsilon_{101}xz\\ & +\epsilon_{011}yz+axyz. \end{aligned}\tag{39}$$

   The seventh term, $axyz$, has been added because it is not possible to reduce the coefficient of xyz in the catastrophe germ $T_{3,3,3}$ to a standard value. The universal perturbation is shown at the bottom of Fig. 10(b).

The net result of this calculation is a reduction of the function $f(x;c)$ given in Eq. (33) to canonical form:

$$\begin{aligned} f(x;c) &= T_{3,3,3} + \mathrm{Pert}(3,6)\\ (33) &= (37) + (39) \end{aligned}\tag{40}$$

We emphasize once more that for $k<6$ control parameters it is possible to assure that any catastrophes that are encountered are elementary, but for $k=6$ (and $k>6$) this is no longer possible, as $T_{3,3,3}$ shows.

3. HOW IT WORKS

Elementary catastrophe theory consists of a collection of theorems about the canonical forms of functions in the neighborhood of degenerate critical points. Catastrophes in the real world consist of processes that exhibit discontinuities and sudden jumps. It is clear that the mathematics provides the right language for describing the physical processes. But how? The mathematics describes potentials that depend on control parameters; processes depend on time. It is tempting to allow control parameters to depend on time, but then the catastrophe functions are no longer strictly potentials. And what of the dynamics describing a physical system? If many equilibria are available, which does the system choose? Finally, how can we recognize when a physical process can be modeled by a mathematical catastrophe function?

These practical questions are the subject of Sec. 3 of this article. The difficulty of relating the dynamics of a system to a potential that describes it is discussed in Sec. 3.1. In most instances the system state is governed either by a local or the global minimum of a potential, and sudden jumps from one state to another occur when the control parameters pass through an appropriate component of the bifurcation set. Although the two conventions presented (Maxwell, Delay) are not complete, they serve well in a preponderance of situations.

When a catastrophe occurs in some physical process, a multiplicity of related phenomena occur. These phenomena are called catastrophe flags. They are treated in Sec. 3.2. The identification of any is a clear indication that the others are present and will be recognized if sought. These flags may be used to identify the mathematical catastrophe function that most accurately describes the discontinuous physical process.

In Sec. 3.3 we illustrate the use of catastrophe theory in determining the sensitivity of failure modes of a complex structure to hidden or unforeseen imperfections. This is done by investigating the catastrophe germ for an optimized system and then determining the universal perturbation for that germ. In the particular example considered, that of a propped cantilever, strong coupling of two "soft" collapse modes yields a "soft" collapse direction and a "hard" direction, one in which a severe and unexpected collapse is possible. Further, analysis of the universal perturbation for that collapse mode reveals that the mode is extremely sensitive to imperfections in either the design or fabrication stages of construction. Finally, the use of catastrophe theory to suggest tests to locate the actual (as opposed to designed) failure load, as well as ways to increase the load at which failure occurs, are suggested.

Since elementary catastrophe theory is the first step in the program of catastrophe theory, all its results and phenomenology will necessarily be present in subsequent developments in this program. The next stage in this program following elementary catastrophe theory is the study of dynamical systems, sets of coupled first-order ordinary differential equations. We show in Sec. 3.4 how the fold and the cusp catastrophe appear in dynamical systems theory under the guise of three elementary bifurcations: the saddle-node bifurcation (A_2), the pitchfork bifurcation (A_3), and the Hopf bifurcation (A_3).

3.1 Catastrophe Conventions

Elementary catastrophe theory is the first tentative step in the program of catastrophe theory. It was motivated above by our desire to describe the qualitative properties of gradient dynamical systems of the form (4). The qualitative dynamics of such systems are determined by a potential function. The local flow in the neighborhood of each nondegenerate critical point (Morse i-saddle) is canonical and the separate flows can be pasted together to construct a global flow.

As the study of elementary catastrophe theory evolved, it became clear that the key to our understanding of non-Morse critical points was the determination of how the critical points moved about, coalesced and disappeared, or were born degenerate and moved apart as the control-parameters changed. The dependence of critical points on control-parameter values, as described by the canonical decomposition (15), provides a complete resolution to the mathematical question posed by elementary catastrophe theory. However, it does not address a corresponding physical question. That is, how does the dynamics depend on the control parameters? Once the control parameters are allowed to vary in time, the system (4) is no longer a gradient system—the potential is time dependent. As a result, knowledge of the shape of the potential is not sufficient to determine the state of the system unless the equations of motion are known.

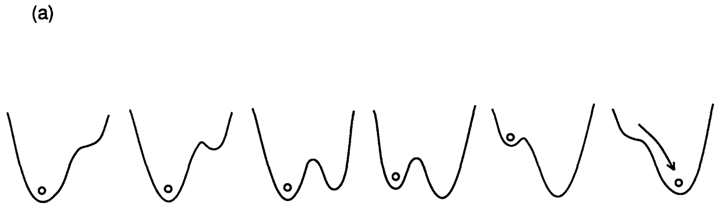
In the absence of a detailed set of equations of motion, the state of the physical system described by an elementary catastrophe must be determined by some infusion of intuition. This is done by adopting one of two standard assumptions. These are the Delay convention and the Maxwell convention (Zeeman, 1977; Poston and Stewart, 1978; Gilmore, 1981).

Delay Convention: The state of a system is determined by a (local) minimum of a potential. As the control parameters change, the state remains at the local minimum as long as that minimum exists. When the local minimum ceases to exist (at a bifurcation set) the system state jumps to a new local minimum.

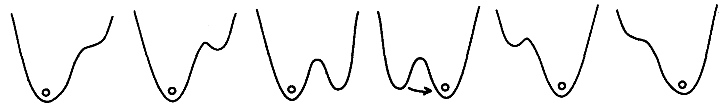
Maxwell Convention: The state of a system is determined by the global minimum of a potential. As the control parameters change, the state remains at the minimum as long as that minimum remains the global minimum of the potential. When the minimum ceases to be the global minimum, the system state jumps to the new global minimum.

We stress again that these assumptions about the behavior of a physical system are required only by our lack of knowledge of the system's equations of motion.

The difference between these two assumptions is illustrated in Fig. 11 for the cusp catastrophe. When $a<0$ the potential may have one minimum or two. We assume the system begins in the unique minimum of the potential. As the control parameter b is changed, a new minimum is created in a fold catastrophe. The original minimum eventually becomes metastable with respect to the new minimum, and finally the original minimum disappears in a fold catastrophe. According to the Delay convention, the system jumps to the new minimum only when the original minimum is annihilated. According to the Maxwell convention, the jump occurs when the two minima become equally deep (at $b=0$). These two conventions are illustrated on the canonical critical-value surface for the cusp in Fig. 11(b). The jumps occur at the parts of the critical-value graph



Delay Convention



Maxwell Convention

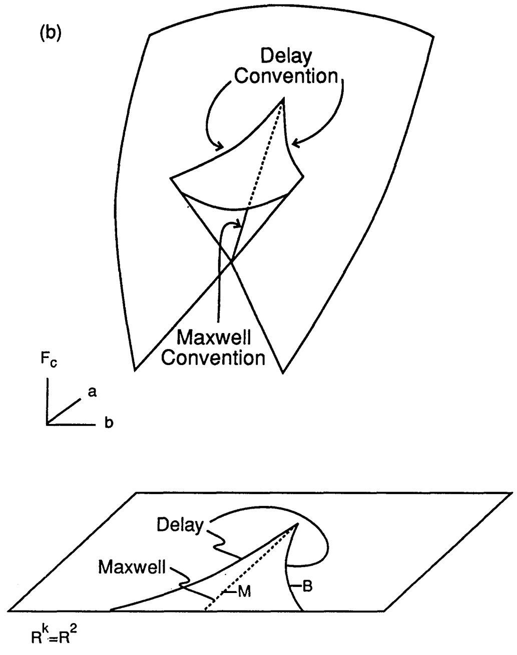


FIG. 11. (a) The Delay convention and the Maxwell convention determine when the jump from one local minimum to another takes place as the control parameters are varied. (b) The two bifurcation sets correspond to pieces of the critical surface which prevent the surface from being a manifold. Under the Delay convention, jumps occur at the creases in the surface, where a local minimum and maximum become degenerate. Under the Maxwell convention, jumps occur at the intersection of two of the leaves of this surface, where the two minima become equally deep.

$$f = f(x_c(a,b);a,b),$$

which prevent the surface from being a manifold. The Delay convention requires jumps to occur at the creases which represent the collision of a local minimum and maximum and which lie over the cusp-shaped curve (21). The Maxwell convention requires jumps to occur at the self-intersection which represents the surface on which the two minima are equally deep and which lies over the half-line $b=0$, $a<0$.

The bifurcation sets for the Delay and Maxwell conventions are sets in the control-parameter space at which jumps to new states take place. These sets are determined by local and global considerations for the two conventions. The bifurcation set for the Delay convention consists of that subset of the bifurcation set for the catastrophe which involves a Morse 0-saddle. For catastrophes more complicated than $A_{\pm 3}$, some components of the bifurcation set involve Morse saddles M_i^n and M_{i+1}^n, $i > 0$. On these components of the bifurcation set the two saddles M_i^n and M_{i+1}^n are degenerate. These components of the catastrophe's bifurcation set are not components of the bifurcation set determined by the Delay convention, since local minima (M_0^n) must be present. The bifurcation set for the Maxwell convention is determined by nonlocal arguments. Once a point on the Maxwell set has been located, the remainder of the set may be constructed by integrating a set of equations of Clausius–Clapeyron type (Gilmore, 1981).

The appropriate choice of convention must balance the rate at which the control-parameters are varied against the noise level of the system—specifically, the probability that a fluctuation in energy will occur in excess of the barrier height separating a local minimum from other minima, including the global minimum. When the noise level is low, it is usually safe to adopt the Delay convention. When large fluctuations occur more rapidly than the control parameters are swept, the Maxwell convention is more suitable.

From Fig. 11 it can be observed that the bifurcation set for the Maxwell convention "lies inside" the bifurcation set for the Delay convention. This is a general feature of catastrophes and has the following physical interpretation. If a system whose phase transition properties are usually described by the Maxwell convention is handled very gently, the jump from a metastable state to a global minimum may not occur at the bifurcation set for the Maxwell convention. The transition may be delayed—but it cannot be delayed beyond the point at which the local minimum ceases to exist—the bifurcation set for the Delay convention. The outer limits beyond which metastability cannot occur for a physical system are called spinodal curves (or surfaces). The spinodal curves surrounding the bifurcation set for the Maxwell convention consist of the bifurcation set for the Delay convention. The spinodal curves for the symmetry-restricted catastrophe

$$A_{+5}\colon f(x;a,c)=\tfrac{1}{6}x^6+\tfrac{1}{4}ax^4+\tfrac{1}{2}cx^2 \tag{41}$$

are shown in Fig. 12.

When the equations of motion for the system are known explicitly, there is no need to make an assumption (i.e., adopt a convention) about the system's behavior. For example, the system state may be governed by a probability distribution, $P(x,t)$, which satisfies a Fokker–Planck equation

$$\partial P/\partial t=\nabla(P\nabla V)+\nabla^2(DP), \tag{42}$$

where V has a time dependence due to the time dependence of some control parameters:

$$V(x;t)=V(x;c(t)) \tag{43}$$

and D is a diffusion constant. Then the probability distribution for the system state can be determined explicitly as a function of time. In this case there is no well-defined bifurcation set—there is an occupation probability for the two minima (and surrounding regions) and that probability changes smoothly in time.

It has been shown that the Fokker–Planck equation can be used to interpolate between the two extreme limits represented by the Delay convention and the Maxwell convention (Gilmore, 1981).

We remark, finally, that the problem of system state is not necessarily resolved by adopting the Delay convention, as appears to be the case in Fig. 11. In that figure there is one remaining minimum when the metastable minimum disappears in a fold catastrophe, so the system has a unique minimum to jump to. But what happens when there are two or more remaining minima that the system can jump to? Does the system jump to the deepest minimum, the nearest minimum, or yet another minimum? On this the Delay

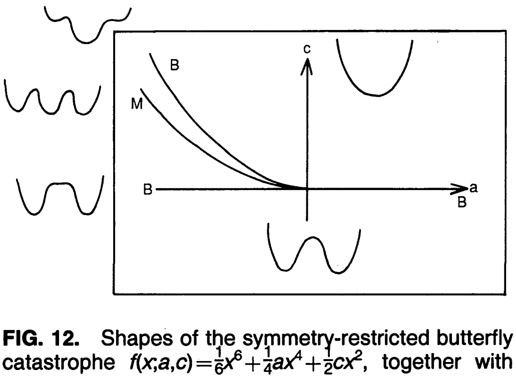

FIG. 12. Shapes of the symmetry-restricted butterfly catastrophe $f(x;a,c)=\frac{1}{6}x^6+\frac{1}{4}ax^4+\frac{1}{2}cx^2$, together with bifurcation sets under the Delay and Maxwell conventions. Spinodal curve for the Maxwell set is the bifurcation set for the Delay convention.

convention has nothing to say. In short, the conventions are incomplete. They can be very useful but they are not substitutes for detailed knowledge of the equations of motion.

3.2 Catastrophe Flags

An important reason for studying the elementary catastrophes is that their properties are canonical. Therefore, predictions based on the properties of an elementary catastrophe in a physical system are canonical. This means that their properties need be studied only once. They can then be applied directly, without change, to any physical system described by that catastrophe. As a result, it is important to be able to determine the presence and type of a catastrophe underlying the behavior of a physical system.

This may be done either deductively or inductively. In the first procedure there is full knowledge of the equations of motion describing the system. When this is the case it is generally possible to make whatever predictions are desired by computing solutions of these equations. It is then possible to predict the behavior of the system without any knowledge of the elementary catastrophes. This, in fact, has been a long-standing operational mode in the physical sciences.

There are, however, instances in which the equations of motion are not known. Then the presence of a catastrophe cannot be deduced (from the equations). It may, however, be induced from the behavior of the system. When a catastrophe is present, the system undergoes (or may undergo) a qualitative change in its behavior. This qualitative change is often accompanied by a number of other phenomena. For any particular system these may be more or less difficult to recognize. The point is that the observation of any will imply the presence of all and that if we look hard enough we will find all these correlated phenomena.

Eight phenomena typically occur when a catastrophe is present. These are called catastrophe flags: in a sense the catastrophe "waves flags" to attract our attention. Of the eight, five are classical: they occur when there is a qualitative change in the system. The remaining three also occur when there is a qualitative change, but they may also be observed before a phase change occurs. This is very important when the phase change represents the transition of a structure from one state to another (i.e., collapse of a bridge). The five classical catastrophe flags are modality, sudden jumps, inaccessibility, sensitivity, and hysteresis (Zeeman, 1977; Poston and Stewart, 1978). The three diagnostic catastrophe flags are divergence of linear response, time dilation, and anomalous variance (Gilmore, 1981). These are now discussed and illustrated in Fig. 13 for the cusp catastrophe.

3.2.1 Modality. In the neighborhood of a catastrophe the system can exhibit two or

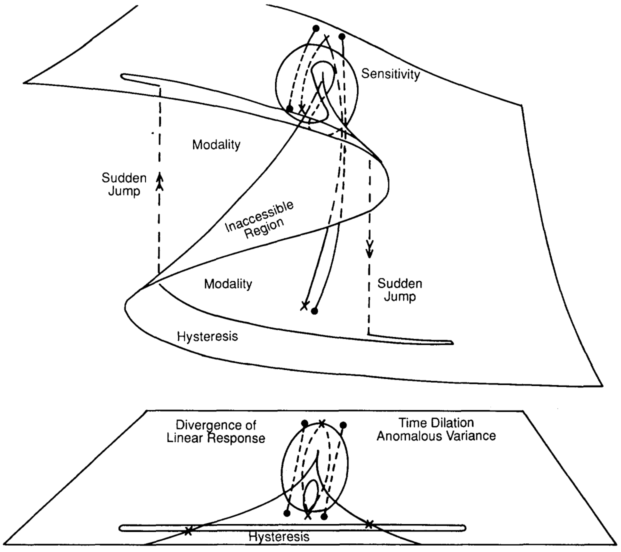

FIG. 13. Eight phenomena (flags) associated with the presence of a catastrophe.

more distinct types of behavior (near a critical point: liquid, gas; near a triple point: solid, liquid, gas). The upper and lower surfaces of the cusp catastrophe manifold represent two distinct types of locally stable behavior in Fig. 13. The intermediate part of this manifold represents an unstable mode of behavior which nevertheless may be observed with sufficient care.

3.2.2 Sudden Jumps. The system may suddenly jump from one mode of behavior to another mode of behavior (liquid, high density, to gas, low density) as the control parameters (intensive thermodynamic variables: temperature and pressure) are varied. These jumps represent the transition from one local minimum to a global or another local minimum. The location of the sudden jumps may or may not be adequately described by one of the two conventions presented in Sec. 3.1.

3.2.3 Inaccessibility. Separating the two or more local minima (M_0^n) responsible for "modalities" is at least one Morse saddle (M_1^n). The Morse saddles M_i^n ($i > 0$) are all dynamically unstable. In the neighborhood of such a saddle the system, if perturbed, will move quickly to a locally stable state. As a result, modality will always be accompanied by inaccessible regimes as represented by the middle sheet of the cusp catastrophe manifold.

3.2.4 Sensitivity. If the system is brought from the single-mode regime to the multimode regime the question arises: what is the final state of the system? For most initial conditions and processes, the final state is robust against perturbations. That is, if the final state lies on the upper sheet of the cusp catastrophe manifold, then a perturbation of either initial conditions and/or processes will leave the final state on the upper sheet. However, there is a small set of initial conditions and/or processes for which this is not true. This sensitivity to (some) initial conditions is shown in Fig. 13. For the process $db/dt=0$, $da/dt<0$ the initial condition with $b=\epsilon>0$ will result in a final state on the lower sheet while the nearby initial condition $b=-\epsilon<0$ lies on the upper sheet. A similar phenomenon occurs for processes that are almost identical, beginning from appropriate initial conditions. We remark that for the elementary catastrophes there is sensitive dependence on *some* initial conditions while in the study of chaos there is sensitive dependence on *all* initial conditions.

3.2.5 Hysteresis. A sudden jump from one modality to another may occur at the bifurcation set for the Delay or Maxwell convention, or anywhere in between. If the process is reversed, the jump back to the original modality may occur at the same control-parameter value as the initial jump (Maxwell convention) or at different control parameter values (any other convention). Unless the Maxwell convention is observed, jumps between the different modalities will exhibit hysteresis. Hysteresis, while not necessarily a part of the catastrophe scenario, can usually be observed with sufficient care even when the Maxwell convention suggests itself (e.g., superheating and supercooling in a liquid–gas phase transition).

The five classical catastrophe flags just described are of little use to the structural engineer looking for the limits of stability of a large structure (bridge, building) or a naval engineer testing a ship's stability. In many instances, transition from one modality to another is not only a catastrophe, but a disaster as well (collapsed bridge, building; capsized ship). For this practical reason it is essential to have a set of catastrophe flags that identify the presence of a catastrophe, and can be used to map out approximately the bounds of the catastrophe (i.e., bifurcation sets) without actually having to enter the multimode regime, or at least make the transition between modes. The three diagnostic catastrophe flags accomplish just this.

3.2.6 Divergence of Linear Response. The response, δx_i, of an equilibrium in state-variable space to a small change in the control parameters, δc_α, is given by

$$\delta x_i=\chi_{i\alpha}\delta c_\alpha, \tag{44}$$

where the linear susceptibility tensor $\chi_{i\alpha}$ is given explicitly by Eq. (25) for a system governed by a potential. As a local bifurcation set is approached, at least one of the eigendirections has a very large response. This is the direction in which two or more critical points are approaching each other. This direction is an eigenvector of the stability matrix, V_{ij}, in Eq. (25). The eigendirection, and the dependence of the diverging eigenvalue (λ_i^{-1}) on the control parameters c_α, can be used to map out the bifurcation set without actually penetrating it (Gilmore, 1981). In the liquid–gas phase transition divergence of linear response manifests itself as the divergence of the compressibility as the critical point is approached from either the single-phase or the multiphase region. Divergence of the compressibility may also be seen, with greater difficulty, as the spinodal lines are approached from within the multiphase region.

3.2.7 Time Dilation (Critical Slowing Down, Mode Softening). In the neighborhood of a nondegenerate critical point the equations of motion for a dissipative gradient system are

$$dx_i/dt = -V_{ij}x_j. \quad (45)$$

For a dissipative system the relaxation to equilibrium following a perturbation occurs on a time scale that is the reciprocal of the smallest eigenvalue of the stability matrix V_{ij}. For a conservative system the spectrum of oscillation frequencies, ω_i, consists of the square roots of the eigenvalues of V_{ij}. Upon approach to a bifurcation set one or more of the eigenvalues of V_{ij} approaches zero. Relaxation to equilibrium slows down (critical slowing down) as the bifurcation set is approached. The dependence of the vanishing eigenvalue on the control parameters can be used to determine where in control-parameter space the bifurcation set occurs. The associated eigenvector can be used to locate where in state space the critical points become degenerate. A similar analysis is possible when one (or more) of the frequencies of a conservative system approaches zero (mode softening). Time dilation is well known to experimentalists. The time required for equilibration near the critical point in the liquid–gas phase transition grows very rapidly as the critical point is approached, making experiments on the equilibrium properties of fluids near their critical points very difficult and time consuming.

3.2.8 Anomalous Variance. When the state of a physical system is described by a Morse critical point, motion about the equilibrium is confined by a quadratic potential well. On approach of another critical point the quadratic potential becomes flattened and motion about the equilibrium becomes less confined. This reduction in localization, or deconfinement, is called anomalous variance. In a gas–liquid system anomalous variance is dramatically observed at the critical point as critical opalescence. This occurs when fluctuations in the size of liquid droplets in the gas phase and gas bubbles in the liquid phase can occur at all length scales, including length scales comparable to optical radiation, producing an anomalously strong scattering of light.

Although catastrophe theory provides a qualitatively correct description of physical properties of a fluid near its critical point, it does not provide a quantitatively correct description of these properties and must be replaced by a better descriptive mechanism for the purposes of making accurate predictions of physical behavior.

3.3 The Dangers of Design Optimization

Large structures are built from many smaller parts. Cost is almost always a major factor in the design and construction of a complex structure, such as a bridge. As a result, a design philosophy has been widely adopted. This is the philosophy of design optimization. The basic idea is to design each component to meet but not exceed its specifications. For example, if an elevated roadway designed to support a load L is to be supported by ten cantilevers, each cantilever should be designed to support some fraction of that load. It makes no sense to design some cantilevers to be stronger (and more expensive) than others: what good will they do when the others have already collapsed, taking the roadway with them?

This is the philosophy of design optimization. It has hidden dangers because complex structures may have hidden or unexpected collapse modes. Further, these modes may have exceptionally sensitive dependence to imperfections in the fabrication/construction stages. We illustrate these ideas and dangers by treating a simple example. This is a propped cantilever designed to support a load F up to some critical load, F_c.

The cantilever is shown in Fig. 14. We assume it has unit length and a force F is applied vertically at the top of the cantilever. The mass of the beam is assumed small compared to the loading force F.

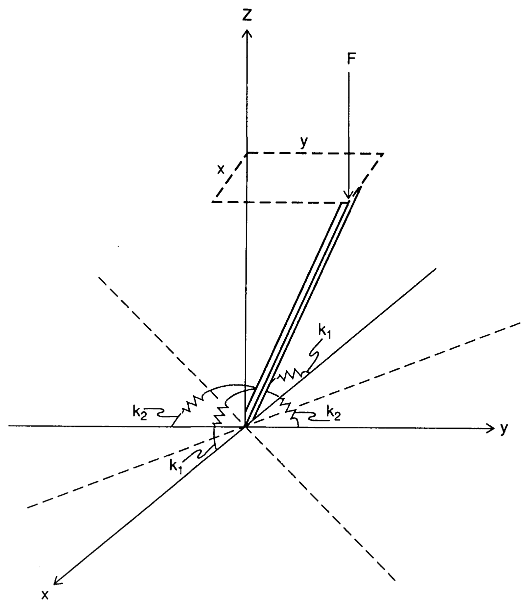

FIG. 14. The cantilever consists of a vertically propped beam supported by springs of spring constant k_1 providing restoring forces in the x–z plane and springs of spring constant k_2 providing restoring forces in the y–z plane. The length of this beam is scaled to 1. Displacements from the vertical are described by the (x,y) coordinates of the top of the beam. Solid axes (x,y) are axes along which a "soft" A_{+3} catastrophe occurs. Dashed axes ($x=\pm y$) are axes along which a "hard" A_{-3} catastrophe occurs.

We assume the collapse modes of this cantilever involve deflection in the x-z plane through an angle θ_1 from the vertical, deflection in the y-z plane through an angle θ_2 from the vertical, or any combination of these motions. We also assume that deflection is counteracted by springs with spring constants k_1, k_2 providing restoring forces in the x-z and y-z planes, respectively. The potential describing this cantilever is

$$V(\theta_1,\theta_2;F)=(2/2)k_1\theta_1^2+(2/2)k_2\theta_2^2+Fz, \quad (46)$$

where z is the height of the top of the cantilever.

It is useful to express this potential as a function of the displacement coordinates $x=\sin\theta_1$ and $y=\sin\theta_2$ of the top of the cantilever. The potential, up to quartic terms, is

$$V(x,y;F)=k_1x^2(1+x^2/3)+k_2y^2(1+y^2/3)$$
$$+F(1-x^2-y^2)^{1/2}. \quad (47)$$

For displacements in the x-z plane with $y=0$,

$$V(x,0;F)=F+(k_1-F/2)x^2+(k_1/3-F/8)x^4. \quad (48)$$

This can immediately be recognized as a symmetry-restricted cusp catastrophe, A_{+3}. A similar potential describes displacements in the y-z plane $x=0$. Since the potential $V(x,y;F)$ exhibits a bifurcation at $k_1-F/2=0$ and $V(0;y;F)$ exhibits one at $k_2-F/2=0$, it makes sense to design the cantilever with equal spring constants $k_1=k_2=F_c/2$, where F_c is the critical load to be supported by the cantilever.

Or does it?

The potential for the optimized cantilever under an arbitrary displacement is

$$V(x,y;F)=F+\tfrac{1}{2}(F_c-F)(x^2+y^2)$$
$$+(F_c/6-F/8)(x^4+y^4)-\tfrac{1}{4}Fx^2y^2. \quad (49)$$

The last term represents a strong coupling between the two displacement directions. This coupling term has severe consequences for the collapse behavior of the cantilever.

As the force F is increased, the potential $V(x,y;F)$ remains locally stable until the critical load F_c is reached. At this load, the fourth-degree term $F_c(x^4-6x^2y^2+y^4)/24$ allows sudden collapse of the cantilever in particular directions. This is not what is expected from investigating the planar potentials $V(x,0;F)$ and $V(0,y;F)$: for these potentials the coefficient of the quartic term is positive at the critical load, so that only a small in-plane displacement occurs after the critical load is exceeded. In other words, the postbuckling behavior of the cantilever in either the x-z plane or the y-z plane is "soft" in the sense that after the bifurcation the stable equilibrium is located near the original stable equilibrium $(x,y)=(0,0)$ in the state-variable space.

In cylindrical coordinates $x=r\cos\phi$ and $y=r\sin\phi$ the potential is

$$V(r,\phi;F)=F+(k-F/2)r^2$$
$$+(k/3)r^4(\cos^4\phi+\sin^4\phi)-(F/8)r^4. \quad (50)$$

The coefficient of r^4 is largest $(=+1)$ for displacements along the $\pm x$ or $\pm y$ axes ($\phi=n\pi/2$, n integer) and smallest $(=1/2)$ for displacements along the axes $x=\pm y$ ($\phi=\pi/4$

$+n\pi/2$, n integer). Along these two different sets of displacement directions the potentials are

$$V(r,\phi=0;F)=F+(k-F/2)r^2+(k/3-F/8)r^4, \tag{51a}$$

$$V(r,\phi=\pi/4;F)=F+(k-F/2)r^2+(k/6-F/8)r^4. \tag{51b}$$

The first potential, representing displacements in the x-z or y-z planes, is a catastrophe of type A_{+3}, with "soft" postbuckling behavior. That is, for loads in excess of the critical load the displacement from vertical increases rapidly but continuously. The second potential, representing coupled displacements ($x=\pm y$), is a catastrophe of type A_{-3}, with "hard" postbuckling behavior. For loads in excess of the critical load the only stable position is horizontal—completely collapsed.

These observations may appear academic. After all, the cantilever remained vertical and supported loads F below the critical load. However, we have not yet considered imperfection sensitivities. These are encountered in the fabrication stages (of the springs, for example) and the construction stages in every large project. The most general perturbation, representing arbitrary imperfections for the cantilever, are obtained by investigating the germ of the potential, which is $(x^4-6x^2y^2+y^4)/24$. The universal perturbation of this catastrophe germ is the eight-parameter function

$$\mathrm{Pert}(x,y;a_{ij})=\sum a_{ij}x^iy^j, \quad i\leqslant 2,\ j\leqslant 2,\ (ij)\neq(00). \tag{52}$$

It is truly remarkable that every imaginable imperfection in fabrication of the individual components (nonuniformity in density of material from which the beam is constructed, unwanted bends in the beam, air bubbles, etc.) as well as every imaginable imperfection in construction (springs along the x axis with different spring constants, springs along x and y axes slightly out of perpendicular, rest height not quite vertical, loading force not quite vertical, etc.) can be represented by a universal perturbation with only eight parameters.

However, even eight parameters will present a complicated problem of analysis. In the present case we can do even better. The failure eigendirections for the soft A_{+3} catastrophe are the x and y axes $(\pm x,0)$, $(0,\pm y)$. Under this catastrophe [Eq. (51a)] the original unperturbed stable solution $(x,y)=(0,0)$ becomes unstable for $F>F_c$, giving rise to new stable equilibria $(\pm[6(F/F_c-1)]^{1/2},0)$, $(0,\pm[6(F/F_c-1)]^{1/2})$. Since the new equilibria are relatively near the old one and are stable, this structural failure is a "soft" bifurcation. This "soft" bifurcation is shown in Fig. 15(a).

The other failure eigendirection, $x=\pm y$, is a "hard" bifurcation and a completely different story. In this case [Eq. (51b)] the new equilibria exist for $F<F_c$ at $(\pm[6(1-F/F_c)]^{1/2}, \pm[6(1-F/F_c)]^{1/2})$. These equilibria are saddles of type M_1^2. If for $F<F_c$ a perturbation moves the system state (x,y) to the neighborhood of any of these saddles, there is the possibility of sudden collapse of the cantilever. This "hard" bifurcation is shown in Fig. 15(b).

As a result of these considerations, in order to study the severe failure modes of the propped cantilever, and in particular the imperfection sensitivity of these modes, it is sufficient to study the imperfection sensitivity of the A_{-3} catastrophe [Eq. (51b)]. Under the most general perturbation, the potential describing failure modes in the weak eigendirection is

$$V(r;b,F)=-\tfrac{1}{24}F_cr^4+\tfrac{1}{2}(F_c'-F)r^2+br, \tag{53}$$

where $F_c' = F_c + a$, and a is one of the two control parameters for the cusp catastrophe. The other parameter, b, describes symmetry-breaking perturbations. The load $F_f = F(F_c',b)$ at which the propped cantilever collapses is determined by the values of F_c', b at which the locally stable equilibrium becomes degenerate with either of the two saddles it separates. This locus is the semicubical parabola (21b), which gives for the failure load

$$F_f=F_c'-\tfrac{1}{2}(3bF_c^{1/2})^{2/3}. \tag{54}$$

This simple expression reveals that the failure load is severely decreased by any symmetry-breaking imperfection ($b\neq0$). The severity is indicated by the power-law dependence: 2/3. An imperfection leading to a small asymmetry in either plane $x=\pm y$ will lead to an unexpectedly large reduction in the cantilever's failure load. The imperfection sensitivity

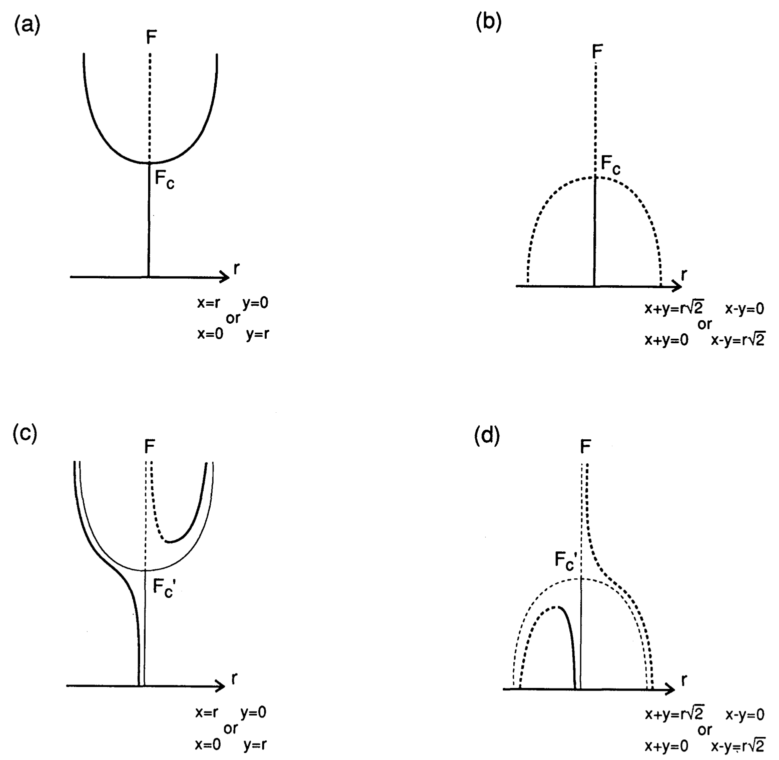

FIG. 15. In all figures stable equilibria (Morse saddles M_0^2) are shown by solid curves and unstable equilibria (M_1^2) are shown by dashed curves. (a) Equilibrium displacement for the "soft" A_{+3} catastrophe along the axes $(x,y=0)$ or $(x=0,y)$. Prebuckling path $(F<F_c)$ is $(x,y)=(0,0)$. Beyond the critical load, $F>F_c$, the postbuckling path is parabolic, with $r\sim(F-F_c)^{1/2}$. (b) Equilibrium displacement for the "hard" A_{-3} catastrophe along the directions $x=\pm y$. Prebuckling path $(x,y)=(0,0)$ is stable for $F<F_c$. There are no stable equilibria for $F>F_c$. (c) The most general perturbation of a cusp catastrophe consists of a linear plus a quadratic term: $(a/2)r^2+br$. The quadratic term $(a/2)r^2$ shifts the critical load: $\frac{1}{2}(F-F_c)r^2+(a/2)r^2+br\rightarrow\frac{1}{2}(F-F_c')r^2+br$, where $F_c'=F_c-a$. The linear term breaks the symmetry. For the "soft" catastrophe A_{+3} the perturbation displaces the equilibrium as shown. (d) For the "hard" catastrophe A_{-3} the perturbation can dramatically reduce the load at which failure occurs, as shown.

of the "soft" and "hard" bifurcations are shown in Figs. 15(c) and 15(d).

Having analyzed the problem, can we do anything about it? The first step is to determine how severe the problem is. To determine the failure load, we make use of the catastrophe flags. The first five (modality, sudden jumps, inaccessibility, sensitivity, hysteresis) are observable when the cantilever collapses. This is precisely the problem we would like to avoid. The remaining three catastrophe flags (divergence of linear response, critical slowing down, anomalous variance) are diagnostics designed precisely for the purposes at hand. That is, the system is subjected to gradually increasing loading. The following data are then recorded:

1. the displacement, r, from equilibrium;
2. the normal-mode frequency, ω, for small oscillations;
3. the amplitude, A, for small oscillations about equilibrium.

These three observables depend in a canonical way on the control parameters $F-F_c'$ and b. Testing is carried out gently and terminated before the collapse of the cantilever. By extrapolating the equilibrium displacement $r(F)$, the normal-mode frequency $\omega(F)$, and the amplitude of small oscillations $A(F)$, the failure load F_f and the control-parameter values F_c' and b at the failure load can be determined (Gilmore, 1981). Such extrapolations are shown in Fig. 16.

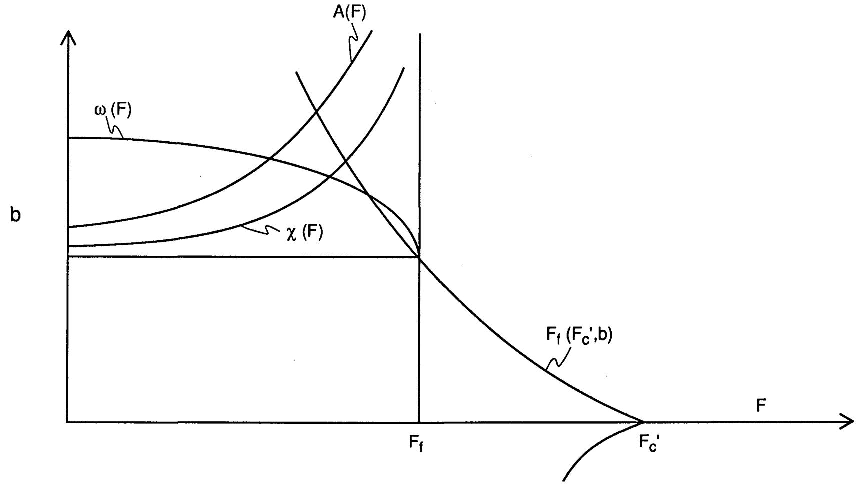

FIG. 16. The failure load $F_f(F_c,b)$ has a 2/3 power-law dependence on the symmetry-breaking parameter b. The value of the load at which collapse occurs (vertical line at F_f) can be located by exploiting the catastrophe flags. This is done by plotting the frequency of small oscillations, $\omega(F)$ (critical slowing down), by determining the linear susceptibility, $\chi(F)$ (divergence of linear response), and by measuring the amplitude of small equal-energy oscillations, $A(F)$ (anomalous variance), all as functions of increasing load F. The amplitude diverges and causes collapse before the failure load F_f is reached.

Once the symmetry-breaking parameter b has been determined, small adjustments to the cantilever can be made to reduce the magnitude of b. Such adjustments may possibly include the nonintuitive steps of decreasing the strength of some component (e.g., reducing one of the spring constants) in order to increase the strength of the compound system.

Much larger compound structures have many more degrees of freedom, and consequently many more failure modes. While some failure modes are clear-cut, others may be very subtle—depending on unexpected coupling between "soft" failure modes, as the example above illustrates. Characterization of the imperfection sensitivity is algorithmic: for any catastrophe germ (the potential of the perfect optimized structure at the failure load) there is a universal perturbation. This is finite dimensional provided that the germ is determinate. It is important to understand the universal perturbation in order to catalog all possible failure modes of the system, both obvious and not, in order to prevent catastrophes from occurring in such complex structures.

3.4 Elementary Catastrophes in Nonlinear Dynamics

Elementary catastrophe theory is the first result in the program of catastrophe theory. As a result, it stands at the base of the pyramid of bifurcations to be expected in nonlinear dynamical systems (see CHAOTIC PHENOMENA). Any bifurcations encountered in elementary catastrophe theory will be encountered in nonlinear systems with greater complexity.

To illustrate how the elementary catastrophes are encountered in more complex nonlinear systems, we survey here how the two simplest elementary catastrophes appear in nonlinear systems at the next level of complexity in the hierarchy of nonlinearity. Such systems are low-dimensional periodically driven dynamical systems or, equivalently, autonomous (time independent) dynamical systems with one more dimension.

In treating two-dimensional periodically driven dynamical systems and three-dimensional autonomous systems it is typical to explore the bifurcation diagram by sweeping one control parameter and locating periodic and aperiodic orbits. When a single control parameter is varied, it is typical to encounter among the catastrophes only the fold. If, however, there is a symmetry present, then the symmetry-restricted cusp catastrophe $[V(x;a)=\frac{1}{4}x^4+\frac{1}{2}ax^2=V(-x;a)]$ may also be encountered.

The fold catastrophe appears in bifurcation diagrams for autonomous dynamical systems as saddle-node bifurcations. These are shown in Fig. 17. In this figure there are several control parameter values at which new stable (solid curve) and unstable (dashed curve) solutions appear. If the system is periodically driven the saddle-node pair consists of a stable periodic orbit and a saddle orbit with one unstable direction. Both orbits have the same period.

Under a broad range of conditions the saddle remains unchanged as the control-parameter values are further increased, but the node undergoes additional bifurcations. Such bifurcations are often of the period-doubling variety. The period-doubling bifurcation is essentially a symmetry-restricted cusp catastrophe. Its relation to the cusp is shown in Fig. 18. As a control-parameter value is increased past some threshold, a stable periodic orbit loses its stability. In a transverse section (Poincaré plane) the unstable point is surrounded by two stable nodes. As the Poincaré plane is swept around the unstable periodic orbit, the two nodes will rotate around the direction of propagation of the Poincaré section either an integer number of times or a half-integer number of times. If the two nodes rotate an integer number of times around the saddle that is between them [Fig. 18(a)], the two nodes belong to two separate periodic orbits, both of which have the same period as the unstable periodic orbit from which they bifurcated. On the other hand, if the two nodes rotate a half-integer number of times around the saddle that they straddle [Fig. 18(b)], they belong to a single orbit whose period is twice the period of the unstable periodic orbit from which they bifurcated.

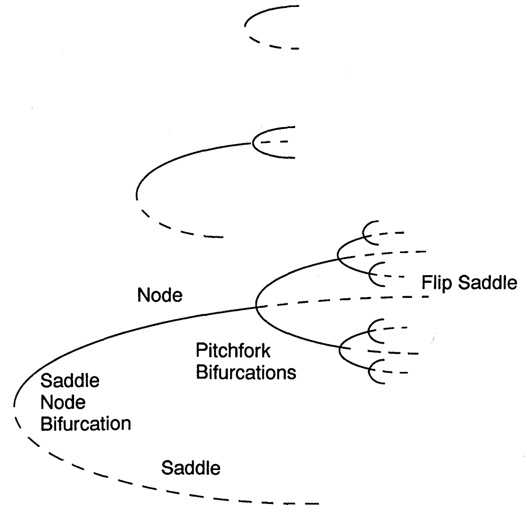

FIG. 17. Fold and symmetry-restricted cusp (also called pitchfork) bifurcations are commonly encountered in nonlinear dynamical systems. At a fold or saddle-node bifurcation a stable orbit (solid lines) and a saddle orbit (dashed lines) are created. At a pitchfork bifurcation, period doubling may occur, leading to creation of orbits of twice the period of the original orbit, which loses its stability.

Saddle-node bifurcations and period-doubling cascades are general features of autonomous dynamical systems. The pitchfork bifurcation with an integer number of twists is atypical in autonomous dynamical systems. However, if there is a symmetry, as occurs, for example, in the Lorenz equations, a period-doubling cascade cannot occur beginning at a symmetric orbit (Gilmore, 1981). As a result, the first pitchfork bifurcation occurs at a symmetric orbit of period T, creating an asymmetric pair of orbits of the same period. Subsequent pitchfork bifurcations from the asymmetric periodic orbits then generate period-doubling cascades.

A simple Hopf bifurcation can also be viewed as a symmetry-restricted cusp catastrophe (Gilmore, 1981). In the neighborhood of a Hopf bifurcation the dynamical equations can be written in polar coordinates as

$$\begin{aligned} dr/dt &= \lambda r \pm r^3, \\ d\theta/dt &= \omega. \end{aligned} \tag{55}$$

During the bifurcation the equation of motion for θ remains essentially unchanged. The bifurcation is therefore described by the radial equation, which can be written in gradient form:

$$\begin{aligned} dr/dt &= -\partial V/\partial r, \\ V(r;\lambda) &= -\tfrac{1}{2}\lambda r^2 - (\pm\tfrac{1}{4}r^4). \end{aligned} \tag{56}$$

A typical Hopf bifurcation is illustrated in Fig. 19. A section of the bifurcation surface in a plane containing the control parameter axis has the standard pitchfork shape.

Since the saddle-node, period-doubling, symmetry-breaking, and Hopf bifurcations are all related to elementary catastrophes, all

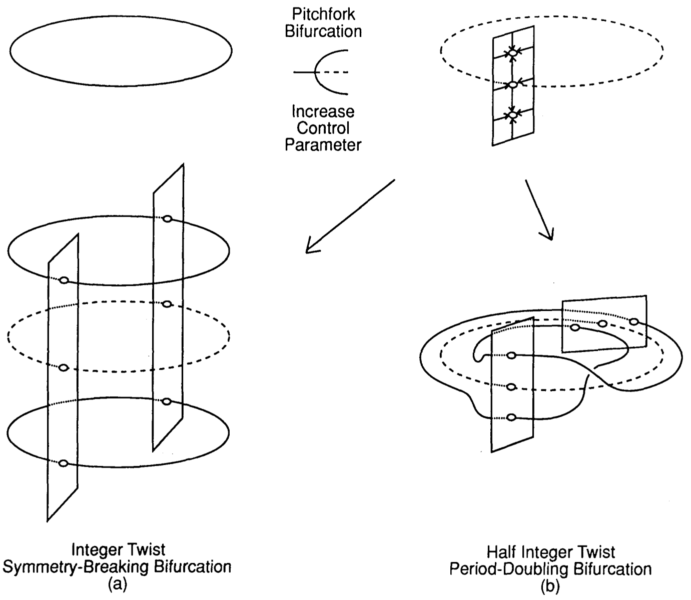

FIG. 18. When a periodic orbit loses its stability in a pitchfork bifurcation, either two new orbits of the same period may be created or one new orbit of twice the period may be created, depending on the local torsion about the original orbit (integer or half-integer).

the phenomenology associated with the elementary catastrophes is present and observable for these bifurcations as well. For example, one can observe modality, sudden jumps, inaccessible regions, sensitivity, hysteresis, divergence of linear response, time dilation, and anomalous variance in all these bifurcations. Furthermore, the behavior of each bifurcation has the same canonical form as that of the corresponding catastrophe (e.g., power-law dependence).

APPENDIX: A BRIEF HISTORY OF CATASTROPHE THEORY

Catastrophe theory burst upon public consciousness in the mid-1970s with a series of articles in widely available sources: *Scientific American, Science, London Times, Time,* and *The New York Times.* The articles themselves were bimodal. At one extreme the *London Times* heralded it as the "main intellectual movement of the century" while the *Science* article announced "The emperor has no clothes."

The theory of singularities of mappings was intensively developed by Whitney, Thom, and Mather in the decade 1955–1965. Thom presented his formulation of the theory of singularities in his eagerly awaited work *Stabilité Structurelle et Morphogénese* (1972). This book was an enigma in both form and substance. It was largely inaccessible to the mathematics community because it was written in the language of biologists, and inaccessible to the biological community due to its presentation of mathematical concepts which seemed to be deep and mysterious.

Yet it held the promise of describing discontinuous phenomena in a systematic way. Zeeman crowned the subject with the florid name "catastrophe theory" and took up the challenge of presenting these mathematical ideas to the larger community of scientists. When challenged to show concrete applications in the real world, he responded with a series of articles of stunning originality which explored the range of possible applications of this new subject.

These applications eventually worked their way into public consciousness through the popular journals. A reaction to the value of catastrophe theory set in. This reaction was

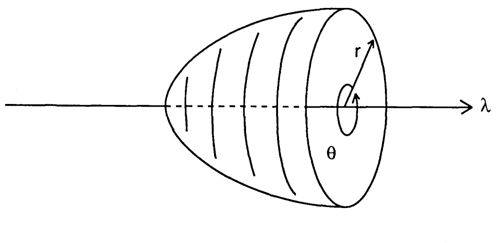

FIG. 19. A Hopf bifurcation can be viewed as a symmetry-restricted cusp catastrophe in the radial direction.

partly as a result of the overblown claims made in its name, partly as a result of the neglect offered to the workers who created the field of dynamical systems theory: Poincaré, Andronov, Pontryagin, Smale, etc., and those currently working in this field. The result was a multiyear public dialogue on the merits of this subject of discontinuities using arguments now long forgotten and best left unearthed, a dialogue of which the public eventually tired.

The appearance of the monographs by Poston and Stewart (1978) and Gilmore (1981) made it clear that this was a subject of substance, which had to be taken seriously, one capable of providing a useful language for the description of discontinuities at both a qualitative and a quantitative level.

GLOSSARY

Anomalous Variance: A catastrophe flag. Amplitude of motion about an equilibrium becomes increasingly large as a degenerate critical point is approached.

Bifurcation: A qualitative change in the properties of a system.

Bifurcation Set: Set of values in control-parameter space at which qualitative changes occur.

Catastrophe: Mathematical—A family of functions, depending on control parameters, in which the number of equilibria changes as the control parameters are varied. Physical—A sudden, discontinuous change in the state of a system.

Catastrophe Flags: Phenomena that occur when a catastrophe (sudden jump) is present.

Catastrophe Germ: A function which describes a degenerate critical point.

Catastrophe Theory: The program for determining how the qualitative properties of the solutions of equations change as parameters appearing in these equations change.

Clausius–Clapeyon Equations: A set of equations which determine the Maxwell set of a catastrophe.

Control Parameters: A set of parameters $c=(c_1,c_2,\ldots,c_k)$ which appear in the equations that describe a physical system.

Critical Curvature: The curvature d^2f/dx^2 of a function evaluated at its critical points $\nabla f=0$.

Critical Point: An equilibrium: a point at which motion does not occur.

Critical Set: The k-dimensional manifold $\nabla_x f(x;c)=0$ for $x\in R^n$ and $c\in R^k$.

Critical Slowing Down: A catastrophe flag. Relaxation to equilibrium takes increasingly long times as a degenerate critical point is approached.

Critical Values: Values of a function at its critical points.

Cusp Catastrophe: The function $A_3(x)=x^4/4+ax^2/2+bx$. So named because the critical set $\nabla_x A_3(x;a,b)=0$ exhibits a cusp on projection to the a-b control parameter plane.

Cuspoids A_{n-1}: A class of functions depending on one state variable x and $n-2$ control parameters. The family of functions $A_{n-1}(x)=x^n/n+\Sigma_{i=1}^{n-2}a_ix^i$ has up to $n-1$ isolated critical points.

Degenerate Critical Point: An equilibrium ($\nabla V=0$) at which the stability matrix $(\partial^2 V/\partial x_i\partial x_j)$ is singular. This requires two or more critical points to be arbitrarily close to each other (degenerate).

Delay Convention: The system state remains in a local minimum until that minimum ceases to exist.

Divergence of Linear Response: A catastrophe flag. Linear response coefficients increase very rapidly as a degenerate critical point is approached.

Dynamical System: A set of coupled first-order ordinary differential equations which may be nonlinear: $x_i' = f(x,c;t)$, where x is a state vector and c are control parameters.

Elementary Catastrophe: A function of one or two state variables (x,y) and one or more control parameters. These functions are used to describe systems in which small causes can produce large effects.

Equilibrium: A point at which all forces vanish; a critical point.

Exceptional Elementary Catastrophes: E_6, E_7, E_8 depend on two state variables and have up to 6, 7, 8 critical points, respectively.

Flow: The motion of a point in phase space under the equations of motion for the system.

Fokker–Planck Equation: An equation that describes the evolution of a probability distribution in the presence of diffusion and driving forces.

Fold Catastrophe: The function $A_2(x) = x^3/3+ax$. So named because the critical set exhibits a fold.

Generic: Typical. Occurs with "probability one."

Gradient Dynamical System: A dynamical system in which the time-independent forcing term is the gradient of a potential function: $f_i(x,c) = -\partial V(x,c)/\partial x_i$.

Hopf Bifurcation: Bifurcation in which a stable fixed point becomes unstable and emits a stable periodic orbit (limit cycle).

Hysteresis: Transitions from one state to another do not occur at the same values of the control parameters when the control parameters are changed in the opposite direction.

Implicit Function Theorem: A theorem of elementary calculus. If a function has a nonzero slope at a point, $\nabla f \neq 0$ at x_0, then it can always be approximated by a linear function at x_0.

Inaccessibility: An unstable physical state separating two stable physical states.

Isolated Critical Point: An equilibrium ($\nabla V=0$) at which the stability matrix ($\partial^2 V/\partial x_i \partial x_j$) is nonsingular.

Maxwell Convention: The system state is always in the deepest minimum.

Maxwell Set: The set of control parameter values at which a function has two or more equally deep minima.

Metastable: Stable to small perturbations but not to large perturbations.

Modal Catastrophe: A catastrophe germ which depends on one or more parameters.

Modality: Distinct types of behavior that a system can exhibit under identical or nearly identical conditions (e.g., liquid–gas states for a fluid).

Mode Softening: A catastrophe flag. Oscillation frequencies approach zero as a degenerate critical point is approached.

Morse *i*-Saddle: The quadratic function $M_i^n(x) = -x_1^2 - \cdots - x_i^2 + x_{i+1}^2 + \cdots + x_n^2$.

Morse Lemma: A normal-form theorem like the implicit function theorem. If a function of n variables has a nonsingular stability matrix (det $\partial^2 f/\partial x_i \partial x_j$) at an equilibrium x_0, it can always be approximated by a quadratic function at x_0. Such a function is called a Morse saddle.

Nongeneric: Atypical. Occurs with "probability zero."

Perestroika: Change in the properties of a dynamical system due to changes in its control-parameter values.

Perturbation: A function which is everywhere small.

Phase Space: A space in which the coordinates of a point define the state of the system.

Phase-Space Portrait: A trajectory (or trajectories) in phase space which describes the evolution of a physical system from one (or more) initial conditions.

Pitchfork Bifurcation: Bifurcation in which a stable fixed point becomes unstable and two new stable fixed points are emitted. Corresponds to a single-well potential developing into a double-well potential.

Quadratic Form: A function of n variables $x=(x_1,x_2,\ldots,x_n)$ which can be written x^tMx, where M is a symmetric $n \times n$ matrix.

R^n: Real n-dimensional space.

Saddle-Node Bifurcation: Bifurcation in which two fixed points, one saddle and one node, are created.

Sensitivity: The final state of a system may change under small perturbations of either the initial conditions or processes applied to the system.

Stability Matrix: The matrix of mixed second partial derivatives of a function: $\partial^2 f/\partial x_i \partial x_j$.

State Vector: A set of parameters $x=(x_1, x_2,\ldots,x_n)$ which describes the state of a system.

Structural Stability: Invariance of qualitative properties under a perturbation.

Taylor Tail: Tail of a Taylor series expansion: all terms beyond a certain degree.

Thom Classification Theorem: A list of elementary catastrophes depending on one or two state variables and up to five control parameters.

Thom Splitting Lemma: A normal form theorem for functions. If a function has an equilibrium ($\nabla f=0$) at which the stability matrix $\partial^2 f/\partial x_i \partial x_j$ has l vanishing eigenvalues, the function can always be written as the sum of two functions, $f(x) = f_{\mathrm{NM}}(y_1,\ldots,y_l) + M_i^{n-l}(y_{l+1},\ldots,y_n)$, where $f_{\mathrm{NM}}(y_1,\ldots,y_l)$ is a function with vanishing first and second derivatives in the l variables corresponding to the vanishing eigenvalues and M_i^{n-l} is a Morse i-saddle in the remaining $n-l$ variables.

Time Dilation: A catastrophe flag. System response takes increasingly long times as a degenerate critical point is approached.

Umbilics D_{n-1}: A class of functions depending on two state variables and $n-2$ control parameters. The family of functions $D_{n-1}(x,y)$ has up to $n-1$ isolated critical points.

Universal Perturbation: Simplest function (i.e., lowest dimension, or number of control parameters) that describes all possibilities that can result when a degenerate critical point is perturbed.

INTRODUCTION

Luminescence spectroscopy is well established as a technique for nondestructive evaluation of materials. An introduction to the literature on the subject is given in the suggestions for Further Reading at the end of this article. By the use of an incident electron beam ("cathode rays") as the source of excitation a very wide range of materials can be studied, including semiconductors, ceramics, geological minerals, polymers, and biological and medical samples. Because the beam is easily focused to a small exploratory probe, the technique is not only very versatile but also capable of providing information with high spatial resolution.

Luminescence of inorganic materials is frequently concerned with low concentrations of point defects, either singly or in small clusters. Phosphors are one exception to this generalization, since high concentrations of additives are commonly required; another is the free-exciton emission from pure quantum-well structures. By contrast, luminescence of organic material is generally produced by intrinsic molecular units of the structure. Unfortunately, electron irradiation is a serious cause of damage to organic material, although the rate of damage varies widely.

When point defects are responsible for luminescence, they can be either intrinsic (vacancies or interstitial atoms) or extrinsic (impurities or dopants). Best understood, at the moment, is the luminescence associated with isolated point defects in rather pure materials. As the technique is very sensitive, extremely low concentrations of impurity can

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

be detected in ultrapure material, even at levels below parts in 10^9 in silicon, for example. The position of an added atom in the lattice is very important. Completely different results can be obtained from a foreign atom depending on whether it is in an interstitial or substitutional site. If the atom is in an interstitial position there may be a variety of sites, each with a different local symmetry and each leading to a different optical effect. Two-atom complexes of dissimilar foreign atoms are also well understood in a number of instances. However, as the number of atoms involved in a luminescence center increases, our understanding of its behavior rapidly decreases. It seems that it is generally the case that as atoms cluster together the associated luminescence properties, if any, are lost, well before any precipitate is formed which might be directly visible by a modern transmission electron microscope.

There are, of course, two extremes of approach to the investigation of materials by cathodoluminescence. One seeks to catalog and characterize rather than explain; the other seeks a detailed electronic and atomic understanding of the light-emitting process. While both undoubtedly have their place, it is perhaps timely to warn those unfamiliar with the technique that the second approach can be extremely laborious, and several common emission lines have been studied with some persistence over periods of ten years or more without yet fully revealing their secrets. Moreover, it is probably the case that cathodoluminescence is a less potent tool for securing fundamental understanding than is photoluminescence. A comparison between the two techniques, cathodoluminescence and photoluminescence, is included in what follows.

1. DIFFERENT FORMS OF CATHODOLUMINESCENCE

In view of the very wide range of applications of cathodoluminescence in different fields of scientific research, it is not surprising that a comparably wide range of equipment has been developed to record the results with different objectives in mind. It is, therefore, very important to be aware of the nature of the apparatus used to generate the results of interest and its operating conditions before attempting to assess them. It is not difficult to find examples where completely different results can be obtained from the same region of a semiconductor specimen examined under different extremes of operating conditions.

Although wide differences of equipment exist, the one common point of examination by cathodoluminescence is that the energy of the electrons used for excitation of the specimen under study is very much greater than the band-gap energy. This characteristic is in clear distinction with photoluminescence, a technique contrasted with cathodoluminescence later in this chapter, and it confers on cathodoluminescence its wide range of application.

The first important distinction between cathodoluminescence systems is the nature of the instrument itself. Four broad categories exist. These are topographic cathodoluminescence, and scanned beam cathodoluminescence performed either in a scanning electron microscope (SEM), in a transmission microscope (STEM), or in an ultrahigh-vacuum chamber used for surface science or analysis.

Although topographic cathodoluminescence can be performed in a scanning electron microscope (Lang, 1980), it is more normally carried out in a simple system which is only capable of bathing the specimen in a broad beam of electrons of relatively ill-defined energy (Hagni and Karakus, 1989). The image will often be recorded on color film with or without the use of filters, although spectrometry is sometimes also performed on the light generated.

The most common form of cathodoluminescence analysis of semiconductors is that performed in a scanning electron microscope adapted for that purpose. The cathodoluminescence images are generated with relatively high spatial resolution by a scanned beam, and although many manufacturers provide attachments for cathodoluminescence experiments, many individually developed systems are also in use. It follows that the performance of this form of instrument varies considerably from one installation to another.

For higher spatial resolution studies a few cathodoluminescence systems have been installed on scanning transmission electron microscopes. These are at present individually developed systems (for examples, see Petroff *et al.*, 1978; Pennycook, 1982; Berger and Brown, 1984; Roberts, 1981; and Myhajlenko, 1984). The high spatial resolution is achieved by the use of thin specimens, albeit at a significant loss of signal. Much attention has therefore been given to efficient collection and detection of the light emitted.

For those interested in light emission from surfaces, cathodoluminescence detectors have been added to surface science equipment (Brillson *et al.*, 1988).

The second important consideration, having established the category of instrument used for generating cathodoluminescence information, is that of operating conditions. These can vary widely and may be linked to the system in use. One important parameter of operation is that of electron energy. In scanning electron microscopes and scanning transmission electron microscopes, this energy can vary widely and is used to control the range (penetration depth) of the electrons. The energy of the beam is deposited in a pear-shaped volume in a bulk sample, and the electron range is given approximately by the expression

$$R=(k/\rho)(E_b)^{\alpha}, \qquad (1)$$

where k and α are material- and electron-energy-dependent constants, ρ is the density of the material, and E_b is the beam energy. For a discussion of this point the reader is referred to the review article of Yacobi and Holt (1986) or to the original work of Everhart and Hoff (1971) or Kanaya and Okayama (1972).

Thus, relatively low-energy electrons give shallow penetration, while high-energy electrons can be used to excite at greater depths or to penetrate surface coatings so as to reach underlying cathodoluminescent layers. The simple control over range of excitation is a very attractive feature of cathodoluminescence. The details of the microscopic processes involved in absorption of energy from the incident electron beam are apparently not very important. The straggling of the beam through large-angle deflections is largely the result of phonon scattering, but this does not contribute directly to energy loss to an appreciable extent. The two major components of energy loss are plasmon excitation and valence-electron excitation with a smaller contribution from core-electron excitation. The loss processes are reviewed, for example, by Reimer (1984). However, there is no evidence to suggest that hot electrons created during energy loss from the high-energy beam lead ultimately to differences between cathodoluminescence (CL) and photoluminescence (PL) spectra. It is a very good first approximation to regard the electron beam as a controllable source for production of excess carriers in a chosen location of the material under study.

A second important operating parameter is the beam current (excitation level). This may well be determined by the experimental conditions since poor light emitters or inefficient collection and detection systems call for high beam currents. One result of the use of high beam currents is that appreciable specimen heating may occur. However, this is a relatively unimportant effect compared with spectral changes which occur as the excitation level is changed. Luminescence spectra are often highly nonlinear. Defect-related luminescence saturates when the defects are all excited, but the level of excitation to cause this depends on the defect density, which can vary enormously. At high excitations super-radiance of intrinsic luminescence can occur through population inversion. At low temperatures excitons can bind together to form multiple bound-exciton complexes or even condense into excitonic droplets at sufficiently high excitations. As a result, great care must be exercised in comparing results obtained from different systems, possibly operated at very different excitation levels.

A third important parameter is the specimen temperature. This is particularly the case for rather pure semiconductors where the so-called edge emission is predominant over deep-level emission (see Sec. 3). Enormous changes occur in the band-edge emission of such materials in the range 2–50 K, say, and indeed the spectral details may often be used to determine the specimen (or else the electron) temperature very accurately. As manufacturers of liquid-helium stages are sometimes rather optimistic about the performance of their products, temperatures quoted in the literature should be treated with caution unless substantiated by direct evidence from luminescence spectra. At a more obvious level there are usually considerable changes between band-edge luminescence at room and liquid-helium temperatures as a result of thermal ionization of shallow acceptors and donors at ambient temperatures.

Some cathodoluminescence systems are equipped to generate monochromatic maps. Clearly, materials generating spectra rich in detail will produce a wide range of monochromatic images, many of which may bear little relationship to the integrated cathodoluminescence image of a simpler system. In some cases it is also important to bear in mind the spectral range over which the "monochromatic" image is collected. A few systems are also equipped for time resolution of images (Bimberg *et al.*, 1985), and the images obtained depend strongly on the time scale over which they were generated.

Two further points should be noted. Cathodoluminescence images from bulk specimens in scanning electron microscopes may also differ markedly from those obtained from thin specimens in scanning transmission electron microscopes. A number of factors contribute to these differences, and it is well known that spectral details change considerably as the specimen thickness is reduced. The proximity of nearby free surfaces affects different emission processes to different extents (some processes can become completely quenched), the effective carrier diffusion length is reduced, and internal stress fields may be altered and internal electrical fields may be generated. The final point, not well understood at present, is concerned with beam-dependent changes induced during examination. These effects are evidently column vacuum dependent and specimen dependent. A number of independent factors can be identified. These include carbon or ice (cooled specimens) contamination effects, hydrogen passivation as a result of hydrocarbons in the system, and displacement or ionization damage of the sample. In addition, well-aligned electron-optical columns with line of sight from specimen to source are also liable to ion damage from the electron gun. This little-appreciated problem is widely overlooked and has been found to be a serious problem in work in this laboratory. The effect can be monitored using nuclear track emulsions in the specimen position which are developed after exposure (Tastrak CR39 has been used for this purpose; see Henshaw, 1982). It can be overcome by introduction of a dog's-leg into the column, although this step is not popular with manufacturers who have spent years developing well-aligned optics.

2. ABSORPTION PROCESSES

The absorption of energy from the incident electron beam occurs by a variety of different processes such as core-electron excitation, plasmon excitation, and phonon scattering. We are only interested in those processes which lead to the creation of electron-hole pairs in the near-ultraviolet, visible, or near-infrared parts of the spectra. These pairs may take the form of free mobile carriers or bound excitons of considerable spatial extent (see Sec. 3) in semiconductors, or of individual localized traps in insulators.

The details of what happens next depend on whether the excited material is a semiconductor or an insulator. In the case of insulators the carriers which are created diffuse until they either combine radiatively or nonradiatively. It is common to associate a lifetime with each of these decay modes, referred to as τ_R and τ_{NR}, respectively, and an overall lifetime τ given by

$$\frac{1}{\tau}=\frac{1}{\tau_R}+\frac{1}{\tau_{NR}}. \tag{2}$$

The nonradiative behavior may be associated with Auger transitions or phonon cascades; nonradiative transitions may occur at internal or surface sites. It follows that any nonradiative process which is particularly efficient will completely dominate the nonradiative lifetime. This may be an internal center, sometimes called a killer center, or surface recombination, which can be very efficient. Clearly, the nonradiative recombination of thin films is likely to be dominated by the surface recombination rate, and a quantity called the surface recombination velocity with units of cm/s is widely used as its measure. Surface passivation treatments such as hydrogen passivation exist to reduce the surface recombination velocity. The radiative lifetime is also a quantity with several potential components. The first and most obvious component is that of free minority carriers before radiative recombination. However, radiative transitions also occur from carriers which become trapped at defect centers. Alternatively, the electrons and holes may combine to make either free excitons before radiative recombination, or else excitons that themselves become trapped by defect centers, later recombining radiatively. It therefore becomes important to distinguish between the capture time of excited carriers and the recombination time after entrapment. The former is inversely related to a carrier diffusion length which can vary greatly from one semiconductor to another. For example, GaAs normally has a minority carrier diffusion length of a few micrometers, while the diffusion length in relatively pure silicon can be several hundred micrometers.

In summary, it is evident that the terms "diffusion length" and "lifetime" cover a great deal of complex detail, and that the precise behavior of the excitation after creation of electron-hole pairs will be strongly temperature and impurity dependent. They are, nevertheless, very useful in solving diffusion equations in investigating the effects of carrier injection by the electron beam. The various recombination routes, radiative and nonradiative, all compete with each other as recombination channels for the excitation which the electron beam creates. Thus cathodoliminescence spectroscopy is quite different from x-ray spectroscopy in electron microscopy where each of the core shell absorptions is independent and the effects are additive. A particularly efficient emission center can completely dominate the cathodoluminescence spectrum.

The situation in insulators is considerably less complicated. The excitation is either directly absorbed by a radiative center, or "activator" as it is called in the case of phosphors, or else transferred to a radiative center by the absorbing center ("promoter" or "sensitizer" in the case of phosphors) (Garlich, 1958; Blasse and Bril, 1970).

3. EMISSION PROCESSES

3.1 Introduction

When light emission occurs there are a number of different processes to distinguish. By far the most important are those giving rise to the relatively sharp and distinctive features on which we shall concentrate. The greatest variety of effects is encountered in the case of semiconductors which have band gaps corresponding to visible or near-infrared emission. It is important to bear in mind the distinction between direct gap materials not requiring phonon assistance and indirect gap materials where phonon assistance is required to achieve photon emission during electron-hole annihilation. Table 1 lists some common materials with the nature of their band gaps and the associated energies at room temperature.

Table 1. Natures and magnitudes of the band gaps of different materials.

Type of material		Type of band gap	E (room temperature) in eV
	Al_2O_3, quartz		~9
Rock salt	LiF	Direct	13.6–13.7
	NaCl		~8
Group IV	Diamond	Indirect	5.48
	Silicon	Indirect	1.110
	Germanium	Indirect	0.664
6H cubic	α SiC	Indirect	2.86
	β SiC	Indirect	2.2
Group III-V	Cubic BN	Indirect	6–8
	GaN	Direct	3.44
	GaP	Indirect	2.26
	AlAs	Indirect	2.15
	GaAs	Direct	1.42
	InP	Direct	1.351
Group II-VI	MgO	Direct	7.70 (85 K)
	ZnS	Direct	3.68
	ZnO	Direct	3.35
	ZnSe	Direct	2.7
	CdS	Direct	2.5
	ZnTe	Direct	2.3
	CdSe	Direct	1.75
	CdTe	Direct	1.5

3.2 Excitons and Excitonic Processes

For semiconductors, at low enough temperatures, an electron in the conduction band will bind with a hole in the valence band to form a so-called exciton. To a reasonable first approximation this free-exciton formation can be treated by Bohr theory to yield values for the binding energy and exciton diameter as follows:

$$E_X = -\frac{m_r^* e^4}{2(4\pi\epsilon_0)^2\hbar^2\epsilon^2} = -13.6\left(\frac{m_r^*}{m_0}\right)\frac{1}{\epsilon^2}\ \text{(eV)}, \tag{3}$$

$$a_x = \frac{\hbar}{(2m_r^*|E_X|)^{1/2}}\,. \tag{4}$$

m_r^* is the reduced mass given by

$$\frac{1}{m_r^*}=\frac{1}{m_e^*}+\frac{1}{m_h^*} \tag{5}$$

with m_e^* and m_h^* averaged effective electron and hole masses, respectively, appropriate to the relevant energy gap. Note that the indirect-gap materials are likely to have particularly anisotropic effective masses (as, for example, in Table 2). e is the electronic charge, $\hbar$ Planck's constant, ϵ_0 the vacuum permittivity, ϵ the static dielectric constant of the material, and m_0 the electron rest mass.

Note that the free-exciton binding energy is closely related in the same approximation to the donor (E_D) and acceptor (E_A) ionization energies, as follows:

$$E_D=(1+\sigma)E_X, \tag{6}$$

$$E_A=E_D/\sigma, \tag{7}$$

where

$$\sigma=m_e^*/m_h^*. \tag{8}$$

Table 2 gives representative values of some of the parameters, energies, and radii which appear in these equations for a few common semiconductors. These energies are useful in estimating the temperatures at which excitons become thermally unstable and donors or acceptors become ionized.

Free-exciton emission (X) is rather weak and rarely observed in cathodoluminescence. There are three reasons for this. First, the exciton field becomes mixed with the photon field present in the crystal generating hybridized states called polaritons. Second, the associated momentum not only leads to considerable line broadening but also gives rise to problems about momentum conservation when a photon is emitted. Third, and most important, is that the free excitons are relatively easily trapped at low temperatures by a variety of centers, notably neutral donors (D^0), neutral acceptors (A^0), and isoelectronic traps (an isoelectronic trap is composed of two neighboring substitutional impurities with the same combined valence as the host atoms which they replace) as well as at present unidentified defects. The large size of the excitons, which comes from the large dielectric constants and small reduced masses of semiconductors, enhances the ease of entrapment. Once trapped, the excitons, lacking momentum, give very sharp emission lines from relatively pure materials at low temperatures. The binding energies (E_{BX}) of the excitons to neutral donors and acceptors are found experimentally to be approximately proportional to the respective donor or acceptor ionization energy (E_i),

$$E_{BX}=a+bE_i, \tag{9}$$

where the constants a and b in the equation (known as Haynes's rule) are characteristic of the semiconductor concerned. As donors are more easily ionized than acceptors (Table 2), acceptor-bound excitons survive to higher temperatures than donor-bound excitons. In fact, the binding energies of excitons to donors and acceptors varies slightly from one impurity or dopant to another, but these variations are normally too small to detect by cathodoluminescence spectroscopy. Materials studied by cathodoluminescence are not normally exceptionally pure or lightly doped, and the operating temperatures are usually not particularly low, more often closer to 30 K than 4 K, so that the resulting spectra are relatively broad. The approximate formulas given above are particularly appropriate under these circumstances.

Table 2. Some typical experimental values for quantities relating to the free-exciton binding energy and its binding energy to neutral donors and acceptors, together with the calculated exciton radius.

Material	m_e^*/m	m_{lh}/m	E_X (meV)	ϵ	E_{D^0X} (meV)	E_{A^0X} (meV)	a_X (nm)
ZnSe	0.16	0.6	−19	8.66	−(2–6)	−(8–12)	3.6
GaAs	0.0665	0.087	−4.2	12.53	−1	−(2.4–2.7)	17.5
InP	0.079	0.12	−5.12	12.61	−1	−(3.5–4)	14
Si	0.9163 (long.) 0.1905 (trans.)	0.153	−14.3	11.7	−(5–5.6)	−(4.2–6.0)	5.2

There is a large variety of more complicated transitions involving excitons, some of which may not be resolvable in cathodoluminescence experiments for the reasons already mentioned. A few of the more important of these will be discussed. First, excitons may bind together (self-trapping) to form excitonic molecules (biexcitons), triexcitons, or, in general, bound multiple-exciton complexes (BMECs). Second, more complex transitions involving bound excitons can occur. When a donor (acceptor) is simultaneously excited, say from its 1*s* to a 2*s* or 2*p* state as the exciton collapses emitting a photon (of reduced energy), the spectral lines are called two-electron (hole) satellites. Examples of two-electron satellites (TES) will be discussed later (Sec. 5). At high concentrations where the impurity or dopant atom separations become comparable with or smaller than the exciton size, excitons will tunnel from one site to another and are no longer trapped. Although these free excitons (FE) will not usually annihilate directly because of the problem about momentum conservation, they may undergo inelastic transitions from 2*s* or 2*p* states down to the ground (1*s*) state, and the associated light emission has been observed in cathodoluminescence spectra from ZnSe (Sec. 5) and are referred to here as FE-(1*s*-2*s*).

The theory of weakly bound excitons, found in semiconductors, was first developed by Wannier and Mott, and so the quasiparticles are often referred to as Wannier or Wannier-Mott excitons. In insulators the binding energy is much higher, the excitons are of atomic dimensions, and they are known as Frenkel excitons in recognition of Frenkel's pioneering work on the theory relevant to this situation.

3.3 Donor-Acceptor Pair, Free-to-Bound, and Band-to-Band Emission

Another very common form of luminescence, with photon energies only slightly lower than those of the excitons, is known as donor-acceptor pair (DAP) emission. In this case an electron on a neutral donor annihilates with a hole on a neutral acceptor emitting a photon of appropriate energy. Although of roughly similar energy, the underlying mechanism is very different and, as a result, a quite different spectral width and shape is observed. The important point about this form of emission is that the participating donor and acceptor atoms are initially in positive and negative charge states, and hence possess an attractive Coulomb energy. The magnitude of this energy depends on the separation between the atoms, and this energy is added when the photon is emitted. Photons emitted from near neighbors will have higher energies than photons from distant atoms, but there is only a relatively small number of potential near-neighbor sites. It follows that the emitted photon has an energy given by

$$h\nu=E_g-(E_A+E_D)+\frac{e^2}{4\pi\epsilon_0\epsilon r}, \tag{10}$$

where E_g is the gap energy and r is the interatomic separation. Relative to the excitonic peaks, a broad peak is predicted with its maximum related to the average separation between the donors and acceptors. The peak will be asymmetric in energy about the maximum with a relatively short tail on the near-neighbor high-energy side and a long tail on the distant-neighbor low-energy side. In addition, the peak position will depend on the excitation level, shifting to higher energy at higher excitations because the distant pairs have low recombination rates and are easily saturated.

In order to observe DAP emission it is necessary to have an appreciable population of neutral donors and acceptors. Even when present in the semiconductor the donors will become thermally ionized at relatively low temperatures even though neutral acceptors remain. When this situation prevails, free electrons from the conduction band will annihilate with holes on the neutral acceptors, giving rise to the so-called free-to-bound (F-B) emission. In most semiconductors the electron is free and the hole is bound to an acceptor, thus neutralized, and this emission is therefore generally referred to as eA^0. The photon energy is given by

$$h\nu=E_g-E_A. \tag{11}$$

Note that a further characteristic of DAP emission is thereby created. As the free-to-bound emission is of higher energy, temperature-dependent experiments will reveal an additional peak on the high-energy side of the DAP peak with increasing temperature. At high enough temperatures the DAP will vanish, being replaced by eA^0 emission. Note that this increase in emission energy with rise in temperature is in the opposite sense from the band-gap variation with temperature, which decreases. Where time-dependent emission can be studied a further characteristic of DAP emission is available. At short delay times near-neighbor emission predominates given an increased peak energy, while at longer times the peak shifts to lower energy.

Finally, at even higher temperatures the acceptors become ionized, and direct cross-gap recombination occurs (band-to-band emission).

3.4 Terminology

The emission processes described so far all have emission energies close to that of the band gap. In older literature this form of emission was called "band-edge" emission to distinguish it from lower-energy "deep-level" or "deep-center" emission. More recent literature refers instead to "near-gap" emission and reserves this term for the sharp high-energy spectral lines of well-resolved low-temperature spectra. In the case of cathodoluminescence the distinction between band-edge and near-gap emission is not so clear-cut. An important, if crude, measure of the quality of a semiconductor specimen is the ratio of the maximum peak height of near-gap or band-edge emission to that of the deep-level emission. High-quality materials are completely dominated by the former, while band-edge emission may be almost entirely absent in the case of material of low quality.

3.5 Deep Center Emission

Many deep centers are nonradiative. Even when radiative, deep levels generally give rather broad featureless emission which is not capable of providing much detailed information about the material under study. However, there are a number of notable exceptions which are well researched and richly informative. Much of the luminescence of insulators fits into this category with equivalent centers occurring in the case of semiconductors. Of course, it follows that any center emitting in the visible region of the spectrum from an insulator must correspond to a deep level in the insulator band gap. Much studied in the past have been the vacancy-related color or *F* (Frenkel) centers in alkali halide crystals. Transition-metal impurities and rare earths are two other common forms of deep centers in insulators. This field has been recently comprehensively reviewed in the book by Henderson and Imbusch (1989).

The reason why the transition-metal and rare-earth impurities give sharp characteristic deep-level luminescence is because the atoms contain inner incomplete electronic shells which are relatively little affected by the atomic environment. The emission observed is therefore closely related to the atomic emission, modified, however, because of the crystal fields to which the atoms are subjected. The symmetry of the site occupied by the atom is therefore critical, and the peaks observed can be labeled as allowed transitions between levels with specific symmetry properties. Group theoretical labels are customarily attached. Very similar behavior is observed by deep-level emission from transition metals in GaAs and InP, but since the band gaps are relatively small the deep-level emission occurs rather far into the red end of the spectrum, calling for a lead sulfide or equivalent detector.

F centers are relatively straightforward to treat theoretically, and hence the luminescent spectra can be analyzed in some detail. The simplest *F* center is that of an electron trapped at a single anion vacancy. An elementary treatment of this problem for alkali halides gives the *F* band emission energy as

$$E_F = 1.13/a^2 \quad (\mathrm{eV}), \tag{12}$$

where a (nm) is the lattice constant of the material. Experimental results plotted as ln E_F vs ln$a$ give a reasonably straight line with a best fit of

$$E_F = 0.97a^{-1.772}. \tag{13}$$

Sharp deep-level emission is also an important characteristic of irradiated silicon. In particular, two centers have been widely studied and are relatively well understood. One of these, called the *G* center, has been the subject of considerable recent research and is now known to result from a complex formed from carbon on an interstitial site together with carbon on a substitutional site (Davies *et al.*, 1987; Davies *et al.*, 1989). The second is the *C* center, which has been identified as a carbon-oxygen complex (Chappell *et al.*, 1988).

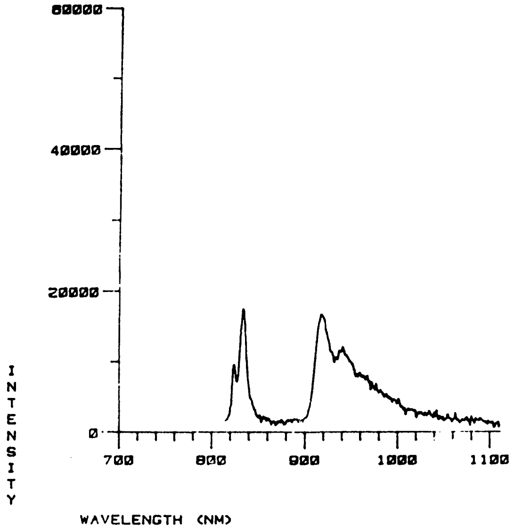

FIG. 1. Cathodoluminescence of GaAs containing copper. The broad copper-related band starts at 900 nm and has reasonably strong phonon coupling. First and second phonon replicas occur at approximately 940 and 960 nm (courtesy of Dr. S. Bailey). Temperature is ~30 K.

3.6 Phonon Coupling and the Configuration-Coordinate Model

The phonon coupling associated with each of the above emission processes provides a further means of distinguishing between them. In general terms the larger the extent of the wave function associated with a center, the weaker the phonon coupling. Excitons, which are extensive, couple very weakly with the lattice. Donor-acceptor pairs, which approach atomic dimensions, couple more strongly. Deep levels couple more strongly still. The *G* and *C* centers in silicon involve such large distortions that the strong local modes induced essentially overcome the indirect nature of the material and hence give rise to very strong emission. In order to discuss these differences it is helpful to introduce the idea often referred to as the configuration-coordinate model. In this simplified model we use the Born-Oppenheimer principle to separate electronic and ionic motion. We try to represent with one parameter, *Q*, called the configuration coordinate, what should in reality be described by a very large number of parameters. This parameter describes the state of distortion at an optical center and is related to the mean outward displacement of the neighboring atoms. We further assume that there is just one mode of lattice distortion, the breathing mode, with angular frequency ω, and that all static and vibrational distortions are of this type. We assume that the distortions can be described by a harmonic oscillator; and although excited states of the center will generally have different values of *Q*, we assume that the breathing mode is unaffected by excitation. Although very useful, this harmonic model misses the parity-breaking vibronic (dipole) transitions which may, in fact, be important.

If the crystal is in its ground state, we can write its energy as

$$V=\tfrac{1}{2}M\omega^2(Q-Q_0)^2, \tag{14}$$

where Q is the configurational coordinate (lattice normal coordinate), Q_0 is the average configuration coordinate in the ground state, and M is an equivalent ionic mass.

On excitation of the electron system an exactly similar vibration is assumed, shifted upwards in energy, and displaced to some new average configuration coordinate Q_0' as a result of the excitation. According to the Born-Oppenheimer principle there is no change of lattice arrangement during transition ($\Delta Q=0$), and vertical transitions occur in this diagram. Excitation from the ground state leads to an excited state with vibrational energy. On relaxing to the energy minimum in the excited state, phonon emission leads to a return to the ground state with vibrational energy. As a result there is an energy shift between absorption and emission which is known as the Stokes shift. The strength of the phonon coupling to the photon emission is determined by the horizontal shift ΔQ ($=Q_0'-Q_0$) between the two parabolas. Large shifts correspond to strong phonon coupling. In dimensionless terms this shift is measured by a parameter known as the Huang-Rhys factor (S) given by

$$S\hbar\omega=\tfrac{1}{2}M\omega^2\Delta Q^2. \tag{15}$$

In terms of S, the Stokes shift is given by $(2S-1)\hbar\omega$. The strength of the phonon replication may be calculated for different values of S. Examples of transitions with small S values can be found in the discussion of results for ZnSe presented in Sec. 5. The copper deep level in Fig. 1 has a relatively large S value. This behavior is easily understood in the qualitative terms introduced earlier. The most weakly bound states have the largest dimensions and hence couple most weakly to the lattice. Electrons couple more weakly to the lattice than holes for the materials in Table 2 because of the ratio m_h^*/m_e^*; electrons in GaAs or InP couple more weakly than in ZnSe for the same reason.

Questions also arise about the details of the phonon coupling. In ZnSe, InP, and GaAs, which are direct-gap materials, the strongest coupling is with zone-center longitudinal-optical (LO) phonons. This can be understood in physical terms as the result of effective coupling to the macroscopic electrostatic field associated with the LO phonons (Dean *et al.*, 1978). By way of contrast, the strongest phonon replicas in the luminescence from silicon involve transverse-optical (TO) phonons. As silicon is an indirect semiconductor it is clear that phonon coupling is required for momentum conservation, and the band structure of silicon reveals at once that the phonons must come from close to the *X* point (Madelung, 1982). However, while in germanium (also indirect) LO and TA (transverse-acoustic) coupling is forbidden by symmetry (Lax and Hopfield, 1961), this is not the case for silicon. A detailed examination of the phonon coupling of light emission from silicon has been given (Smith and McGill, 1976).

3.7 Summary

In summary of this section, the characteristics of particular spectral details of interest can generally be used to determine the origin of the cathodoluminescence emission. Apart from the emission energy, peak shape, and peak width, three other characteristics are of great value in seeking an identification, namely, the temperature dependence, excitation level dependence, and time dependence of the peak. Unfortunately, none of these last three experiments is easy to perform. Each can be affected by beam-induced changes, and temperature or excitation level experiments should be concluded by returning to the initial conditions to check whether any time-dependent changes have occurred. In addition, the temperature range and control is likely to be rather limited in cathodoluminescence experiments. Time resolution is perhaps the most promising approach, and Bimberg *et al.* (1985) have obtained some impressive results by the use of this technique. In particular, excitonic and DAP lines are easily distinguished by their very different transition times. However, very short time scales of picoseconds or nanoseconds are likely to be involved, and so considerable modification of conventional electron-optical equipment is required to exploit the technique.

4. COMPARISON BETWEEN CATHODOLUMINESCENCE AND PHOTOLUMINESCENCE

Although superficially similar, there are, in fact, considerable differences between these two different methods for generating emission spectra from solids. One of the major differences is the electron energies normally used in cathodoluminescence in comparison with the photon energies used in photoluminescence. The high electron energy means that cathodoluminescence is very versatile and can be applied both to insulators with large band gaps and to small band-gap semiconductors. Another attractive feature of the high voltage is the ease of control of electron range by altering the operating voltage. However, there is no equivalent to the technique of tuning the photon energy to near the band gap of the semiconductor being studied or to an absorption peak of an insulator. This technique, called photoluminescence excitation spectroscopy (PLE), provides some of the richest spectral detail and permits the measurement of Stokes shifts. The range of excitation can also be controlled in photoluminescence by this technique since the absorption coefficient varies very rapidly with change of wavelength near an absorption edge.

An additional price to pay in performing cathodoluminescence as compared with photoluminescence is the much greater likelihood of beam-induced changes to the specimen. This can occasionally be advantageous when the electron beam is used to create luminescence centers which did not exist before irradiation. A case in point is in the production of *G* centers in silicon (Canham *et al.*, 1987). As other radiation-induced centers become better understood in the future, this aspect of cathodoluminescence might become quite useful.

One of the big advantages of photoluminescence on very pure materials is the ease with which experiments can be performed with the sample immersed in liquid helium below the λ point. However good the liquid-helium-cooled stages become in electron microscopes, such low temperatures are unlikely to be attained, and there will always be some difficulty in deducing the actual specimen temperature.

Although cathodoluminescence has the obvious advantage of small lateral spot sizes, this is not generally effective because of the large electron range in bulk specimens and the subsequent carrier diffusion. Only in the case of scanning transmission electron microscopes is the benefit of high spatial resolution realized, and even then only after investing a considerable amount of effort into the design of the system. Once achieved, however, there is the added and in some cases essential information provided by the ability to image directly and identify extended crystal defects such as dislocations, stacking faults, grain boundaries, or precipitates.

In summary, for samples of small dimensions or fine microstructure which are not of the highest purity and perfection, cathodoluminescence is a relatively quick, relatively high spatial resolution technique for providing, often in a nondestructive fashion, valuable information not otherwise easily obtainable. Moreover, when the facility exists on a scanning electron microscope it can be available as a routine examination procedure of samples under study.

5. PHYSICAL APPLICATIONS OF CATHODOLUMINESCENCE

5.1 Introduction

Cathodoluminescence is a technique with a long history. In this section I have picked a few topics from recent research which have made an important impact on either pure or applied physics. For references to the earlier literature the section on Further Reading at the end of this chapter should be consulted. This includes recent reviews emphasizing the relevance of cathodoluminescence to the study of ceramics, geological materials, organic materials, and in medical science. I restrict my examples largely to semiconductors.

The first aspect of recent cathodoluminescence which deserves to be emphasized relates to the rather obvious point that luminescence centers are not necessarily homogeneously distributed. While few would doubt this conclusion, it is most important to have concrete evidence about the spatial distribution of active centers. Cathodoluminescence has begun to provide such information on an impressive scale. It has revealed depth dependences of active centers in cross sections through epitaxial layers, marked inhomogeneities in bulk materials, and epilayers (Chu *et al.*, 1981; Chin *et al.*, 1984), sometimes associated with dislocation cell boundaries, sometimes as a result of processes occurring during growth without the presence of extended crystallographic defects (Warwick and Booker, 1983). Luminescence variations associated with dislocations, stacking faults, so-called oval defects in molecular-beam epitaxy (MBE) layers, grain boundaries, and homostructure and heterostructure interfaces have all been revealed (Bailey and Steeds, 1989a,b; Steeds, 1989b).

Three examples will be discussed as illustrations of the nature of the information which can be obtained. Two were studied by cathodoluminescence in a STEM, the third by cathodoluminescence topography in a SEM. They are each concerned with dislocations; the first is the change of cathodoluminescence observed near a single grown-in dislocation in liquid encapsulation (LEC) InP substrates annealed at a high temperature (1023 K); the second is the creation of an unusual deep level (called Y_0) at dislocations in epitaxial layers of ZnSe; the third is the observation of colored dislocations in natural diamond. Each is believed to be the result of impurity segregation to the dislocation, and none is well understood at present. The study of luminescence effects arising from impurity segregation to dislocations is in its infancy. Nevertheless, it offers a very attractive means of examining the gettering and diffusion effects associated with dislocations which have been realized in general terms for a long time, but which until now have largely defeated the attempts made to obtain detailed experimental information about them.

5.2 Quenching of Excitonic Emission at Dislocations in InP

The spectrum shown in Fig. 2(a) is typical for thin samples of good quality InP at the temperature of acquisition. The peak labeled D^0X is excitonic in character and comes mainly from donor-bound excitons. The slightly lower energy peak labeled eA^0 is in reality a mixture of DAP and free-to-bound emission at this temperature. It has a longitudinal-optical phonon replica displaced about 40 meV on the low-energy side. The relative heights of the exciton and eA^0 peaks are affected by the specimen thickness, the exciton peak being more strongly quenched as the specimen thickness drops below 1 μm. Figure 2(b) shows a spectrum acquired with the electron beam centered on the threading dislocation illustrated in Fig. 3. As proof of the apparent exciton quenching, monochromatic images were formed in each of the major peaks D^0X, eA^0, and the deep level C. Dramatically different spatial distributions of intensity were obtained (Fig. 4). It should be noted that the black spot on the exciton map at the position of the dislocation is not related to dislocation black spots often observed in SEM cathodoluminescence experiments (normally on GaAs). The latter results are obtained in integrated cathodoluminescence at room temperature and are also very much broader than the spot in Fig. 4. When the experiment was repeated on similar LEC InP which had not undergone the high-temperature heat treatment, similar behavior was not observed, and there was no dramatic change of intensity of any peak near the dislocations.

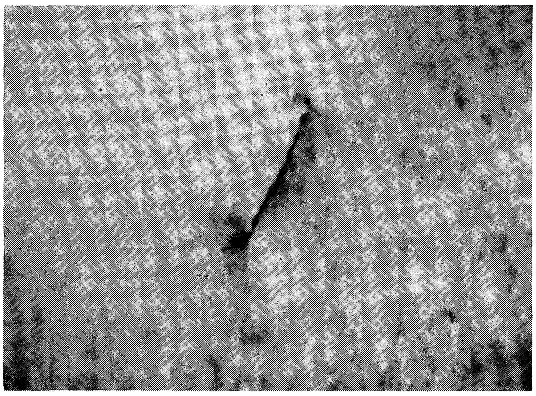

FIG. 3. The dislocation under investigation in Figs. 2 and 4; its length is approximately 0.5 μm.

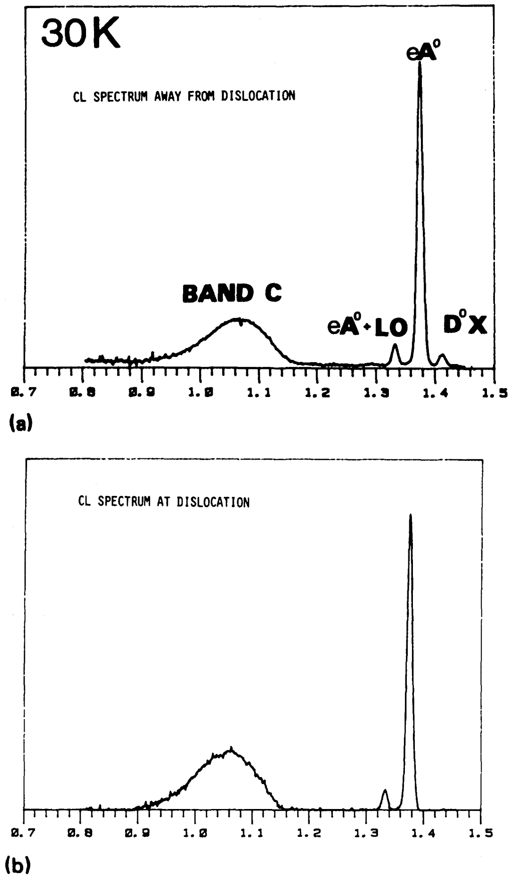

FIG. 2. Cathodoluminescence of InP with the electron beam directed at (b) a grown-in dislocation in an electron transparent region and (a) an adjoining dislocation-free region. The horizontal scale is measured in eV. Note the absence of a D^0X peak in the lower curve. [Reproduced from Myhajlenko *et al.* (1984) by courtesy of the Institute of Physics.]

5.3 Y^0 Emission from Dislocations in ZnSe

The second observation concerns dislocation emission in ZnSe. Thick (2–5 μm) epilayers were grown by metal organic chemical vapor deposition (MOCVD) on GaAs substrates. A typical low-temperature spectrum from a ~1-μm-thick specimen studied by cathodoluminescence in a STEM is shown in Fig. 5. As the spectrum is rich in detail the various features of the spectrum will first be described. The complex near-edge spectrum (2.65–2.8 eV) can be interpreted as coming from four distinct processes. The highest energy peak, labeled D^0X, comes from donor-

(chlorine) bound excitons. For regions of the specimen with high chlorine concentrations, excitons tunnel from one donor to another and undergo inelastic scattering, giving rise to the second highest energy peak [FE-(1*s*-2*s*)]. In terms of the discussion of phonon coupling by Eq. (15) in Sec. 3, the bound-exciton emission in this figure has a very small *S* value, the TES emission has a slightly higher value, while the FE-(1*s*-2*s*) emission has a still higher *S* value, but considerably less than that of the copper emission in Fig. 1.

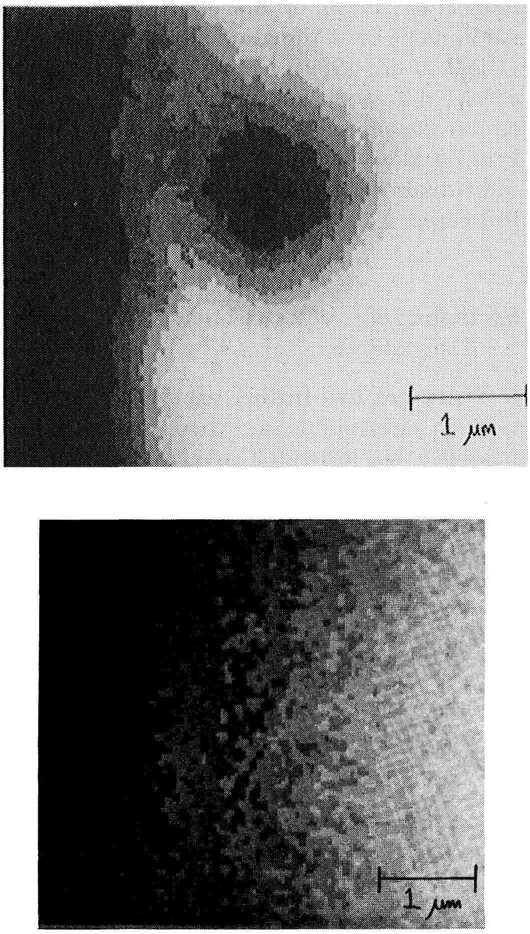

FIG. 4. Monochromatic cathodoluminescence images centered on the dislocation in Fig. 3. The upper image was formed with D^0X emission, and the black circular region is centered on the dislocation. The lower image was formed in the eA^0 peak of Fig. 2. The increase of intensity from left to right of the images is a consequence of the increase in thickness of a wedge-shaped specimen. [Reproduced from Myhajlenko *et al.* (1984) by courtesy of the Institute of Physics.]

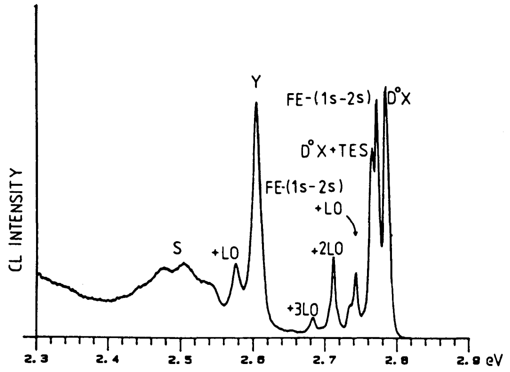

FIG. 5. Cathodoluminescence spectrum of a ~1-µm-thick undoped epitaxial layer of ZnSe. An explanation is given in the text for most of the peaks. (Reproduced by courtesy of Dr. J. L. Batstone.)

The monochromatic maps formed in these two highest energy peaks sometimes reveal marked anticorrelations, the one being bright where the other is dark and vice versa, as would be expected since they represent extremes of chlorine concentration variation. The third peak, which appears as a low-energy shoulder to the FE-(1*s*-2*s*) peak, is a two-electron satellite of excitons bound to neutral donors. It has the same spatial distribution as D^0X. There follows a series of longitudinal-optical phonon replicas of the FE-(1*s*-2*s*) and TES transitions of ever lower-energy emission as the number of phonons increases. The excitons are quite strongly bound in ZnSe (Table 2) and hence quite compact, so that the phonon coupling is stronger than in GaAs or InP (Fig. 2) but still relatively weak compared with DAP emission (small Huang-Rhys factor). However, there are evidently some anomalies in the series of replicas. Structure in the first phonon replica is the result of separate contributions from the FE-(1*s*-2*s*) and the TES processes. However, the TES emission is relatively weakly phonon coupled, and its contribution to the second phonon replica is not detectable. The second phonon replica from the TES peak has a second contribution from an independent process, as is indicated by its anomalous height and its peculiar shape. This conclusion was unambiguously confirmed by forming monochromatic maps in the TES peak and each of the three phonon replicas. The four images show very similar spatial distributions of intensity, but the images formed in the second and third phonon replicas show additional intense sources of light not present in the two higher energy images. On examining the regions from which this intense emission occurred by transmission electron microscopy small precipitates were observed, sometimes with associated punched-out loops. The origin of this emission is not yet clear.

The final peak in this spectrum to be discussed is that labeled Y^0 in Fig. 5. This peak varied considerably in intensity from one sample to another, suggesting impurity involvement, and has some very surprising properties (Dean, 1984). Although a deep level, the peak is both very narrow and only relatively weakly phonon coupled in comparison with what might have been expected. The complex S in Fig. 5 shows more characteristic deep-level behavior. Further confirmation of the excitonic nature of the Y^0 emission was obtained from temperature variation experiments which revealed the same emission energy dependence as that of the near-edge excitonic lines (Batstone and Steeds, 1986). Dean (1984) concluded that the emission was associated with dislocations in ZnSe, and cathodoluminescence experiments conclusively established this fact (Myhajlenko *et al.*, 1984). However, there remains a good measure of uncertainty about the details of the emission. On the one hand, there is evidence of impurity involvement with the dislocations; on the other hand, much of the detailed Y^0 behavior fits remarkably well the dislocation exciton model of Bozhokin *et al.* (1982) and developed by Lelikov *et al.* (1989) for dislocations in indirect-gap materials.

5.4 Colored Dislocations in Natural Diamond

The third example, that of cathodoluminescence topography of dislocations in natural diamond, is not quite so recent (Hanley *et al.*, 1977). Nevertheless, it effectively illustrates what can be achieved in a relatively simple fashion and leads to another story about possible impurity involvement with dislocation luminescence in a much wider band-gap material. In this case thick specimens were studied at room temperature in an SEM operated at 30 kV, with electron penetration of about 10 μm. Both blue-violet and green-yellow dislocations were observed, as illustrated in Plate 1.

5.5 Dislocation-Related Luminescence in Si

Each of the above studies has depended on the high spatial resolution easily achievable by cathodoluminescence. A related issue, hotly pursued at present, is that of the dislocation-related luminescence observed in silicon (Sauer *et al.*, 1985). According to different points of view, some of the emission lines are the consequence of dislocation excitons (Lelikov *et al.*, 1989), or alternatively from transition-metal contamination of the dislocations (Higgs *et al.*, 1989). Unfortunately, the long carrier diffusion distance and the high dislocation densities in the samples which have been studied prevents the examination of individual well-characterized dislocations in this case.

5.6 Dislocation Velocity and Misfit Dislocations

There are two further aspects of dislocations in semiconductors where cathodoluminescence has provided invaluable information. One of these is the measurement of dislocation velocities in bulk GaAs at high temperatures by the use of cathodoluminescence in an SEM to reveal the dislocations (Maeda *et al.*, 1983). The nondestructive nature of this method makes it very attractive for this purpose. The second is the use of cathodoluminescence to reveal misfit dislocations at heterostructure interfaces in epilayers (Petroff *et al.*, 1980). There is considerable current interest in the critical thicknesses of strained layers which result in the introduction of misfit dislocations. Use of cathodoluminescence imaging not only provides a convenient nondestructive method for observing misfit dislocations at buried interfaces (e.g., Watanabe *et al.*, 1989; Fitzgerald *et al.*, 1989), but by using monochromatic imaging it is possible to detect misfit dislocations at different levels in a complex multiple-interface structure independently of each other, if different regions of the structure emit in different parts of the spectrum (Steeds and Bailey, 1987).

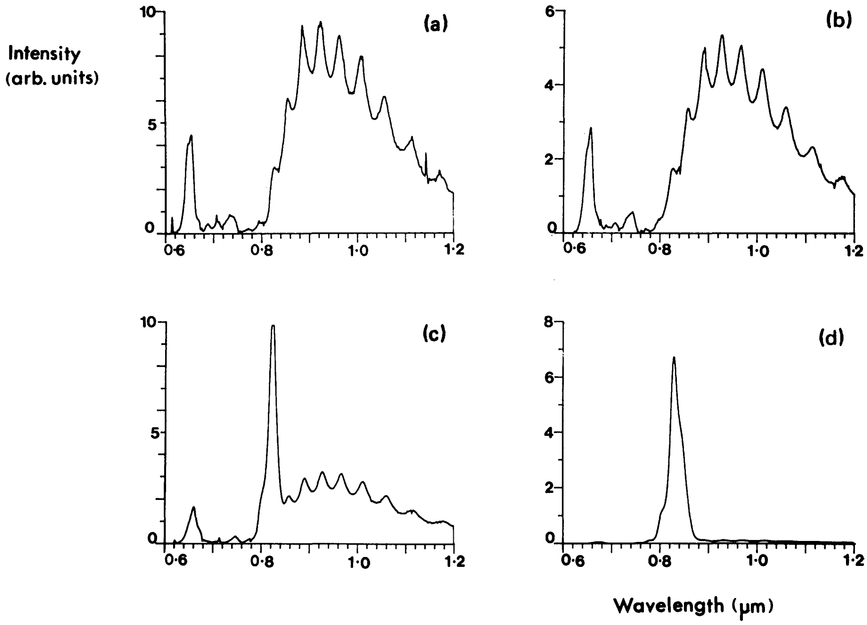

FIG. 6. Cathodoluminescence spectra obtained from a plan-view GaAs/AlGaAs double-heterostructure laser at increasing electron-beam pumping levels in the sequence (a)–(d). The arbitrary units of the vertical scales differ in each separate part of the figure. [From Steeds (1989), reproduced by courtesy of Les Editions de Physique.]

5.7 Abruptness of Semiconductor Quantum-Well Interfaces

Another problem of considerable topical interest is the flatness of interfaces grown by MBE. Cathodoluminescence imaging provides a convenient approach to investigation of this problem if single quantum-well specimens are available with sufficiently flat interfaces to be consistent with the spatial resolution available. Most of the experiments have been performed on GaAs single quantum wells with AlGaAs barriers. Layer growth is followed by reflection high-energy electron-diffraction (RHEED) oscillations, and on completion of growth of both GaAs and AlGaAs layers a pause of 2 min or so is introduced so as to reduce the interface roughening (Fukunaga and Nakashima, 1986). Growth-interrupted samples showed fine structure in the single quantum-well emission spectra. Each substructure peak was interpreted as coming from regions with flat interfaces and extending distances which were large compared with the two-dimensional exciton size. Adjoining peaks were believed to come from regions one monolayer different in thickness. The relative heights of the peaks from a single quantum well were found to vary with time on the picosecond scale. Short times gave stronger emission from the narrower portions of the well, but this decreased at longer times as the excitation diffused into broader regions (Tu *et al.*, 1988). Monochromatic cathodoluminescence images formed in the substructure peaks from a particular well were found to reveal intensity variations on the 2–3-μm scale, and these were interpreted as island sizes over which the interfaces were flat and uniformly spaced (Petroff *et al.*, 1987; Bimberg *et al.*, 1987). Later experiments by Bimberg *et al.* (1988) showed the dependence of the scale of the variations on the growth temperature and time, and spectrally resolved cathodoluminescence images revealed the diffusion of excitation across the islands. Other work on this topic produced monochromatic images with a high degree of anticorrelation as would be required for regions of different thickness (Steeds, 1989a, reporting experiments of Wang). However, these results probably cannot be understood in quite such simple terms (Ourmazd and Warwick, 1989; Warwick, 1989). The island sizes deduced by the cathodoluminescence imaging are not consistent with the considerably smaller extent of monolayer flat regions measured directly by the high-resolution imaging mode of transmission electron microscopy. Moreover, measurements at Bell Laboratories on the same samples as those used by Petroff *et al.* (1987) indicate that the substructure peaks vary considerably in energy separation from one position to another across a wafer. It has to be concluded that the large-scale structures of monochromatic cathodoluminescence images represent regions of different average well width, and that these average values will not necessarily correspond in integral numbers of monolayers in the quantum well.

5.8 Electron-Beam Pumping of Lasers

There is some interest in electron-beam pumping of lasers (Potts *et al.*, 1988; Colak *et al.*, 1987). Thin samples of heteroepitaxial layers may be prepared for STEM cathodoluminescence examination by selective removal of the substrate by use of an appropriate etchant. The samples are then studied in plan view with the incident electron beam penetrating through the epilayers. On account of the large refractive index difference at the top and bottom surfaces of the sample, strong internal reflection occurs, and this can be used to induce local superlinearities of emission and to investigate local changes of behavior, relevant to lasing properties. An example is shown in Fig. 6. The spectra were obtained from a conventional GaAs/AlGaAs double heterostructure laser prepared for STEM examination as described and pumped in a transverse rather than a longitudinal mode (Steeds, 1989a, reporting work of Myhajlenko in Bristol). The GaAs, prepared by MOCVD growth, revealed rather a broad emission spectrum crossed by a succession of thin-film interference fringes in the region from 800 to 1200 nm. With increasing pumping current in the sequence (a)–(d) the interference fringes shifted as the refractive index of the GaAs changed with increasing carrier density. From Fig. 7, which presents these results graphically, the AlGaAs emission at about 650 nm increases linearly with the pumping current, but the GaAs emission, initially linear [(a),(b)], becomes strongly superlinear for higher levels of pumping [(c),(d)].

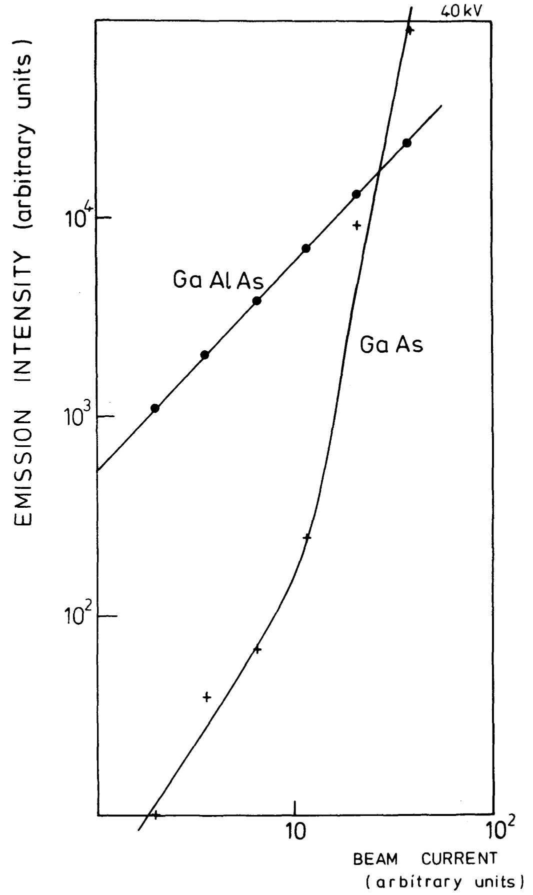

FIG. 7. Dependence of the emission intensity of the AlGaAs and GaAs peaks in Fig. 6 as a function of the electron-beam current [from Steeds (1989), reproduced by courtesy of Les Editions de Physique].

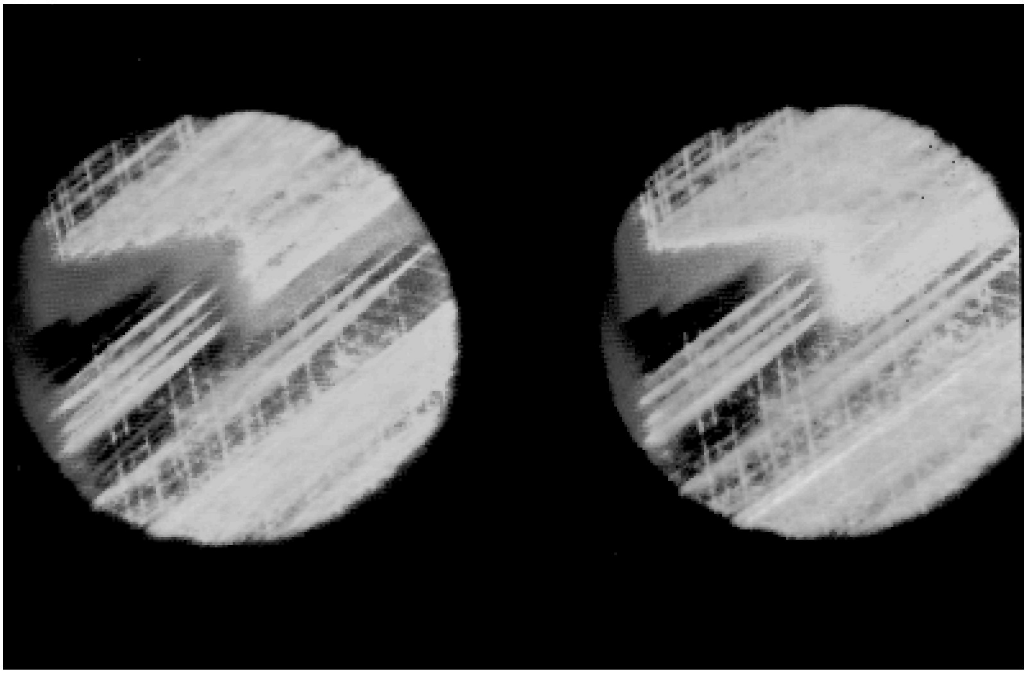
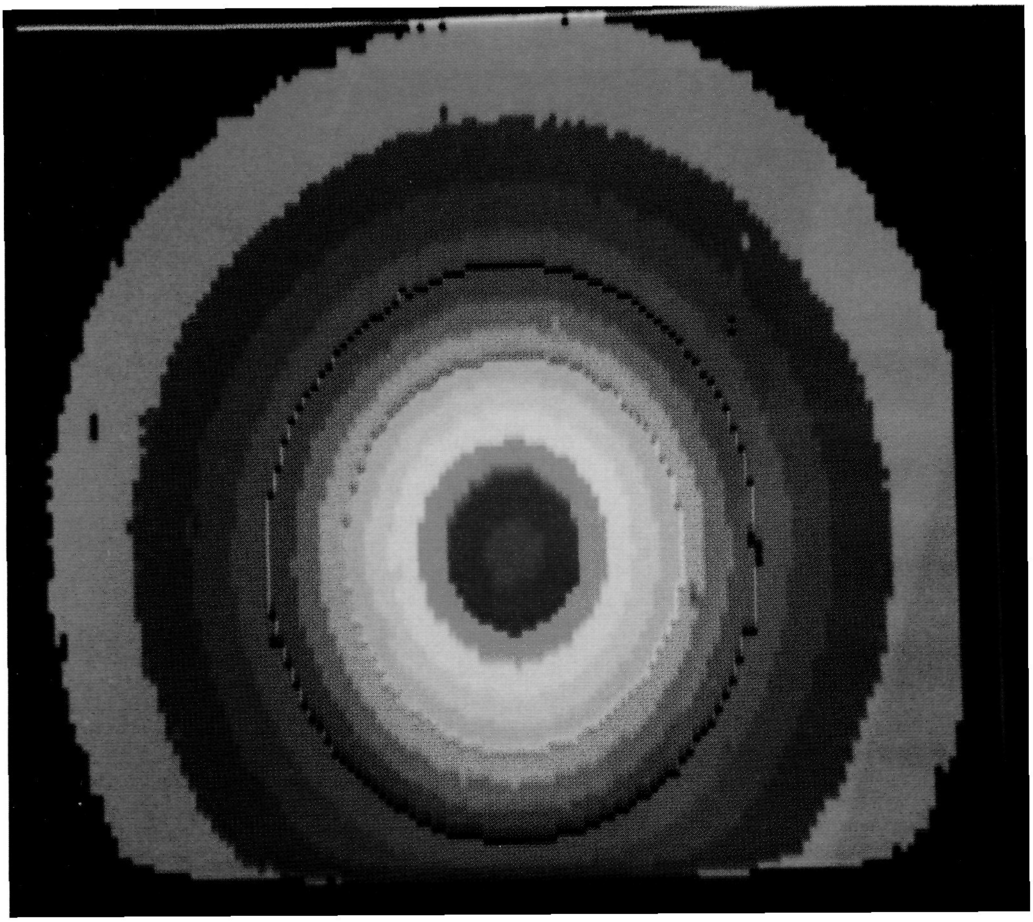
5.9 Investigation of Radiation Damage

The final example of recent applications of cathodoluminescence to semiconductors concerns near-threshold investigation of displacement damage in silicon. A modern 300-kV transmission electron microscope is probably the ideal means of undertaking such studies once the possibility of an accompanying ion beam is totally eradicated. The source has a well-defined energy (down to a few eV), has a continuously variable accelerating energy, and can be directed at any chosen region of a specimen, with a wide range of beam currents, with the specimen in any chosen crystallographic orientation, and at any temperature in the range 20–1300 K. It has recently been shown that silicon implanted with car-



Vol. 3 – PLATE 1. Cathodoluminescence topographs showing two types of visible luminescence from dislocations in natural diamond. The dislocations become visible locally in diamond regions where nitrogen impurity, which produces blue luminescence from the diamond matrix, has a low concentration. Individual violet-emitting dislocations are juxtaposed among the yellow-green slip bands. The topographs were photographed through a polarization filter which was oriented in the left image so as to reduce the intensity of the principal violet-emitting lines relative to the unpolarized emission from the yellow-green slip bands. The diameter of the field is approximately 0.3 mm with an electron-beam energy of 35 kV. (Unpublished work of Professor A. R. Lang, FRS, published by permission.)



Vol. 3 – PLATE 2. False color representation of the variation of intensity of the G emission line with position in the silicon sample which was locally irradiated. Red indicates high intensity (in the irradiated region) and black low intensity with shorter wavelengths in false color representing lower intensities and long wavelengths higher intensities. (Unpublished work of F. Johnson, reproduced by permission.)

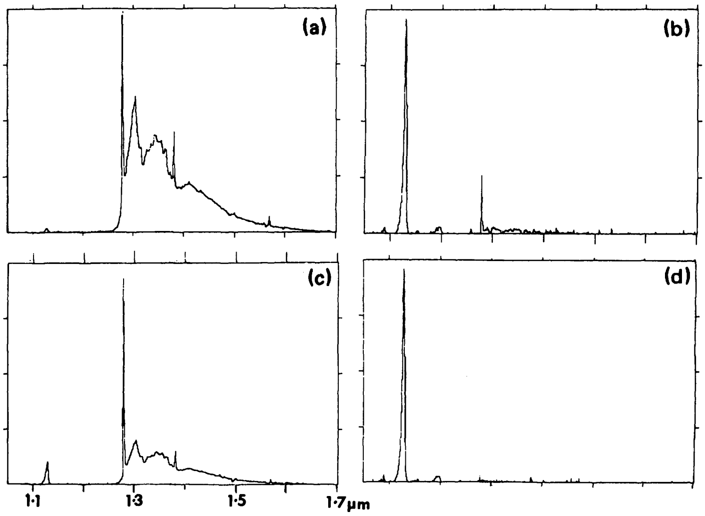


FIG. 8. Variation of cathodoluminescence spectra from electron-irradiated silicon as a function of distance from the irradiated region. The emission from the irradiated region is dominated by the *G* emission spectrum with a sharp peak near 1.3 μm (a). At a distance of about 250 μm (d) the spectrum is characteristic of free excitons in silicon, and the strongest peak near 1.1 μm is the TO phonon replica. (Unpublished work of F. Johnson, reproduced by permission.)

bon can be converted into efficient light-emitting diodes (emitting at 1.3 μm) by a process involving electron irradiation (Canham *et al.*, 1987). The *G* center involved in the emission is now well understood, as mentioned earlier (Sec. 4). We used our 300-kV TEM to irradiate float-zone silicon, containing carbon as an impurity, in the vicinity of the displacement threshold at about 100 kV. Figure 8 shows the variation of cathodoluminescence spectra with distance from a 15-μm-diam electron-irradiated area of 4000-Ω cm float-zone silicon containing $\sim 10^{16}$ cm^{-3} of carbon. The *G* center with strong emission near 1.3 μm was still detectable when the electron-beam-exciting cathodoluminescence was incident about 250 μm away from the irradiated region [Fig. 8(d)] because of long carrier diffusion lengths in silicon. However, the spectrum was then dominated by the characteristic free-exciton emission center with a transverse-optical coupled peak at 1.130 μm. The STEM cathodoluminescence system was used to produce false color images representing the intensity variation of the *G* center emission with distance of the incident beam from the electron-irradiated region (Plate 2).

GLOSSARY

A^0X, D^0X, and X: Conventional descriptions of excitonic (X) emission processes. A^0 represents a neutral acceptor, D^0 a neutral donor. A^0X (D^0X) indicates photon emission from an exciton bound to a neutral acceptor (donor).

Activator: An element added to a phosphor to enhance its light-emission properties.

Auger Transition: A transition in which an excited electronic state returns to its ground state by imparting its energy to a second electron which is emitted.

Band-Edge Luminescence (Edge Emission): The light emission from an excited semiconductor of photons with energy close to that of the band-gap energy.

Carriers: A collective name for mobile charged particles which may be electrons or holes or both.

Deep-Level (Deep Center) Emission: Emission from crystal defects which create energy levels within the band gap, well separated from either the conduction or valence-band edges. Some deep levels emit light when excited, but many do not. They cannot be treated by hydrogenic theory.

Edge Emission: Same as band-edge luminescence.

Excitons: Bound electron-hole pairs. They may vary in size from atomic dimensions to rather large, weakly bound pairs with radii of some tens of atomic spacings which can be treated, to a reasonable approximation, by Bohr theory.

Excitonic Droplets: A low-temperature condensation of large numbers of individual excitons into liquidlike objects within an indirect-gap semiconductor.

Free to Bound (F-B): The conventional description of the emission line resulting from the annihilation of a free electron (hole) and a bound hole (electron). eA^0 is the particular F-B transition where a free electron combines with the hole bound to a neutral acceptor (A^0).

FE-(1*s*-2*s*): An emission line associated with the transition of a free exciton from a 2*s* (or 2*p*) to a 1*s* state.

Interstitial Sites: Positions in a crystal structure which lie between the sites occupied by the atoms which comprise the ideal structure.

Misfit Dislocations: Dislocations at the interface between two dissimilar materials with different lattice constants which help to accommodate the mismatch between the atomic structures.

Multiple-Bound-Exciton Complexes: Just as atoms can sometimes bind together to form diatomic, triatomic, etc., molecules, so can excitons bind together to form complexes which contain two, three, four, or more excitons.

Passivation: Surface treatments which reduce the nonradiative surface recombination of carriers.

Phonon: A mode of distortion of the lattice during thermal vibration.

Photoluminescence: Luminescence excited by photons (light) which are sufficiently energetic to excite optical centers in a crystal or to lift electrons out of the valence band into the conduction band.

Plasmon: A quantized oscillation of the conduction-electron gas relative to the positive ion lattice.

Polaritons: Particlelike entities caused by the mixing between photons and excitons of similar wave number in a semiconductor.

Quantum Well: A thin planar two-dimensional layer of a semiconductor embedded in a semiconductor of larger band gap. The thickness of the embedded layer is less than the electron coherence length.

Sensitizer: An element added to a phosphor to enhance its ability to absorb incident radiation and transfer it to an emitting center.

Substitutional Sites: Sites in a crystal structure normally occupied by atoms of the host material but capable of replacement by impurities or dopant atoms.

INTRODUCTION

Cellular biomechanics is defined herein as the analysis of the passive and active mechanical behaviors of individual living cells by the use of continuum mechanics field theories. This includes classical disciplines of solid mechanics, fluid mechanics, and viscoelasticity, but also requires additional concepts such as osmotic pressure, gelation, active contraction, and growth. All living tissues are made up of individual cells plus extracellular constituents produced by cells. These extracellular products may be the main constituents of a tissue such as bone, cartilage, or tendon, but even in these cases, the tissues are maintained by cellular activity. Growth or atrophy in response to changes of stress is mediated by cellular processes.

The identification of the cell as the ubiquitous living unit of all tissues was a concept that was established only in the 19th century.

Since then extensive microscopic and biochemical investigation has established the morphology and function of the great variety of internal structures of many different cell types. The active processes of growth and locomotion have also been observed in detail. However, the mathematical description of deformation and active motion of cells using continuum mechanics theory has been extensively developed only in the past two decades. This is due in part to the complexity of most cells, which have a variety of internal structures such as nucleus, fibrous structures, gels, vesicles, and membranes. Moreover, the properties of these structures individually are not known, and so the predictive power of analysis is limited. Nevertheless, the range of cellular deformations and active motions being elucidated by rational field theories is rapidly expanding.

Historically, the red blood cell has probably received the most attention because it is a relatively simple cell and its rheology is important to mechanics of blood flow (see BIORHEOLOGY). The molecular mechanics of muscle contraction has also been extensively studied. In recent years, many other cells such as leukocytes, endothelial cells, fibroblasts, and even neurons have been tested and described in quantitative terms. Theories of active motions and cell locomotion are less well developed than interpretations of passive mechanical properties. In many cases, the qualitative nature and source of mechanical driving force of active motions and growth have not been identified in detail. In the subsequent sections, some of the main areas of presently developed analyses are outlined.

1. CELL ANATOMY AND CONSTITUENTS

All animals and plants are formed by cells which are small semiautonomous units enclosed in a thin membrane (Fig. 1). Some microbes consist of a single cell, but higher animals contain billions of cells plus extensive extracellular components that cells produce. However, the individual cells of higher animals can live, grow, and multiply outside the body in appropriate cell culture media.

The cell membrane is a thin (5-nm) bilayer of phospholipids which separates the interior of the cell from the external world. It is one of the distinguishing features of living matter. Cells may also have internal units enclosed in membranes, such as the nucleus and other organelles. Primitive cells which do not have a separate nucleus, such as bacteria, are called procaryotes. Higher forms which have a nucleus containing the reproductive DNA and RNA molecules are called eucaryotes. In this article, most cells considered will be eucaryotes, except perhaps the red blood cell which starts out life with a nucleus but dispenses with it before joining the bloodstream.

FIG. 1. Schematic anatomy of animal and plant cells. (From Alberts *et al.*, 1989, by permission.)

Figure 1 shows generalized sketches of animal and plant cells. Besides the nucleus, there are various organelles enclosed by membranes including mitochondria, Golgi apparatus, endoplasmic reticulum, and lysosomes. The spaces between these organelles are filled with cytosol, a complex solution containing various proteins and fibrous structures. These are mostly actin, tubulin, and intermediate filaments. A comprehensive treatment of eucaryote anatomy, biology, and biochemistry can be found in the book by Alberts *et al.* (1989).

Plant cells (Fig. 1) have a cell wall which is external to the plasma membrane and is composed of cellulose, up to 10 μm thick. Plant cells also have vacuoles which are fluid filled and act as space fillers to some extent.

1.1 Cytoplasm Properties

From the standpoint of material properties, the interior of the cell is a heterogenous composite consisting of a mixture of solid, gel, and fluid components. The overall behavior is generally viscoelastic. For some purposes, some cells can be represented as uniform viscoelastic solids. For detailed description of internal motions or local deformations, the individual components need to be recognized. The subdivision most frequently needed first is to describe the cell as a thin membrane filled with a viscoelastic fluid or solid, depending on the cell involved. Next, the cytoplasm may be represented as a two-phase material, for example, an actin gel filled with a thin fluid. For particular cells, for example, white blood cells, the nucleus needs to be recognized as a separate entity with its own membrane, forming a much stiffer unit than the cytoplasm. The degree of subdivision depends on the phenomena under consideration. The principal types of constituents are discussed in the paragraphs below.

It is also important to recognize that living tissues may undergo rapid transformations from fluid to gel, or internal stress generated by molecular interactions as in muscle contraction. These active motions are under complex and delicate biochemical, neural, and mechanical controls. This feature of living matter means that cell mechanical properties are not fixed, but the constituents may change state, form, and internal stress in response to small biochemical changes or neural impulses (see Stracher, 1983).

1.1.1 Actin. Actin is the most abundant cytoskeletal protein and forms the basis of many cytoskeletal structures such as pseudopodia, intestinal villi, hair cells of the ear, and the cortical shell, about 0.5 μm thick, that is found just under the cell membrane of many cells. Actin is also one of two principal proteins of all muscles. Actin is the so-called thin filament of skeletal muscle along which the thick filament (myosin) moves to produce muscle contraction. Actin also forms the less organized structure of smooth muscle and so-called stress fibers which occur in many cells such as leucocytes, fibroblasts, and endothelial cells.

An important aspect of actin as a cell constituent is that it occurs in two forms. As a structural element it is a fiber called F-actin and as a monomer which is easily carried in liquid suspension it is called G-actin. The polymerization of G-actin to F-actin and the inverse process are closely regulated and essential processes in many cell motions and growth. G-actin occurs in most cells at a concentration above that at which F-actin fibers would form spontaneously, but are prevented from doing so by capping proteins, mainly profilactin. When F-actin filaments form, the polymer is asymmetric in the sense that one end (called the plus end) has a higher rate of growth than the other (minus end). Assemblies of actin filaments form stress fibers and many other cell structures (Stossel, 1982). Such gels are held together by a variety of actin-binding proteins such as filamin, tropomyosin, and α-actinen. Myosin can act to contract an actin gel. This is the basis of active amoeba movements. A typical actin gel will be only 1% or 2% actin, with pores of the order of 20–100 nm which are filled with an aqueous solution of various constituents which may include a supply of G-actin for further growth of the gel. In most cells, growth of the actin cortical layer or protrusions is controlled by special proteins on the inner surface of the cell membrane. The plus ends of actin filaments terminate and grow at the membrane (see Ishikawa *et al.*, 1986).

1.1.2 Myosin. Myosin is a specialized molecule which is found to some extent in all cells and all animals. Together with actin, it forms the basis of muscle contraction. A myosin molecule is about 150 nm long, consisting of a long thin (about 2-nm) coiled section at the end of which are located two heads. These heads have an affinity to actin and can perform a rocking motion by which the myosin moves along an actin filament, towards its plus end. This action is the molecular basis of all muscle contraction and force generation. It is a process that consumes energy, or, more accurately, converts chemical energy into work. The energy comes from hydrolysis of adenosine triphosphate (ATP).

In skeletal muscle, myosin molecules are arranged in bundles which are the so-called thick filaments. The myosin heads are oriented in opposite directions on each end of the filament so that when the myosin heads move along the opposing actin filaments, a contraction results (see BIOMECHANICS OF LIVING ORGANISMS, Fig. 5). Smooth muscle has a more random arrangement of actin and myosin filaments, but it is again their interaction which produces contraction. Myosin may be assembled into filaments and more or less oriented systems as needed within a cell, such as in the formation of a contractile ring when a cell divides: an actin-myosin ring girdles a single spherical cell and, by steady contraction, divides it into two daughter cells. Myosin is also found in stress fibers which contract during cell locomotion, and in adhesion bands of epithelial cells (Alberts *et al.*, 1989).

1.1.3 Microtubules. Microtubules form the basis of a second system of structural support and cellular motion, quite different from and intermingled with the actin-myosin system. Microtubules are hollow tubes formed of tubular arrangements of the molecule tubulin. There are 13 molecular subunits around the circumference of a microtubule arranged in a very regular helical pattern. The resulting tube is a stiff, straight hollow cylinder having a diameter of about 25 nm and a typical length of 10 μm; the microtubule length may be 200 μm.

Microtubules are found in two kinds of arrangements. One forms the core of cilia and flagella. The other is a more distributed form in the cytoplasm of many cells. In many cells, microtubules are found as single tubes emanating from specialized centers called centrosomes usually near the cell nucleus. The arrangement of microtubules resembles pins in a pin cushion. In the cytoplasm, microtubules are often not stable in their length or position. Microtubules have directional structure, like actin, and have plus ends which extend by polymerization rapidly and minus ends which grow slowly. Microtubules are most often found in a state of dynamic instability in which the length of each tubule either increases or decreases. Microtubules may be capped by certain proteins which then stabilize the microtubules. Uncapped microtubules can depolymerize rapidly. Selective capping can guide the arrangement of microtubules.

The microtubules in the cytoplasm of many cells, including neural axons, form a guidance and transport system of vesicles and other organelles. Vesicles are moved along microtubules by interactions with the proteins dynein and kinesin at a rate of up to 2 μm/s. Microtubules have also been implicated in directional control of cell locomotion (Euteneuer and Schliwa, 1986). Usually a cell moves in the direction in which most microtubules are pointing. Many aspects of microtubule dynamics are discussed in Soifer (1986).

1.1.4 Intermediate Filaments. A third system of cytoskeletal elements is formed by the intermediate filaments, so named because they are intermediate between the thick and thin filaments of muscle cells. They form a connected network, especially around the nucleus of most cells, but form a stable, open network throughout the cell. This network has been described as ropelike or cablelike. It connects to most of the other structures in the cell.

Intermediate filaments are made up of four types of proteins, all of which have a common central portion. The first type is an acidic keratin, which is the principal protein in epithelial cells, hair, nails, feathers, scales, and rhinoceros horn. The second type is vimentin, which is found in muscle and other cells. The third is neurofilament, which occurs in neurons. The fourth is nuclear lamin, which surrounds the nucleus in many cells.

Intermediate filaments appear to be structural elements, i.e., they provide mechanical support of other cell structures and stiffen the cells against deformation by external forces. They are not generally formed and decomposed rapidly like actin and myosin and are not involved in contractile processes. The large number of variations of intermediate filaments appears to be associated with different cells and connections. The variety of intermediate filaments can be seen in the book edited by Wang *et al.* (1985).

1.1.5 Nucleus. In eucaryote cells, the nucleus is a separate compartment with its own plasma membrane enclosing the DNA and associated protein synthesis apparatus. The membrane of the nucleus is a double layer. Its two bilayers are connected at pores through which a traffic of proteins into and out of the nucleus is regulated. Each pore is surrounded by specialized granules that control transport through the pores. The opening of the pores is only about 9 nm.

The outer membrane of the nucleus is continuous with the endoplasmic reticulum. This is a thin space enclosed by two bilayer membranes. The nucleus has two layers of intermediate filaments associated with it, one inside and one outside the double nuclear membrane. The inner intermediate filament layer is relatively thin and compact, but the outer layer is like a loosely woven nest surrounding the nucleus (Alberts *et al.*, 1989). These structures and the closely packed DNA and associated proteins make the nucleus a much stiffer entity than the cytoplasm outside the nucleus or the cell as a whole. This is evident, for example, in leukocytes in a blood smear. The nucleus is still rounded although the rest of the cell is quite flattened.

The nuclear envelope keeps the DNA and associated proteins separated from the rest of the cell cytoplasm. DNA transcription and RNA processing goes on inside the nucleus. However, during cell division, the nuclear membrane and surrounding structures are broken down; then division takes place and two new nuclear membranes are formed in the daughter cells. During cell division, the cell is like a procaryote which does not have a separate nuclear compartment.

1.1.6 Other Constituents. Eucaryotic cells have several specialized membrane compartments in addition to the nucleus. Most of these function as sites of production of particular proteins. From the standpoint of total number and volume, mitochondria are most prominent. These ellipsoidal compartments are 2–3 μm long and are the principal site of ATP production. This is the fuel for muscles as well as many other energy-consuming reactions. From the standpoint of membrane surface, the endoplasmic reticulum is most important. It may have 10 or 20 times the surface area of the outer plasma membrane of the cell. The endoplasmic reticulum encloses only a thin, lamellar space. The outer surface of its membrane contains ribosomes which manufacture lipid for membranes and intramembranous proteins.

Another important compartment is the Golgi apparatus which is a stack of disk-shaped compartments which processes lipid and other proteins which are dispatched in membrane vesicles. There are also a number of smaller organelles and vesicles found in different cells with special functions. These include delivery of enzymes and signaling proteins.

The mechanical properties of the individual compartments described above are generally not known. In large deformations of the cell, these internal structures probably behave as more or less rigid bodies. The surrounding cytosol forms a viscoelastic fluid, and the specialized organelles may be regarded as solid particles in suspension in the cytosol. When actin gel forms or microtubular structures stabilize, a portion or all of the cell may be regarded as a viscoelastic solid. The time scale and degree of deformation will enter into the choice of an appropriate model. Various cases are discussed in subsequent sections below.

1.2 Cell Membrane Properties

All cells are enclosed by a lipid bilayer membrane which acts as a barrier to entry and exit of all components. By virtue of a variety of special proteins which float in or on the lipid bilayer, cell membranes perform many active functions in transport of ions, transducing mechanical and biochemical stimuli, generating neural signals, and initiating immune responses.

From a mechanical standpoint, the lipid bilayer itself is a two-dimensional liquid sheet. It resists any change in its surface area, but offers little resistance to deformation otherwise. In most cells, the lipid membrane is attached to the underlying cytoskeleton via intramembranous proteins which are firmly anchored in the lipid bilayer. The term cell membrane may include some layers of cytoskeleton as well as lipid membrane. This is

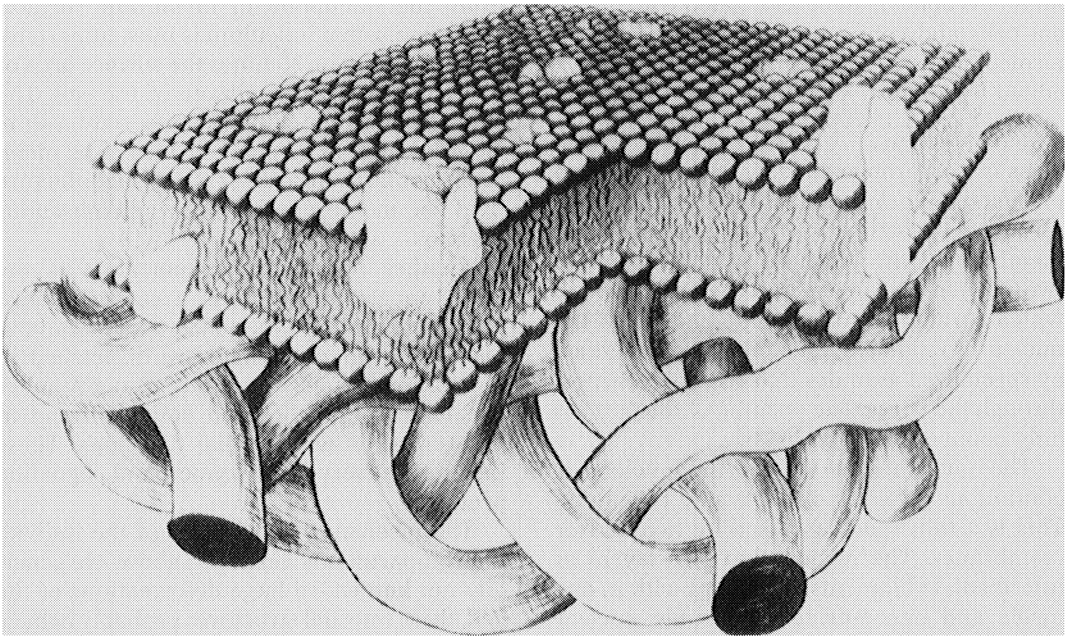

FIG. 2. An idealized sketch of the red blood cell membrane. The lipid bilayer is fluid and is supported by the spectrin network (cytoskeleton) which provides shear elasticity and strength. (From Evans and Skalak, 1980, by permission.)

the case for the red blood cell in which a network layer of spectrin is attached to the cytoplasmic side of the lipid bilayer (Fig. 2). The red blood cell membrane properties usually reported are those of the composite of lipid bilayer and spectrin cytoskeleton (see, e.g., Hochmuth, 1987).

1.2.1 Lipid Bilayer. The lipid bilayer, which is the principal membrane component of all cells, is a structure that forms spontaneously when amphipathetic molecules are placed in an aqueous environment. Amphipathetic means there is a polar head group at one end which is hydrophilic and fatty acid chains on the other end which are hydrophobic. Cell membranes are made up of phospholipids which have two hydrophobic hydrocarbon tails. The molecules of the bilayer orient themselves with the hydrophilic heads pointing outwards on each face of the membrane and the hydrophobic tails on the inside of the membrane. This structure is remarkably stable, although it is quite fluid with regard to motions of the molecules and shear deformations in the plane of the membrane. The hydrophobic and hydrophilic forces hold the thickness of the bilayer to within a narrow range. The polar head groups on each face are then like a monolayer which has a fixed concentration of molecules (about 2.5×10^6 molecules/μm^2). The compressibility of this layer is quite low, and so it resists any attempt to change its surface area. The fluidity of each leaflet of the bilayer results in rapid diffusion of lipid molecules in the plane of the bilayer. The lateral diffusion coefficient is about 10^{-8} cm^2/s. On the other hand, interchange of lipid molecules between the two leaflets is a very slow process. The cell membrane retains an asymmetry throughout its life. There are several different phospholipids in cell membranes. Those which have choline in their head group are found mostly in the outer leaflet. This and other differences result in different surface charges on the two surfaces. Another difference of inner and outer faces is that glycolipids are found only on the outer face. Cholesterol also occurs in both leaflets of the cell membrane. It moves readily from one layer to the other, and so it does not contribute to asymmetry but does reduce the viscosity of the bilayer.

1.2.2 Intramembranous Proteins. The structural functions of providing a seal and fluidity of a cell membrane are provided by the lipid bilayer, but most biochemical functions are carried out by membrane proteins which float in the lipid layer. Some such proteins have been shown to attach to only one leaflet of the membrane or the other. Some intramembranous proteins cross the entire membrane and have functional parts on both faces.

Membrane proteins have fixed orientations with respect to being located on the interior or exterior faces of the cell membrane. They are usually free to diffuse in the plane of the membrane and have a rotational mobility. In lateral diffusion, the diffusion coefficient will usually be half or less than that of lipid because they are much larger molecules. For many purposes, intramembranous proteins are not left free to diffuse, but are restricted to some part of the cell, like neurotransmitter receptors at a synapse. They may be organized in patches, like gap junctions which serve as connections and channels of communication (via small ions) between neighboring cells. They may also be organized in strands, such as tight junctions between endothelial cells which serve to confine blood proteins within the circulation. Patches of membrane proteins are involved in vesicle formation. The charge carried by such a patch of protein on the cytoplasmic side of a cell membrane readily induces vesicle formation by bending the membrane.

1.2.3 Cytoskeletal Components. The lipid of cell membranes is usually free to diffuse and flow in the plane of the membrane independently of the cell cytoplasm beneath it. The membrane is often tethered to cytoskeletal elements via the intramembranous proteins so that the lipid bilayer and the cytoskeletal layer cannot separate in the direction normal to the membrane surface. The cytoskeleton and lipid bilayer then function as a unit in respect to mechanical properties and deformations.

The cytoskeletal structure and properties are most extensively known for the red blood cell membrane. This is due in part to the importance of the red blood cell in blood rheology and in part because the red cell membrane cytoskeleton is readily isolated and has a relatively definite structure (Fig. 2). The spectrin network stabilizes the lipid membrane of the red blood cell into its characteristically smooth shape. The shear elasticity and viscosity of the red blood cell membrane are due almost entirely to the cytoskeleton (see Cokelet *et al.*, 1980).

In most other cells, other than red blood cells, the extent of the cytoskeleton attached to the cell membrane is much less well defined, but is a thicker (about 0.5–1 μm) layer, often consisting of an actin gel. This cortical layer may be under active tension due to myosin, and the surface of the cell is usually wrinkled. Thus, the mechanical properties of the plasma membrane plus the cytoskeleton are dominated by the cytoskeleton. The anchorage of the cytoskeleton of actin to a cell membrane is not so completely known as for the red blood cell. The actin filaments are known to terminate with their plus ends at the cell membrane in many cases and to have special proteins to anchor them to the plasma membrane.

1.2.4 Area Elasticity. The lipid bilayer of cell membranes has a number density of phospholipids (molecules per unit area) which is quite stable. In order to expand the surface area of a cell membrane, isotropic tensile stresses must be applied in the plane of the membrane to overcome the intermolecular attractions and hydrophobic forces. In such an isotropic stretching of a membrane, the area elastic modulus K is defined by

$$K = \frac{\Delta T}{\Delta A / A}, \qquad (1)$$

where ΔT is an increment of isotropic tension (i.e., equal in all directions in the plane of the membrane), and ΔA is the increment of area in a portion of the membrane having initially the area A. Equation (1) is a two-dimensional analog of the three-dimensional bulk or volumetric modulus of a solid. The units of T and K are dyn/cm. The membrane tension T is the integral, over the thickness of the membrane, of stress in the membrane (dyn/cm^2).

For the red blood cell, K has been measured by pipette tests (see Evans and Skalak, 1980) to be about 450 dyn/cm. This value is attributed primarily to the lipid bilayer itself rather than the cytoskeleton which is readily expanded in surface area.

An important characteristic of lipid bilayers is the fact that pores open and the membrane may rupture if the area strain ($\Delta A/A$) is greater than 0.01 to 0.02 (1% or 2% increase in area). The isotropic tension required for such rupture is of the order of 10–20 dyn/cm.

In the red blood cell, large deformations are possible with essentially no change of surface area because of the initial disk shape. In other cells, the plasma membrane is often wrinkled to begin with and contains many pits or attached vesicles. The cell can then deform without increasing the plasma bilipid membrane area by unwrinkling the membrane, like the bellows of an accordion.

1.2.5 Shear Elasticity and Viscosity. Since a bilayer lipid membrane is essentially a fluid, it does not exhibit appreciable elasticity in shear, but does have a definite shear viscosity, which is of the order of 10^{-5} P cm (Waugh, 1982). Most cells have a cytoskeleton attached which has a shear elasticity and shear viscosity which are larger than and predominate over that of the bilayer lipid membrane. For red blood cells, the membrane surface shear elasticity has been derived from pipette tests (see Evans and Skalak, 1980). The shear elastic modulus is defined by

$$\mu = T_{xy}/2\epsilon_{xy}, \tag{2}$$

where T_{xy} is the shear resultant in the membrane and ϵ_{xy} is the shear strain. For the red blood cell, μ is about 7×10^{-3} dyn/cm. This includes the contribution of the cytoskeleton. For other cells, the comparable value of shear elasticity is much higher, but not well established because the bulk properties of the cell interfere with obtaining separate membrane values easily.

The shear viscosity of the red blood cell membrane has been estimated from pipette and other tests (see Hochmuth, 1987). The shear viscosity η of a membrane is defined by

$$\eta = T_{xy}/2\dot{\epsilon}_{xy}, \tag{3}$$

where T_{xy} is the membrane shear stress which causes the shear rate $\dot{\epsilon}_{xy}$. For the red blood cell, η is about 10^{-5} dyn s/cm (P cm or surface poise) (Waugh, 1982). Most of this viscosity is due to the cytoskeleton.

1.2.6 Bending Elasticity. A lipid bilayer has a small resistance to changes in curvature, like a liquid crystal, due to crowding and expansion on opposite faces of membrane when the curvature is changed. Because the two leaves of the membrane are free to slide over each other, the bending stiffness is small. In most cells, the cytoskeleton stresses completely dominate the lipid bilayer in regard to determination of overall shape of the cell. At the scale of small vesicles, the control of curvature by local molecular forces predominates. In the red blood cell, the membrane bending stiffness is important to explain its resting shape, but is usually negligible under large deformations. The bending stiffness B for a membrane is defined by

$$B = M/K, \tag{4}$$

where M is an isotropic bending moment per unit length (dyn cm/cm), which bends a flat membrane into a uniform sphere of curvature $K = 1/R$, where R is the sphere radius. For the red blood cell membrane, including the cytoskeleton, B is about $(1\text{–}2)\times10^{-12}$ dyn cm.

The moduli defined by Eqs. (1)–(4) are expressed in terms of simple experiments for clarity. In a general dynamic deformation the several elastic and viscous effects are superimposed and the deformations may be large. The simple forms of Eqs. (1)–(4) must then be expanded to proper tensor forms, including the large deformation geometry appropriately (see Evans and Skalak, 1980).

1.3 Physical Processes

To account for the active motions of cells, the study of their biomechanics must include various active processes. Active motions cannot be explained on the basis of passive properties and response to external forces. Rather, they involve changes in internal forces and/or rearrangements of charges or mass.

The principal sources of active motions are contractile forces (as in a muscle), polymerization, and osmotic pressures. Effects of cell adhesion and membrane fusion may also be components of active processes.

1.3.1 Polymerization. Changes of cell shape and properties are generally accomplished either by active contraction or by polymerization. The main molecules involved in polymerization are actin and tubulin. Actin gelation occurs at the leading edge of pseudopods and lamella of locomoting cells such as leukocytes, fibroblasts, and endothelial cells. Gelation results in a change of properties from a viscoelastic fluid to a viscoelastic solid. Solation is the inverse process which breaks down the gel into a fluid state. In the process of locomotion, portions of a cell may repeatedly cycle through gelation and solation.

The polymerization of tubulin leads to the formation of microtubules, but not to the formation of a gel. The microtubules generally remain as stiff, straight rods. Their length, number, and orientation may change continuously by polymerization and disassembly. They are prominent in neural growth cones of actively extending axons. It is possible that the process of polymerization may do work in thrusting a pseudopod or other extension of the cell forward. Hill (1981) has shown that it is thermodynamically possible for a polymerization process to do work, but such forces have not been measured or clearly identified in cell movements.

1.3.2 Osmotic Pressure. Osmotic pressure differences can drive fluid across a semipermeable membrane, according to Starling's law:

$$j=K(p_1-p_2-\pi_1+\pi_2), \tag{5}$$

where p_1, p_2 are fluid pressures on either side of the membrane; π_1, π_2 are the corresponding osmotic pressures; and K is a permeability. If a red blood cell is placed in a solution of lower osmolarity than blood plasma, water enters the cell according to Eq. (5) until the internal pressure rises and the flux j drops to zero. This kind of swelling is a possible process in cell motion. Oster *et al.* (1982) have proposed a model of the extension of the acrosome of a sperm by osmotic pressure. In this case there is an influx of fluid which drives the acrosome extension. It is not clear whether or not osmotic pressure is involved in cell locomotion in which repeated cycles of forward movement take place. It is possible that the gelation and solation of actin leads to local osmotic pressure changes because the effective osmolarity varies as the state of the actin and its associated proteins change. Oster (1989) has suggested this as the driving mechanism of lamellipod extension.

1.3.3 Active Contraction. The interaction of actin and myosin results in an active contraction which is the basis of most active motion and force generation observed in both muscle and nonmuscle cells. The heads of the myosin molecules pull themselves along the actin filaments by a rocking motion like a ratchet. This forces a relative motion of the actin and myosin filaments, sliding lengthwise. The geometric arrangement of actin and myosin in a skeletal muscle is highly organized and compact. In smooth muscle it is less organized. In nonmuscle cells which contract, the actin network may be quite random and temporary. For example, the actin-myosin contractile ring which forms during cell division is rapidly assembled during mitosis and then disassembled after cell division is completed.

Microtubules and intermediate filaments are not generally associated with active contraction, but microtubules are involved in active motions in cilia, flagella, and transport of vesicles as described in the next section.

1.3.4 Tubulin Molecular Motors and Laser Tweezers. The discovery and identification of microtubule-based motion and transport in cells has been elucidated only in the last 20 years. Current status of the field may be seen in detail in the two volumes on cell movement edited by Warner *et al.* (1989). Microtubules are involved in two kinds of active motions. One is the bending type of motion of flagella and cilia. The other is active transport of vesicles along microtubules. Although these appear to be quite different kinds of motion, they are associated with the same kinds of interactive molecules, namely, dynein and kinesin.

In flagella and cilia there is a central structure called the axoneme made up of nine pairs of microtubules arranged in a circle and a central pair, all of which are interconnected into a stable structure (Fig. 3). The dynein molecules are attached to the axoneme at regular intervals and have inner and outer arms that interact with neighboring microtubules. The activation of the dynein molecules tends to slide neighboring microtubules longitudinally past one another. The asymmetric distribution of this motion and its periodic control so as to produce bending waves observed in flagella are necessary, but the details are not entirely clear. There are protozoa in which flagella perform three-dimensional helical rotary motions. In these there is a rotation of the outer microtubules with respect to the central element.

The motion of vesicles along microtubules within the cytoplasm of various cells is accomplished by the same kind of dynein molecules as are found in cilia and flagella. However, in

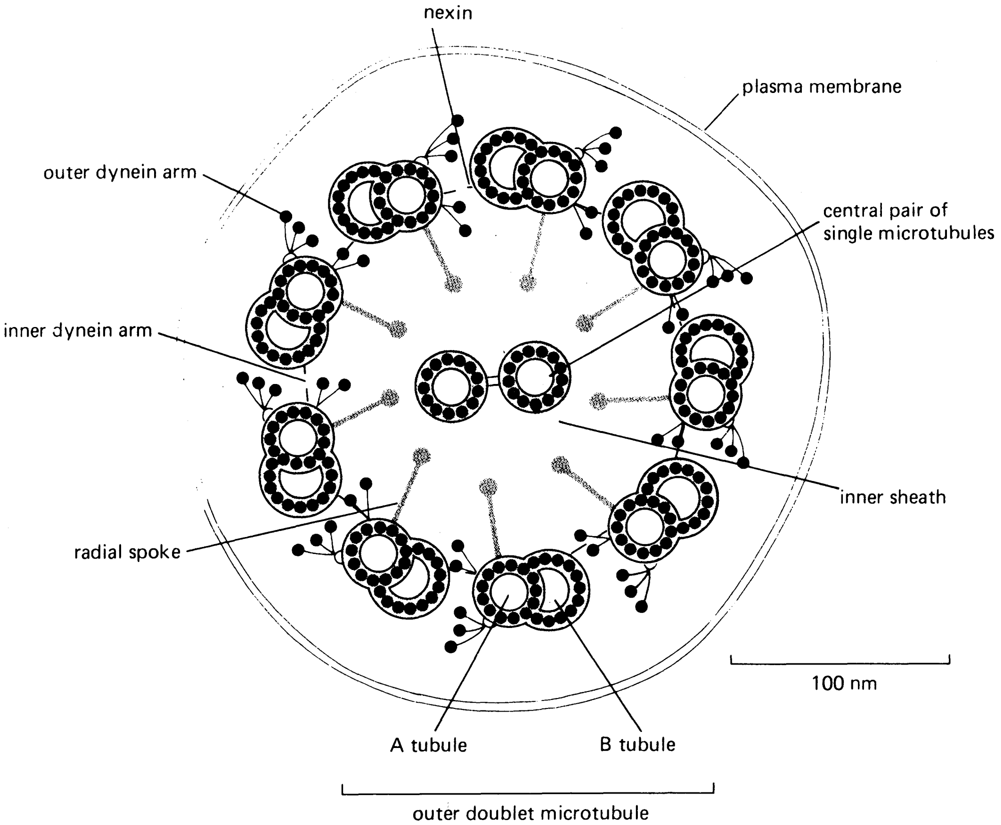

FIG. 3. A schematic sketch of the cross section of a cilium. The various projections from the microtubules occur at regular intervals along the cilium. (From Alberts *et al.*, 1989, by permission.)

this case, the dynein is attached to the membrane of the vesicle or other particle that is transported. The relative motion of the components is due to a walking or ratchetlike motion of the dynein arms along the oriented structure of the microtubules. This resembles, to some extent, the motion of myosin heads along actin filaments.

Another large molecule, kinesin, is also capable of moving vesicles and small particles along microtubules. Kinesin moves vesicles toward the minus (slow-growing) end of a microtubule. Dynein produces motion toward the plus end. Transport of vesicles along microtubules is the basis of so-called fast axonal transport of vesicles in both directions along axons.

The transport of kinesin- and dynein-coated beads along microtubules has been tracked with a precision of 1–2 nm (Sheetz, 1990) by the use of so-called laser tweezers. Small particles in a sharply focused microscopic laser beam can be tracked and manipulated within a closed chamber (Buican *et al.*, 1989). The basic principle is that diffracted photons exert a force on the diffracting particle due to their change of momentum. In a gradient of light intensity a net force can be exerted. This effect centers a particle in the laser beam and can be used to move or track the particle in a controlled manner.

An interesting demonstration of microtubule motor activity can be performed *in vitro* by anchoring the motor molecules, either dynein or kinesin, to a glass surface. Then microtubules in suspension can be seen to be propelled longitudinally along their axis when they settle. The motor action requires the presence of ATP which is hydrolized and serves as the energy source of all active motions associated with interactions with microtubules.

1.3.5 Adhesion and Cell Junctions. The cells of most tissues are connected to each other and to various extracellular matrices produced by cells. The junctions between cells serve as important biochemical barriers or communicating channels. Cell junctions also serve as mechanical connections to prevent opening under stress. In most tissues, the major stress-bearing components are extracellular, as in tendon and bone. These tissues, nevertheless, have living cells interspersed in the extracellular matrices which maintain the tissue in a functional state. Some external appendages such as hair, nails, hoofs, horns, and feathers have no living cells in them. Epithelial cells, which form the outer layer of the skin and line the intestines, are unusual in that there is little external matrix so that any stress applied to them is carried through the cells via junctions connected to the internal fiber systems of the cells. However, they are underlain by a system of extracellular collagen fibers which provide most of the strength of skin.

Cell junctions may be classified as occluding, communicating, and anchoring types. Occluding junctions are called tight junctions and are formed by bonds between lines of molecules which are intramembranous proteins of adjacent cells. Such junctions prevent or retard passage of molecules between cells. The tight junctions of endothelial cells which line all blood vessels keep the protein efflux from the blood to a low level.

Communicating junctions are of two types. One is gap junctions in which matching intramembranous proteins from adjacent cells form a channel through which small molecules (mol. wt. up to about 1000) may pass freely. These junctions are under some control and are shut down if one cell is injured or dies. Another type of communication between cells is through synapse, as in neural cell junctions. Here there is no direct transfer of mass; transmitter molecules are released into the intercellular space which they cross by diffusion and then are received by special receptors on the neighboring cells.

Anchoring junctions also have special structures residing in and on the plasma membrane of the cell. Cytoplasmic plaques called desmosomes protrude through the cell membranes of adjacent cells and form a bond like a spot weld. Cells are attached to an extracellular matrix by half of a desmosome called a hemidesmosome.

Blood cells are unique in that they normally function as separate entities rather than establishing firm bonds to other cells. The adhesion of blood cells and proteins is important to the rheology of blood, to clotting mechanisms, to leukocyte function, and in pathologic conditions. Normally, red blood cells are kept separate by the shear stresses in flowing blood, but if blood is brought to rest, the red cells quickly aggregate. Leukocytes normally flow without adhering to other cells, but adhere to the vascular endothelium when stimulated by a chemoattractant such as is released by an injured tissue. In this case the leukocytes will actively penetrate the endothelial wall and migrate toward the injury. This process of locomotion also requires transient adhesion. The process of phagocytosis, for example, when a leukocyte ingests a bacterium, also requires adhesion of the leukocyte and bacterium. The physical basis of cell-to-cell adhesion is developed in the book edited by Bongrand (1988).

2. MECHANICS OF BLOOD CELLS

Blood is a suspension of several different types of cells in a plasma which is clear Newtonian fluid. In its bulk behavior, blood is non-Newtonian and exhibits a shear-thinning behavior due to the presence of the blood cells. Most of the cells in blood are red blood cells (erythrocytes), normally occupying a volumetric fraction (hematocrit) of about 40%–50% of the total blood volume. White blood cells (leukocytes) are normally much less numerous than erythrocytes (about 1:600) and occupy about 0.3% of the total volume. Platelets are more numerous than white cells, but are smaller and occupy about 0.5% of the total volume.

The bulk rheology of blood is determined by the properties of the plasma and red blood cells primarily because the volumetric fraction of leukocytes and platelets is small. Leukocytes are more important in capillary flow where they may block a vessel completely. Platelets are important to the formation of clots and respond to injury very quickly. Otherwise, the rheological effects of platelets are negligible (see BIORHEOLOGY).

2.1 Red Blood Cells

The study of the physical properties and behavior of red blood cells is more extensive than for any other cell probably because it is an important cell to blood rheology and hematology and because it is a simple, discrete, and readily accessible cell.

Human red blood cells are disks about 8 μm in diameter and 2.5 μm thick with a dimple in each face [Fig. 4(a)]. At rest, the surface is a smooth axisymmetric shape with an average surface area of about 130 μm^2 and a volume of 98 μm^3 (Fung, 1981). The surface area is about 30% greater than that required to enclose the same volume in spherical form. Hence the disk shape can be and is distorted in flowing blood to a considerable extent without any change in the surface area or volume. The red blood cell can be stretched to about double its resting diameter without injury.

2.1.1 Membrane Properties and Cell Shape. The properties of the red cell membrane usually reported pertain to the bilipid plasma membrane plus the cytoskeleton of spectrin on the inner membrane surface (Fig. 2). For a general deformation, the principal membrane stresses T_1, T_2 in the plane of the membrane may be approximated by (Evans and Skalak, 1980)

$$T_1=\frac{\mu}{2}(\lambda_1^2-\lambda_2^2)+K(\lambda_1\lambda_2-1)+2\eta\dot{\lambda}_1/\lambda_1, \quad (6)$$

$$T_2=\frac{\mu}{2}(\lambda_2^2-\lambda_1^2)+K(\lambda_1\lambda_2-1)+2\eta\dot{\lambda}_2/\lambda_2, \quad (7)$$

in which λ_1 and λ_2 are the principal extension ratios (final length of a line element divided by initial length) in the two principal axes of deformation; $\dot{\lambda}_1/\lambda_1$ and $\dot{\lambda}_2/\lambda_2$ are the strain rates in the principal directions. The coefficients μ and K are the shear and area elastic moduli and η is the membrane viscosity, as discussed in the preceding section.

For a complete description of the membrane properties, the behavior in bending must be specified also. Assuming the bending moment is isotropic, it can be approximated in principal axes of the membrane curvature by

$$M_1=M_2=B(K_1+K_2)/2, \quad (8)$$

where K_1 and K_2 are the changes in the curvatures from the unstressed state and B is the bending stiffness discussed in the preceding section.

The use of the stretch ratios λ_1, λ_2 and the curvature changes K_1, K_2 imply that there is a known unstressed state of the membrane. However, such information is not definitely known. The normal biconcave shape of the red blood cell may or may not have residual stresses in it. If the unstressed shape of the cell is assumed to be spherical, then it can be shown that a shape very close to the observed red blood cell shape can be achieved by deflating the uniform sphere to the appropriate volume. If the unstressed shape of the cell is assumed to be the normal disk shape [Fig. 4(a)], then during osmotic swelling, the shape eventually approaches a sphere [Fig. 4(b)]. The shapes shown in Fig. 4(b) are minimum strain-energy shapes within the constraints of constant surface area and specified volumes.

If the initial, stress-free curvature of the cell is altered, or the ratio of the shear modulus times the square of the cell diameter to the bending modulus is changed, then a variety of different rest shapes may be obtained (Stokke *et al.*, 1986). *In vitro*, a large variety of shapes are observed (e.g., echinocytes having many spicules or stomatocytes which are cup-shaped). These shapes are usually the result of biochemical modifications of the membrane. These changes usually influence the stress-free curvature (also called the spontaneous curvature).

2.1.2 Hemoglobin Properties. The hemoglobin solution inside the red blood cell has been shown to be a Newtonian fluid with a viscosity of about 6.2 cP, i.e., about five times the viscosity of blood plasma or water and about twice the apparent viscosity of whole blood at high shear rates (see Cokelet *et al.*, 1980). The density of hemoglobin is a few percent higher than that of plasma which is sufficient to be able to measure blood velocity ultrasonically. For purposes of red blood cell and blood rheology studies, the hemoglobin is well approximated by an incompressible Newtonian fluid.

2.1.3 Pipette and Flow-Chamber Tests. The mechanical properties of red blood cells have been derived from various microscopic tests, such as pipette, flow-chamber, and siev-

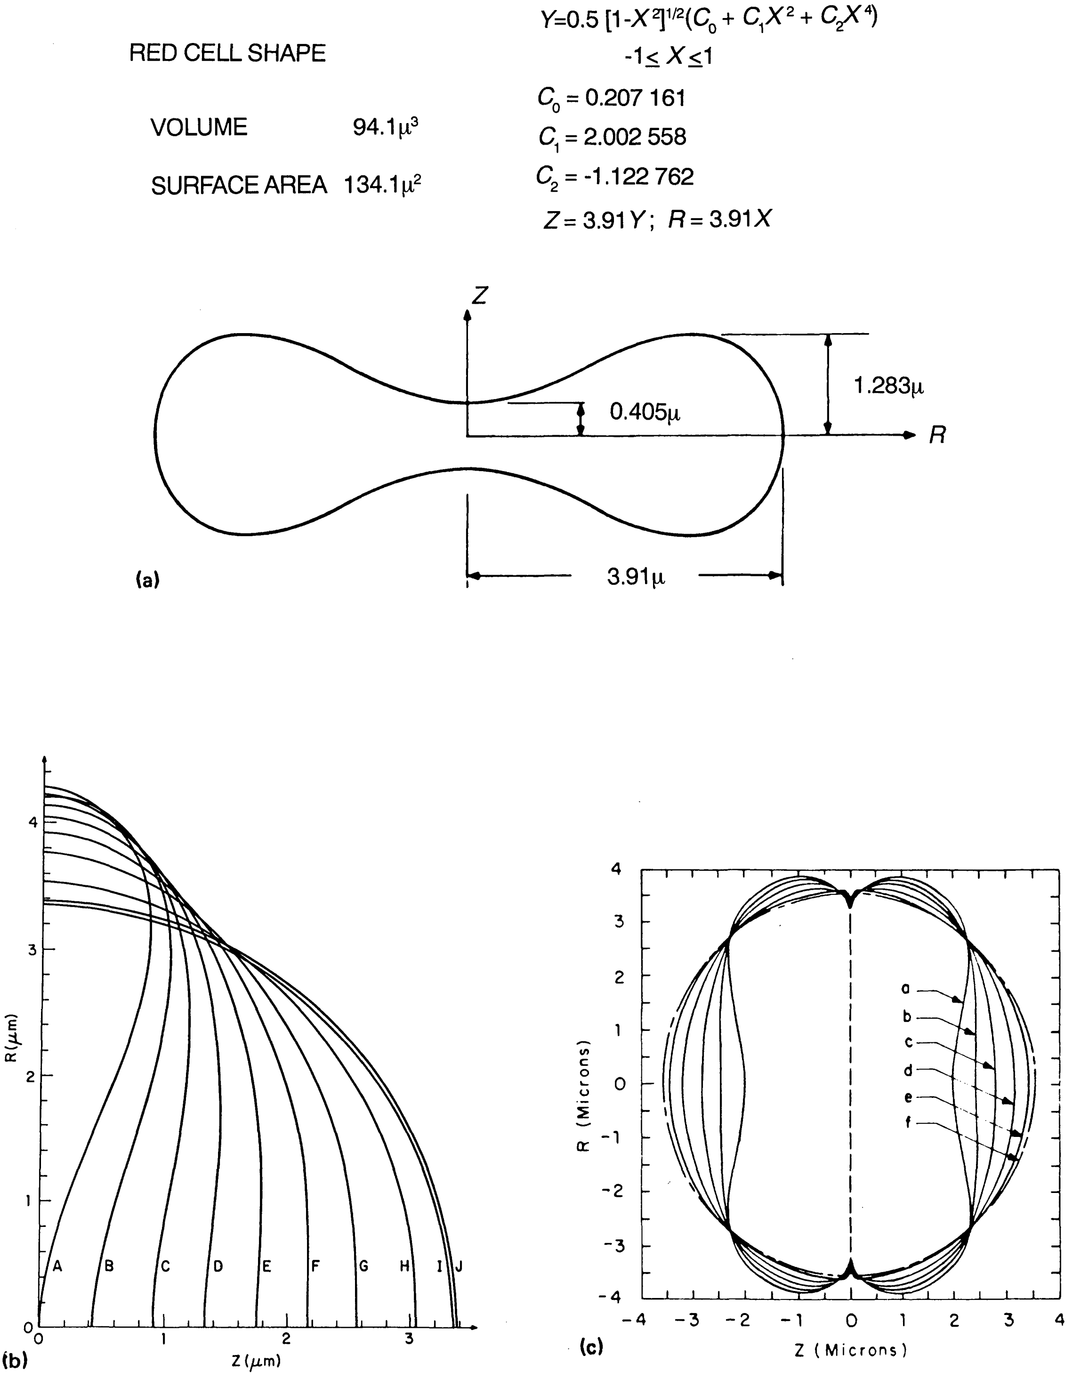

FIG. 4. (a) Red blood cell shape assumed for free suspension, at rest. (From Skalak, 1980, based on Evans and Fung, 1972, by permission.) (b) Computed shapes of various stages of swelling of a red blood cell. Curve *B* was taken to be the unstressed shape. Curve *A* is computed for subnormal cell volume. The surface area is constant until the state *I*. (From Zarda *et al.*, 1977, by permission.) (c) Computed two-cell rouleau shapes assuming initial shapes as in (a). The successive shapes (a)–(f) correspond to increasing adhesive energies. The dashed line is the limiting sphere theoretically reached at infinite adhesive energy. (From Skalak, 1984, by permission.)

ing experiments. In pipette experiments, a portion of the cell is drawn into the tip of the pipette, which is about 2 μm in diameter. In this experiment the portion of the cell outside the pipette retains its normal disk shape and the pressure difference required to draw a tongue of cell membrane into the pipette is interpreted in terms of the shear elastic modulus of the membrane (see Evans and Skalak, 1980). This experiment may also be used to estimate the bending stiffness of the membrane from the pressure required to buckle the membrane around the tip of the pipette (Evans, 1983).

The pipette experiment performed on a swollen red cell can be used to derive the area elastic modulus of the membrane by aspirating enough of the cell so that the remainder is spherical. By further increasing the pressure, the membrane is stretched in isotropic tension and the surface area increment can be calculated from the increase in the length of the membrane tongue inside the pipette (see Evans *et al.*, 1976).

The viscosity of red blood cell membranes can be estimated from time-dependent pipette experiments (Chien *et al.*, 1978) and by stretching a cell which is fixed to a glass slide (Hochmuth *et al.*, 1979). The time of recovery of the normal red cell shape is about 0.3 s, which, together with the shear elastic modulus, allows an estimate of the membrane viscosity.

Another type of microscopic experiment is the so-called flow chamber in which fluid is passed between closely spaced parallel plates (gap width about 125 μm). If red cells are allowed to settle in such a chamber, some adhere to the wall. Then, by pumping fluid through the gap, a known fluid shear stress can be applied to the cell. The experiment can be observed directly through a microscope. From measurements of the stretching and recovery time of the cell, the elastic shear modulus and membrane viscosity can be estimated.

2.1.4 Flickering. When red blood cells are observed in a suspension without any macroscopic flow, the cells do not appear to be entirely stationary, but the membrane has a small random motion which is termed flickering. Some components of the motion are slow enough and over a sufficient area to be detected visually through a microscope. Flickering has been reported as early as 1890. It is attributed to thermal fluctuations, like Brownian motion of small particles in a fluid. The red blood cell is too large and deformable to exhibit Brownian motion as a whole, but the membrane is sufficiently flexible to be transiently deformed by the thermal molecular motions of the surrounding liquids. It is restored to its equilibrium shape primarily by its bending elasticity. For small deformations of the dimple of the red blood cell membrane, the shear and stretching energies are of higher order so bending modes predominate.

In the analysis of flickering it is assumed that all modes are independently excited and that there is an equipartition of energy in all modes. The mean bending strain energy in each mode is set equal to $k_B T$, where k_B is Boltzmann's constant and T is the absolute temperature. Quantitative estimates of the bending stiffness of the red blood cell membrane were made by Brochard and Lennon (1975). Their results are lower than those found by more direct measurements. Refinements of the method (see Schneider *et al.*, 1984) may explain the discrepancy.

2.1.5 Capillary Flow. The diameters of most capillary blood vessels are about the same as or even a little smaller than the diameter of red blood cells. Hence red blood cells are normally quite deformed when flowing in capillaries. Due to the red cell flexibility, the increase in pressure gradient due to the presence of the cells is a factor of two or three times that for the same velocity of plasma alone. The factor depends on the velocity of flow because the cells are deformed to a greater extent at high velocity (see Skalak *et al.*, 1989). In bulk flow, as in large arteries, the apparent viscosity of blood is also shear-rate dependent due to the deformability of the red cells (see BIORHEOLOGY).

In small capillaries (< 7-μm diameter), red blood cells usually move in single file and tend to be more or less axisymmetrically located. As the diameter of the vessel and the hematocrit increase, a nonaxisymmetric arrangement with two or more rows tends to form. When two rows form, the cells tend to be arranged in an alternating pattern which is sometimes called a zipper arrangement (see Cokelet, 1987). An arrangement with two rows of cells arranged with each pair of cells in the same cross section of the vessel is unstable (Sugihara-Seki and Skalak, 1989). The alternating arrangement (like a Kármán vortex street) is stable. At larger vessel diameters, (> 15-μm diameter) the arrangement of cells is observed to be irregular. In capillary flow, the red blood cells generally move more rapidly than the mean velocity in the vessel because they occupy the central portion of flow where the velocity is greatest. This is called the Fåhraeus effect which is detectable in vessels up to about 200 μm in diameter (Cokelet, 1987). There is another result, largely due to the Fåhraeus effect, which is called the Fåhraeus-Lindqvist effect. This refers to the fact that the apparent viscosity of blood decreases as the vessel diameter decreases below about 300 μm (see BIORHEOLOGY).

2.1.6 Rouleau Formation. Whenever blood is brought to rest, the red blood cells aggregate, typically forming cylindrical stacks called rouleaux because they resemble rolls of coins. When two red blood cells touch, they slide or roll until the two disk profiles are quite accurately aligned axisymmetrically [Fig. 4(c)]. Depending on the strength of the adhesive molecular species, the cells will be more or less deformed. The spacing between adjacent cells is uniform and is proportional to the molecular weight of the adhesive species.

Red blood cells normally carry a small negative charge so that work must be done to draw the cells together during adhesion. This energy is supplied by the chemical potential decrement of the adherent species. An unusual aspect of adhesion of cells, in contrast to adhesion of most inert materials, is that the adhesive energy per unit area for a particular cell and concentration of adhesive molecules is not constant. During the forcible separation of two cells the adhesion energy increases as the contact area decreases. This behavior is attributed to the mobility of the molecules and the proteins within the cell membranes. The ligand molecules attached to the cell surface outside of the contact area can move to the contact area by diffusion. In addition, when two cells are gradually pulled apart, the tension developed in the ligands tends to slide them along tangentially to the membrane and sweep them into the contact area. The concentration of bonds between two red blood cells by this mechanism has been demonstrated by fluorescent measurements by Vayo (1986). A theoretical treatment including effects of movable bonds on leukocytes has been given by Tözeren *et al.* (1989). Various cell adhesion phenomena are discussed in the book edited by Bongrand (1988).

2.2 White Blood Cells

The rheology of leukocytes is less definitively explored and is much more complex than that of red blood cells. The presence of a nucleus and many organelles makes the passive properties viscoelastic and nonlinear (Chien *et al.*, 1984). In addition, the possibilities of active motion and rearrangements of the cell interior can produce cell locomotion and phagocytosis which do not occur in red blood cells.

2.2.1 Passive Properties: Pipette and Poking Tests. The passive properties of leukocytes can be probed by micropipette aspiration and by observing their recovery after deformation (Fig. 5). White blood cells are much stiffer than red blood cells and recover from a deformation much more slowly. Whereas a red blood cell will recover its biconcave shape in about 1/3 of a second, a white blood cell deformed into an ellipsoidal shape may take 60–100 s to recover its spherical shape. In free suspension, the fact that it does recover a spherical shape has been interpreted to indicate that the cortical shell of the cell is under a small active tension. The cortical shell is a layer of actin gel primarily, about 0.5 μm thick, just below the plasma membrane. The contractile stress is due to a small amount of myosin present and acts like a small surface tension.

Most of the cytoplasm of a leukocyte is in a constant state of Brownian motion and is a viscoelastic fluid in its bulk behavior. It has been modeled as a Maxwell fluid (Dong *et al.*, 1988) for small deformations and as a Newtonian fluid (Evans and Young, 1989) for large deformations. The apparent viscosity for large deformations is about 2000 dyn s/cm^2. Due to the cortical tension, there is a critical pressure in a pipette aspiration experiment below which the cell will not fully enter the pipette.

For small deformations, the passive behavior of the leukocyte can be represented as a homogeneous sphere of a viscoelastic solid, usually called a standard solid, made up of a Maxwell element (a spring and a dashpot in

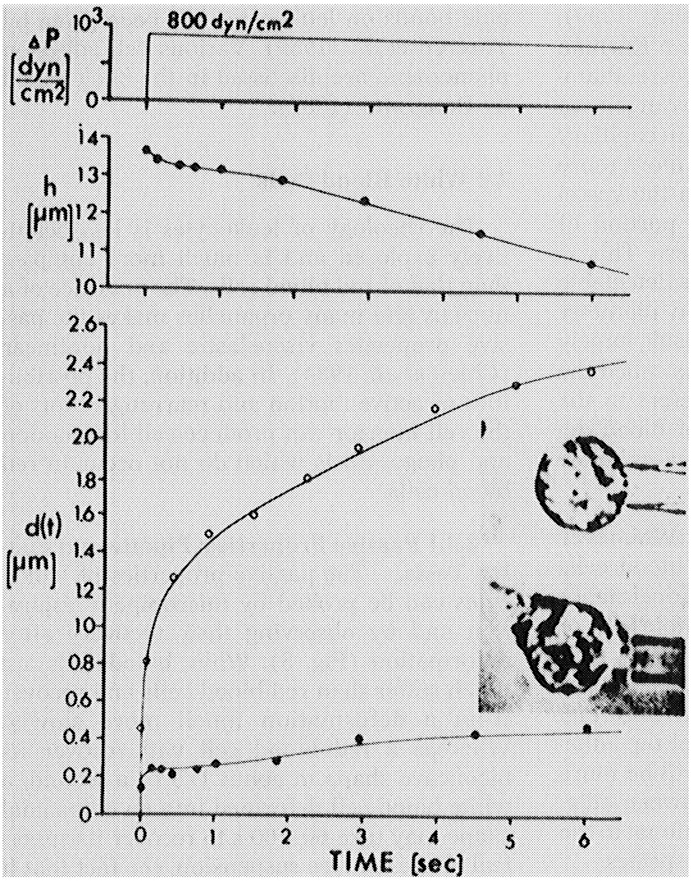

FIG. 5. Micropipette aspiration pressure ΔP and deformation $d(t)$ for a neutrophil which was aspirated at the main cell body (open circles) and at a small protopod (solid circles). The length h is the major axis of the cell. (From Chien *et al.*, 1984, by permission.)

series) in parallel with another spring (which represents the cortical shell). This model is convenient to compare results from cells of different types or various biochemical reagents (Sung *et al.*, 1982).

Another kind of test which has been applied to leukocytes as well as other cells is an indentation experiment dubbed "cell poking" (Zahalak *et al.*, 1990). In this technique a small flat-ended cylinder, a few microns in diameter, is pressed into the surface of a cell which is attached to a rigid substrate. The force required for indentation is calculated from the deflection of a slender glass beam which supports the indenter. A very fine (0.1-μm) control of the indenter is achieved by a piezoelectric driver. The results on leukocytes show a greater stiffness by a factor of 2 to 10 over that derived from micropipette experiments. So far, the reasons for this discrepancy are not known.

2.2.2 Pseudopod Formation. The pseudopods of leukocytes are typical cell extensions consisting of thin rods or sheets that are actively protruded from the cell body. In leukocytes, it may be seen in electron microphotographs that the interiors of pseudopods have a uniform appearance with very few, if any, organelles or granules. The pseudopods consist mainly of actin gel, and it has been established by fluorescence studies that pseudopods grow by addition of actin monomers to the actin gel polymer at the tip, i.e., at the cell membrane.

A theory of pseudopod formation has been given by Zhu and Skalak (1988) in which the driving force for the pseudopod extension is actin polymerization at the tip of the pseudopod. It is implied that the polymerization process can push the cell membrane outwards. This also acts to draw G-actin by convection and diffusion from the cell body to the tip of the pseudopod. The process of pseudopod formation is under biochemical control, but full details are not known. Chemoattractants sensed by the cell membrane trigger a series of internal responses. The level of calcium ion appears to be one of the chief regulators of actin polymerization.

The retraction of a pseudopod appears to be a different process than its formation. The solation of the gel takes place at the base of the pseudopod where it joins the cell body. A contractile force in the cortical shell of the cell is required to pull the cell back into spherical shape.

Pseudopod formation is the basis of phagocytosis in which a leukocyte engulfs a bacterium or other foreign object, like a small plastic bead. The pseudopods are thin sheets in this case and adhesion plays a role in stabilizing the leukocyte contact to the bacteria or particle. When the pseudopod sheet completely surrounds the bacteria, the leukocyte membrane fuses so that the bacteria is wrapped in a cell membrane and completely internalized after which it can be killed and digested.

2.2.3 Capillary Flow. The flow of leukocytes in capillaries is quite different from that of red cells which are readily and quickly deformed by the stresses in normal blood flow. Leukocytes pass freely through capillaries which are larger than about 8-μm diameter, but move more slowly than red cells because they are larger and the Fåhraeus effect is smaller. As a result, red blood cells often catch up to leukocytes in capillaries in a so-called train formation.

If a leukocyte encounters a narrow capillary, it may block it completely while it is slowly deformed by the driving pressure. This may take a minute or more. This is one source of the apparently random variations of velocity found in capillary flows.

Another distinction of leukocyte behavior is that, in small venules, the leukocytes may adhere to the wall or roll along slowly. They can even adhere and actively move upstream against the flow. Such adhesion and motion are part of the processes of defense against bacteria or cell injury by leukocytes.

2.2.4 Sieving Tests. A clinical test of blood cell deformability can be based on the time it takes to pass a fixed volume of blood through a fine porous filter at a fixed pressure, or by measuring the pressure for a fixed flow rate. A typical filter is a thin polycarbonate sheet, about 13 μm thick, in which pores about 5 μm in diameter have been produced by radiation and etching. Such tests were originally thought to measure red blood cell deformability, but it has been shown experimentally and theoretically (Skalak *et al.*, 1987) that the results are more nearly indicative of the number and condition (activated or nonactivated) of the white blood cells present. The stiffer white cells tend to clog the pores and cause a disproportionate rise in pressure. The early phases of such tests can be used as a measure of red blood cell deformability before white cells are trapped in significant numbers.

3. CELL MOTILITY

Many different kinds of cells during some phase of their life actively move from one location to another. Some, like fibroblasts, may be motile most of the time, while others, like endothelial cells, may relocate only to compensate for injury or other changes. Cells of the body usually require a solid substrate or neighboring cells to react against to produce their own motion and cannot swim in a fluid. On the other hand, micro-organisms are usually adapted to swimming in free fluid.

The driving mechanisms of cell motility are of two kinds. In cells of the body, locomotion is the result of rearrangement of the internal cytoskeleton by gelation, solation, and contraction. Adhesion and release is also necessary. In free-swimming micro-organisms and in cilia the microtubule structures remain fixed in place relative to other cell structures and in composition, but perform oscillatory deformations that produce movement. These different modes of motility are discussed in more detail in the following sections.

3.1 Flagella and Cilia

The basic driving mechanism or motor is the same in flagella and cilia. The active element is an arrangement of microtubules in an axoneme consisting of nine pairs of tubes in a circle plus one central pair (Fig. 3). Flagella, like the tail of a sperm, usually act singly and have a wavelike motion. Cilia beat back and forth with different configurations in the forward and backward strokes. Cilia occur in huge numbers, such as $10^9/\text{cm}^2$ in the human respiratory tract, and act in concerted waves.

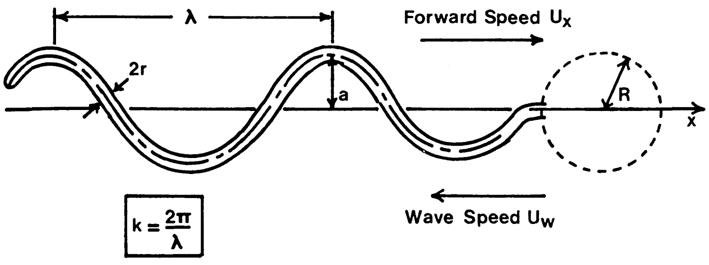
3.1.1 Flagella Mechanics. The motion of flagella, viewed in successive frames of a video, looks like a large-amplitude sine wave which propagates toward the rear (Fig. 6). This backward motion produces the forward propulsive force. The entire mechanical system of elastic forces and active bending of the flagella and the external viscous fluid flow have been analyzed in considerable detail (Holwill, 1989). It has been shown that to overcome the elastic flexural stiffness and viscous forces, the active bending moment must be distributed along the length of the flagella. In fact, the activation of dynein needs to be coupled to the bending movement of its neighbors in a mechanical way to produce a propagating wave. The asymmetry required to produce a bending motion from the relative sliding motion provided by dynein activity is provided by activation of only one-half of the circular cross section. Another requirement is that free sliding of tubules relative to each other is prevented. This is provided by radial spoke elements.

The details of the control system that produces a traveling wave and a definite beat frequency are not entirely clear. The maximum frequency is in the range of 50–100 Hz. This suggests that biochemical and mechanical events occurring in the movable dynein arms must be locally coupled and propagate like falling dominoes. One theory suggests that the active bending moment is turned off when the curvature reaches a predetermined level (Brokaw, 1989). The frequency and even the direction of the wave propagation are sensitive to calcium levels. The action of calcium has been identified as operating through the regulatory protein calmodulin (Otter, 1989).

The fluid mechanics of the external flow and forces generated by flagella motion are developed on the basis of drag coefficients for the forces exerted on an element of length *ds* of the flagella in the directions normal and tangential to *ds* (Lighthill, 1975). Taking components of these forces in the direction of motion and integrating along the length of the flagella yields the appropriate propulsive force. In the steady state, this propulsive force is balanced by the viscous drag of the cell body which is also computed by viscous, low-Reynolds-number flow theory.

3.1.2 Cilia Motions. The beating of cilia is coordinated so that waves are propagated in one direction, like waves on a wheat field in the wind. In the trachea, the direction of wave propagation is toward the mouth. In microorganisms that use cilia for propulsion, the wave direction is toward the rear. The beating of each cilium goes through a cycle of about 0.1–0.2 s in duration. The power stroke in the direction of propagation takes place quickly with the cilium nearly straight and fully extended. During the return stroke, the cilia is bent so it lies close to the surface.

Organisms that swim by cilia motion are usually in the range of 20–2000 μm in length. The number of cilia of a single protozoan may be 200–10^6. Individual cilia range from about 5 to 15 μm in length. The scaling of organisms that swim by cilia motion has been studied by Sleigh and Blake (1977). It is shown that the efficiency of cilia propulsion decreases as L^{-1} where L is the body length. This is due, in part, to the fact that very large numbers of cilia are required as the size of the animal increases and the ratio of cilia length to body length decreases. The theoretical upper limit of efficient size is about 350 μm. Larger ciliated animals swim with low efficiency. On the



Parameters used to describe undulatory propulsion

FIG. 6. Schematic of undulating flagella motion indicating opposite directions of wave motion and forward speed. (From Holwill, 1977, by permission.)

other hand, the ratio of wave amplitude to wave length of most cilia waves is found to be near a theoretical optimum (Holwill, 1977).

3.2 Amoeba Motility

The locomotion of an amoeba generally proceeds in a series of cyclic stages rather than a continuous motion. The typical time for a cycle is in the range of 1–10 min during which the cell may elongate, put out extensions, and move forward perhaps half a body length. A central feature of amoeboid movement is the protrusion of a pseudopod or lamella from the leading edge in the direction of motion. The physical basis of the motive force for such protrusion is not entirely clear. One kind of theory postulates an actin-myosin interaction which always produces contraction of the actin network and can thus generate internal flows (Dembo, 1989). Another force that may be involved is osmotic pressure (Oster and Perelson, 1987). In any case, the solation and gelation of an actin network is part of the cyclic process. The polymerization of the actin itself may be a source of propulsive force (Zhu and Skalak, 1988). These various theories are outlined in the following sections.

3.2.1 Two-Phase Models. Two-phase models consist of an actin gel or network component which is considered to be solid or a very viscous fluid, plus a fluid phase which occupies the pores of the network. In some regions the network may be dense and solid. In other places the network may be so sparse that the cytoplasm is essentially fluid. In any case, the two phases interpenetrate and may have some relative motion. This produces a viscous drag force on the network. This force may also act in reverse; a contracting network can move fluid along via this viscous drag. In addition to the solation, gelation, and contraction of the network, mass transport can take place by diffusion and by pressure-driven convection forcing fluid through the network.

A set of equations and boundary conditions has been proposed by Dembo (1989) and solved numerically for a model of internal motion in *Amoeba proteus*. The basic equations are the conservation of mass of actin and of the fluid, equations of motion of the actin network and the fluid, and an equation on a control substance which may be concentration of calcium, but is not positively identified. The distribution of the control factor is determined by a diffusion and convection equation as it is carried by the fluid phase. A rate of automatic decay of the control substance is also postulated. The control substance regulates the contractile stress generated by the network. At the forward end of the amoeba, the concentration of the control substance is high. The gelation or solation of the network is assumed to depend on the density of the network. It is postulated that there is an equilibrium density toward which the network evolves with a time constant of about 12 s.

Numerical results (Dembo, 1989) show a close approximation of the steady internal flow observed in *Amoeba proteus* when it is fixed to a substrate. This is a so-called fountain flow in which fluid flows forwards in the center of the amoeba, spreads out at the anterior end, and returns with a sheath (endoplasmic layer) of actin gel which moves steadily toward the rear of the cell. In Dembo's numerical solutions, it is shown that the kind of reaction-diffusion system of equations for interpenetrating networks is prone to instability of static fields, but can produce steady internal motions.

3.3 Leukocytes and Fibroblasts

The projection of pseudopods of leukocytes and fibroblasts is a cyclic process in time, but appears to be a more homogeneous process than in amoebae with respect to variations through the thickness of the projection. Fountain type of flow is not observed in the sense of a core region of fluid moving forward and a shell of network moving backward. There is another kind of steady motion observed called treadmilling in which the front edge of the cell is stationary but actin filaments move steadily backwards, away from the cell membrane. The implication is that actin in solation (G-actin) percolates through the actin gel (F-actin) and polymerizes at the membrane surface. The treadmilling of actin gel in a pseudopod is established by fluorescent markers and photobleaching techniques (Wang, 1985). The driving force for the treadmilling motion, or for pseudopod extension, is not entirely clear. One possibility is that the pressure at the tip of a pseudopod is elevated by local osmotic effects. The cleavage of actin and profilin of the G-actin complex by enzymes at the cell membrane could be the cause of increased osmolarity. This possibility is discussed by Oster and Perelson (1987). The role of osmotic pressure has also been developed in acrosomal extensions (Oster and Perelson, 1987). The fact that raising external osmolarity inhibits acrosomal protrusion favors the role of osmotic pressure.

Another possible source of protrusion force is the polymerization process itself. If the gelation is controlled at the membrane, the addition of actin molecules to the existing network would force a relative motion of separation of the membrane and the existing network. This polymerization force could thrust the network backwards as in treadmilling or push the membrane forwards as in pseudopod extension. Equations governing such pseudopod growth and numerical solutions are discussed by Zhu and Skalak (1988). Hill and Kirschner (1982) have discussed the theoretical possibilities of work done by polymerization, but it has yet to be demonstrated directly experimentally.

3.3.1 Sequence of Locomotion Cycle. The typical cycle of cell locomotion starts with protrusion of a pseudopod or lamellapod. The second step is attachment of the pseudopod to the substrate or to the surrounding cells or extracellular matrix. If there is no attachment, the pseudopod will be retracted. If the pseudopod is attached, a third and last phase ensues which is a contraction of the body of the cell and to some extent of the pseudopod. The net result is to pull the body of the cell forward over the pseudopod. During this process, there may be previous attachments that are now at the rear of the cell. Sometimes long, thin strands of actin filaments stretch from the old attachments to the cell body. These are the so-called stress fibers, although the stress in them is not known and they are more likely to be stretched passively rather than actively. The breaking of posterior attachments and reabsorption of the stress fibers into the cell body completes the cycle. The cell is then ready to start a new protrusion. The breaking of the posterior bonds suggests that cell adhesion is time dependent so that during cell contraction, the weakest bonds break, appropriately at the rear. The contraction probably extends over most of the cortical shell of the cell by actin-myosin interaction. Points of attachment have been shown to connect directly to interior actin filaments so that contractile stress can be transmitted to the boundary (Alberts *et al.*, 1989).

3.3.2 Mechanics of Contraction A bipolar myosin molecule (one with an active head on each end) can slide two actin filaments past each other indefinitely if ATP is supplied. This action can contract an actin network. When myosin reaches a junction of the actin network, it may shift to a new actin filament and continue contraction. *In vitro* gels can be contracted to a small fraction of their original extent. Another process which makes this possible is that the cross-linking molecules which form the actin network junctions dissociate and reassociate repeatedly. The temporary release of junctional bonds means that myosin has the opportunity to contract the gel further over a period of time much more than it could without breaking network bonds.

If the opposing forces are sufficient, contraction is stopped, but a steady force may persist. This is the condition that likely occurs in the cortical shell of cells which are in a static position, such as the free-floating leukocyte with a spherical shape or an endothelial cell in a layer which is confluent and not altering its geometry in response to changing stress fields. These kinds of stresses are a type of prestress or residual stress at the cellular level. Various aspects of the mechanisms and regulation of cell motility are discussed in the book edited by Ishikawa *et al.* (1986).

4. CYTOKINESIS AND GROWTH

Cytokinesis refers to the process of cell division which begins by the formation of a cleavage furrow which then contracts and divides a cell in two (Fig. 7). This mechanical event is preceded by several steps during which the internal structures of the cell, particularly the nucleus and its chromosomes, are divided into two sets which are sequestered at opposite ends of the cell. The mechanics of these early phases involve microtubular guidance, but are not yet analyzed in quantitative terms of forces and resistances. The cleavage phase has been described to some extent by mathematical models (Akkas, 1990).

Growth takes place by cell division followed by an increase of size of individual

cells. The arrangement of large numbers of cells into tissues and organs is called morphogenesis. The form and functioning of all tissues depends on the appropriate behavior at the cellular level. All development is driven by the interactions of individual cells. This interactive process is extremely complex. It is basically controlled by the genetic code which gives each cell its instructions for manufacture of proteins, enzymes, and extracellular components. The instructions for tissue formation, size, and shape are less explicit and depend on interactive response between cells and between the organism and the external environment. Mechanical rearrangement processes may utilize differential adhesions, cell locomotion, cell differentiation, and cell metamorphism from one form to another. For example, stem cells of the bone marrow give rise to red blood cells, leukocytes, and platelets.

4.1 Mechanics of Cell Division

The mechanics of cell division usually refers to two main processes, namely, the movement of chromosomes (during anaphase) and the subsequent cleavage of the cell into two cells (cytokinesis) (Fig. 8). However, many additional mechanisms are operative during mitosis which are well known in that they are clearly identified and analyzed as to the form and movement of the components involved. But the forces and the specific control mechanisms that bring about the observed results are not known in detail. Most accounts of the mechanics of cell division contain no numerical values for forces, viscosities, or other properties, but simply describe the events that take place. The number of different components involved is large, including internal membranes that disassemble and reassemble, chromosomes that divide, microtubules, centrosomes, actin, myosin, organelles, and endoplasmic reticulum, to name just some of the principal constituents. The concerted relative movements in space and time of these components will have to be described by a multiphase, multiply interactive media theory with both Brownian motion (random events) and highly specific and symmetric events all combined, while keeping track of the location, size, and properties of hundreds of entities.

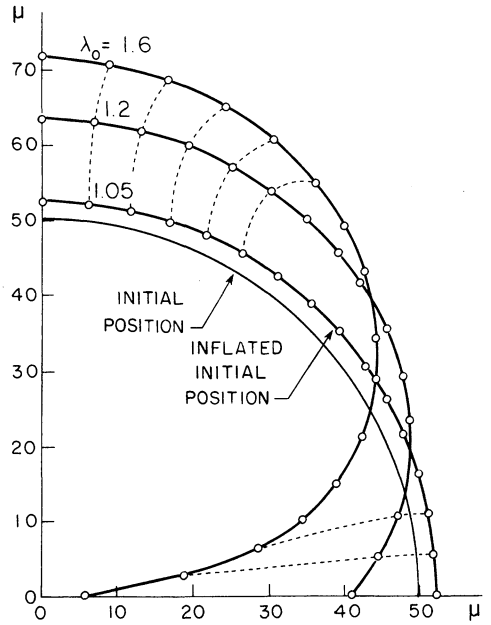

FIG. 8. Computed shapes of cell undergoing cytokinesis. The curves show one-quarter of the field of Fig. 7(b). The dotted lines are particle paths. (From Akkas, 1980, by permission.)

Nothing like this has been attempted. The mechanics theory applied to date is to models of one or two components only.

4.1.1 Contractile Ring Models. When a cell divides, it elongates slightly from a spherical shape and then a furrow appears, girdling the cell around the smaller diameter. Just below the membrane in the cleavage furrow, a contractile ring is formed which is made up of actin and myosin filaments. This contractile ring is diffuse at its inner boundary and may be only 0.1 μm thick and 10 μm wide. There are about 5000 F-actin filaments, each about 15 nm thick, in a typical contractile ring. The connection of the contractile ring to the cell membrane has not been demonstrated, but observation shows that as the contractile ring contracts, the membrane remains closely apposed to it.

Models of cell division assume that the contractile ring exerts a circumferential tension and that the rest of the cell behaves in a passive manner, as a viscoelastic fluid. The contraction of the contractile ring proceeds from the full diameter of the cell down to essentially zero and the ring then disappears (Fig. 8). The origin of the contractile ring is most probably from actin and myosin already present in the cortical shell. It appears that cytokinesis is preceded by a rounding of the cell which may indicate a general contraction of the cortical shell which is somehow enhanced at the equator by the influence of the two mitotic asters which are then separated by the cleavage.

In the modeling shown in Fig. 8, it is essential that the cortical shell be able to expand during cytokinesis because the surface area of the two daughter cells is greater than that of the original cell. The total volume is assumed to remain constant during cytokinesis. The cytoplasmic actin gel of the cortical shell can be readily expanded by slipping or releasing and reforming cross-linking proteins. The plasma bilipid layer of the membrane cannot increase its area more than 1% or 2% without rupture. It supplies the apparent increase in surface area by unfolding of wrinkles and protrusions on the surface of the cell.

4.1.2 Chromosome Control. In the early stages of cell division during so-called metaphase, Fig. 7(a), the chromosomes are aligned on the equatorial plane which later becomes the cleavage plane. The positions of the chromosomes appear to be controlled by microtubules which are the principal active element in the internal rearrangements during mitosis. Early in mitosis a bipolar structure of microtubules forms called the mitotic spindle. Microtubules radiate from two centers, called spindle poles. Proteins called kinetochores attach chromosomes to microtubules from the spindle poles. The two sets of chromosomes are pulled to the spindle poles by microtubule shortening. The poles themselves are pushed apart by sliding of microtubules which overlap, Fig. 7(b). Once two new nuclei are formed, microtubules are largely disassembled and cytokinesis proceeds. The magnitudes of forces and drags in these complex movements have not been evaluated to date.

4.2 Morphogenesis and Growth

Growth implies an increase of size which may or may not be accompanied by a change in form or topology. If only size changes, without any change of shape, the growth is said to be self-similar or isotropic, i.e., the growth is equal, percentagewise, in every direction and dimension. In many cases, a change of shape takes place without adding any new types of tissue nor by changing topology, but by unequal rates of growth in different directions. Such growth often results in different dimensions, a, b, both being functions of time and being related by $a=kb^m$. This is called allometric growth, where m is an allometric exponent and k is a constant. Allometric growth can transform a sphere into an ellipsoid, but not into a torus, which requires a topologic change.

Changes in topology and the diversification of groups of cells into different tissues are implied in the term morphogenesis. In various cases, morphogenesis and growth may proceed independently. In the frog, the fertilized egg (about 1 mm in diameter) divides repeatedly to become about 30 000 cells in about 10 h without an increase in mass. At this stage the embryo is called a gastrula which represents a considerable stage of morphogenesis although there is no growth in the sense of adding mass. Before gastrulation, the embryo already has developed some differentiation in that the external cells have tight junctions so the embryo is effectively sealed. Internal to the spherical embryo, cells are connected by gap junctions which may function as channels of communication.

The process of gastrulation is a major event which occurs in the development of all embryos. Gastrulation starts from a blastula which is a sphere with a distinct surface layer of epithelial cells. This epithelial layer is first invaginated and then proceeds through the interior of the cell to form, topologically, a torus. The central tube evolves into the gut. The interior of the torus evolves muscles, nerves, and other organs. The gastrula is topologically a torus, but its outer form is still more or less spherical with a thin tube down the middle (Akkas, 1990).

The next step in embryological development is formation of the neural tube (Fig. 9). The external layers of the dorsal ectoderm thicken and then fold to form a tube that later develops into the spinal cord and brain. The tube formation involves asymmetric growth and adhesions as outlined in the next section.

4.2.1 Role of Adhesion. Cell-to-cell adhesion is a central mechanism to the coherence of tissues and to morphogenesis in several ways. Without adhesion, tissues would become liquid masses without resistance to indiscriminate mixing.

Adhesion not only holds tissues together, but may be an active force in sequestering similar cells. In a blastula, cells with lower adhesiveness will form the exterior epithelial layer. This idea comes from the observation of droplets of different liquids. A droplet of lower surface tension will tend to envelope a droplet of higher surface tension. In cellular sheets or masses, there is no appreciable surface tension of the kind found on liquid droplets (except in the lung where there is a moist air-tissue interface). In cellular sheets, the connection of the cytoskeletons of neighboring cells via desmosomes allows stress to be transmitted from cell to cell. Then the contractile mechanism (actin-myosin) within each cell can produce a tension in a sheet of cells, which on the macroscopic scale acts like a surface tension.

The contractile stress in a sheet of cells can give rise to a bending moment and curvature of the sheet if the plane in which the tension acts is not at the mid-depth of the sheet. A cortical tension in the outer half of an epithelial cell layer can give rise to a tendency for invagination as in gastrulation.

Differentials in adhesiveness between various parts of a sheet of cells can give rise to differential stretching in the plane of the sheet. Anisotropic tension fields can change the shape of cells involved. A compression in one direction may occur with elongation in the perpendicular direction. In this situation, another phenomenon may occur which is a rearrangement of cells by a change of neighbors. To illustrate the idea crudely, a square patch of 16 cells, oriented in 4 rows of 4 cells each, could be rearranged into two rows of 8 cells each. Such rearrangements occur during gastrulation and other morphogenetic events. This allows large changes in the form of a tissue without subjecting individual cells to the same degree of distortion.

4.2.2 Pattern Formation. Patterns of the structure and coloring of various organs come about through the interactive behavior of individual cells. Any information that leads a cell to perform an appropriate differentiation or pattern is called positional information. Tracking of cell groups from embryo to birth indicates that positional information is available early in development and is retained to much later stages.

Positional information is already present in the fertilized egg in the frog because it is not a uniform sphere, but has a yolk displaced from the center toward one pole which ultimately becomes the tail of the embryo. After gastrulation, further positional information is somehow recorded so that appropriate areas develop the forelimbs and hindlimbs and, internally, the various organs, glands, and circulatory and nervous systems.

One theory of the nature of positional information involves concentration gradients of a trigger or control substance called a morphogen. If such a substance is generated in one area, say in the head, and it is distributed through the embryo by diffusion, then positional information can be derived from the concentration of the morphogen at some time in the life of a cell. It appears that once positional information assignment is given to a group of cells, they retain the memory of their position indefinitely and develop into the appropriate type, size, and arrangement of cells. By transplanting parts of a wing bud, the local imprinting of developmental history is shown to be associated with the transplanted cells, rather than the local area to which they are transplanted (see Connelly *et al.*, 1981).

The existence of positional information and memory of it is quite clearly established, but the identification of the nature of the positional information and the manner of its interpretation is not yet entirely deciphered. For the limbs of the chick embryo, retinoic acid has been identified as a morphogen. But in most cases, the substance or nature of the positional signal is not clear. Similarly, it is clear that there must be a role for the expression of the genetic code in the recording and interpretation of positional information. It appears likely that positional information involves interpretation of the genetic code in such aspects as what parts or products should be suppressed and which parts should be utilized or expressed. The choice of the part or state of the genetic code interpretation is a likely form of cell memory of its positional information. But these details are not precisely known.

An interesting aspect of the use of positional information is a concept of successive refinement or local differentiation developed as positional information is utilized. Thus, as a limb bud grows, it develops fingers in the correct numbers and positions based on local relative positional information. In lower forms which reproduce limbs readily, a principle of intercalation has been suggested, which is that development proceeds so as to make positional values continuous. This provides local control to produce preset arrangements and sizes. In this way it is possible for a cell, by communication with its immediate neighbors, to perform the correct differentiation or tissue production to make the whole animal in all its complex parts follow a preset plan. In recent literature, various growth patterns have been analyzed by comparison to idealized fractal forms (see Ishizaka *et al.*, 1987). But the direct link of the genetic code to fractal instructions is not yet entirely clear.

In many cases, the results of interpretation of the genetic information depend on external factors being present. To begin with, water and nutrients must be available, but stresses due to gravity, muscles, and visual and audible signals all influence development. Thus both genetic and epigenetic (environmental) influences are necessary for normal development. Although the end results are attributable to individual cell behavior, theories of morphogenesis are usually based on continuum field theories and phenomenological equations. An extensive exposition and discussion of pattern formation, in both space and time, as controlled by reaction-diffusion equations is given in the book by Murray (1989).

GLOSSARY

Actin: A type of fiber found in most cells. One of the two principal components of muscle.

ATP: Adenosine triphosphate.

Axoneme: A tubular cylindrical structure which is the main element of flagella and cilia.

Blastula: An early stage of embryonic development consisting of a spherical mass of cells enclosed in an ectodermal layer.

Centrosomes: Small specialized structures in a cell from which microtubules extend.

Contractile Ring: A band of actin-myosin which girdles a cell and divides it by contracting.

Cytokinesis: The stage of cell division in which the parent cell is cleaved in two.

Cytoskeleton: The fibrous, solid components of interior cell structure.

Desmosome: A specialized connecting spot between two cells which joins fibers from each cell for stress transmission.

Dynein: A large molecule capable of producing force and motion along microtubules.

Ectoderm: The specialized outer layer of cells in a developing embryo.

Epigenetic: Pertaining to factors external to an animal or embryo which influence its development.

Erythrocyte: A red blood cell.

Eucaryote: A cell with a separate nucleus as in mammalian cells.

Flagellum: The tail of a sperm or microorganism which undulates to propel it in swimming.

Flickering: A small local motion of the red blood cell membrane due to Brownian motion.

Gastrulation: A process of embryonic development in which a spherical blastula evolves a central tube (gut).

Intermediate Filament: A fiber found in most cells forming ropelike networks.

Kinesin: A large molecule capable of producing force and motion along microtubules.

Leukocyte: A white blood cell.

Metaphase: A phase of the process of cell division in which chromosomes are aligned on a central plane.

Microtubule: A hollow cylindrical fiber composed of tubulin, found in most cells.

Mitosis: The process of cell division.

Morphogen: A substance whose distribution imparts positional information to cells in an embryo.

Morphogenesis: The development of a characteristic form or structure of a growing body.

Myosin: An active molecule which develops contractile force in muscle and other cells.

Procaryote: A cell without a separate membrane-coated nucleus, as in bacteria.

Pseudopod: An extension of a cell in the form of a rod or sheet, actively protruded.

Rouleau: A stack of red blood cells.

Stress Fibers: Strands of actin in cells or their extensions.

Treadmilling: A molecular motion in which molecules are added to one end of a fiber while they are removed from the other end.

Vesicle: A small, circular, membrane-covered particle (~ 60-nm diameter).

INTRODUCTION

Ceramic materials are the source of some of our most ancient cultural artifacts as well as some of the most advanced technologies of the late 20th century (Kingery and Lense, 1985). Ceramics are traditionally defined as the products of firing nonmetallic minerals at high temperatures. In the field of materials science and engineering, these ceramic products are often defined by what they are not, viz., a ceramic is a nonmetallic, inorganic solid material. This latter definition distinguishes the ceramic from metals or polymers, the other two basic categories of engineered materials. A brief overview of ceramic science and technology will be followed by a systematic discussion of the various categories of these important materials.

1. CERAMIC SCIENCE AND TECHNOLOGY

The scientific foundation of ceramic technology is widely considered to have been most effectively outlined by Kingery (1960). This classic treatment was updated and expanded by Kingery, Bowen, and Uhlmann (1976). The nature of ceramic materials can be initially appreciated by considering a typical oxide, such as Al_2O_3. As an oxide compound of metallic aluminum, the ceramic has two principal advantages, viz., chemical stability in a wide variety of severe environments and a significantly higher melting point than the unoxidized metal (2020 °C compared to 660 °C). As such, Al_2O_3 is a widely used refractory, i.e., a high-temperature-resistant material. The superior chemical and temperature-resistant properties of ceramics are countered by tra-

ditionally inferior mechanical behavior, especially a characteristic brittleness. Structural applications of ceramics have been severely limited as a result. Substantial progress has been made, however, in the past two decades in producing ceramic materials with increased strength and resistance to fracture. In Sec. 4.1.3, the important concept of fracture toughness will be introduced as a central parameter in the expanded role of structural ceramics. Perhaps the most celebrated development in this area has been the research on candidate materials for the "ceramic engine," in which adequate mechanical properties are available to permit metal replacement in the design of an automotive power plant. In this configuration, the inherent temperature resistance of the ceramics allows significantly higher engine operating temperatures and correspondingly higher Carnot efficiencies. In Sec. 3.2, the advances in ceramic-powder processing technology necessary to produce this new generation of structural materials will be briefly reviewed.

An important feature of many ceramic materials, especially the silicates, is an ability to be formed easily in a noncrystalline state. The resulting vitreous or glassy materials are the subject of separate articles in the *Encyclopedia* and will not, in general, be discussed here. An exception will be the glass–ceramics, a relatively new family of ceramic materials in which the product shape is formed in the glassy state and is then devitrified or crystallized by an appropriate thermal treatment. Relatively complex product shapes are possible due to the glass-phase forming step, and good mechanical properties result from the fine-grained, low-porosity microstructure produced by the devitrification step. Excellent thermal shock resistance is produced by the use of low-thermal-expansion coefficient compositions, e.g., lithium aluminosilicates.

As with traditional silicate glasses, many crystalline ceramics have applications based on light transmission. This and other optical properties will be discussed in Sec. 5. Ceramic materials also have numerous, traditional applications based on their electronic and magnetic properties. Ionic and covalent bonding produces characteristically low electrical conductivity in traditional ceramics and resulting applications as dielectrics. Various ceramic compositions have commercially important magnetic behavior (see MAGNETIC MATERIALS). The ferrites are common examples. Perhaps no more dramatic development has occurred in applied physics during the past decade than the discovery of superconducting behavior in certain oxide ceramics (Strongin *et al.*, 1987) (see HIGH-TEMPERATURE SUPERCONDUCTIVITY). These "high-temperature" superconductors raise the possibility of significantly new technologies based largely on their associated magnetic behavior. Thin-film devices appear to be the most likely initial area of development. These recent advances will be discussed in Secs. 6 and 7, along with more traditional electrical and magnetic properties.

2. CATEGORIES OF CERAMIC MATERIALS

Ceramic materials can be conveniently categorized by chemical composition and atomic- and microscopic-scale structure. The first three categories are chemical in nature, with the last two based on structure.

2.1 Silicate Ceramics

Silicon and oxygen together account for approximately 75% of the elemental composition of the Earth's crust. As a result, the SiO_2-based silicates are abundant and economical raw materials. Many of the traditional ceramics fall within this category. Pottery and related whiteware ceramics have been commercial products since roughly 4000 B.C. Common brick, tile, and sewer pipe constitute the structural clay products. This wide range of silicate ceramics reflects the diversity of the silicate minerals available to local manufacturing plants. Table 1 summarizes the general compositions of typical silicate ceramics.

2.2 Nonsilicate Oxide Ceramics

Table 2 gives examples of various nonsilicate oxide ceramics. Magnesia (MgO) is a traditional refractory material widely used in the steel industry. Many of the nonsilicate oxides, however, are among the more advanced structural ceramics. Many are commercially available as essentially single-compound compositions, although impurity levels can range from a few parts per million (ppm) for so-called "advanced ceramics" or "fine ceramics" to several weight percent in the

Table 1. Compositions of some silicate ceramics.

Ceramic	Composition[a] (wt %) SiO_2	Al_2O_3	K_2O	MgO	CaO	Others
Silica refractory	96					4
Fire-clay refractory	50–70	45–25				5
Mullite refractory	28	72				...
Electrical porcelain	61	32	6			1
Steatite porcelain	64	5		30		1
Portland cement	25	9			64	2

[a] Approximate, indicating primary components. Impurity levels can vary significantly.

industrial refractories. (Although both are commonly used, the term "advanced ceramics" is gaining wider favor than "fine ceramics" to label these contemporary materials.) Chemical separation and subsequent processing to produce relatively high-purity advanced ceramics results in a substantially more costly product compared to the silicate ceramics made from locally available and generally impure minerals. It is useful to note that even the advanced ceramics are sometimes referred to by traditional mineral names, e.g., "corundum" for Al_2O_3.

Table 2. Some nonsilicate oxide ceramics.

Primary composition[a]	Common product names
Al_2O_3	Alumina, alumina refractory
MgO	Magnesia, magnesia refractory, magnesite refractory, periclase refractory
$MgAl_2O_4$ (= $MgO \cdot Al_2O_3$)	Spinel
BeO	Beryllia
ThO_2	Thoria
UO_2	Uranium dioxide
ZrO_2 (stabilized[b] with CaO)	Stabilized (or partially stabilized) zirconia
$BaTiO_3$	Barium titanate
$NiFe_2O_4$	Nickel ferrite

[a] Some products, such as the industrial refractories, may have several weight percent oxide additions and impurities.

[b] Pure ZrO_2 has a phase transformation at 1000 °C in which the crystal structure change produces a catastrophic volume change. A 10-wt % CaO addition produces a cubic crystal structure stable to the melting point (~2500 °C), making "stabilized" zirconia a highly useful refractory. Lesser CaO additions can produce a two-phase microstructure, with cubic zironica being one of the phases. This "partially stabilized" zirconia has superior fracture toughness (Sec. 4.1.3).

2.3 Nonoxide Ceramics

Some nonoxide ceramics, such as silicon carbide, have been common industrial materials for several decades (Hampshire, 1986). SiC is widely used as a furnace-heating element and as an abrasive material. Other nonoxide ceramics, such as silicon nitride, have been the focus of substantial research and development in the past two decades as candidates for advanced structural ceramics. As with the use of mineral names mentioned in the preceding section, commercial names are sometimes used to identify these materials, e.g., "carborundum" for SiC. Table 3 lists various examples of nonoxide ceramics.

2.4 Glass–Ceramics

Glass–ceramics were among the early advanced ceramics (McMillan, 1979). As the name implies, they begin as relatively ordinary glassware (see GLASSES), and, by a care-

Table 3. Some nonoxide ceramics.

Primary composition[a]	Common product names
SiC	Silicon carbide
Si_3N_4	Silicon nitride
TiC	Titanium carbide
TaC	Tantalum carbide
WC	Tungsten carbide
B_4C	Boron carbide
BN	Boron nitride
C	Graphite

[a] Some products may have several weight percent additions or impurities.

Table 4. Compositions of some glass–ceramics.

Glass–Ceramic	Composition (wt %)							
	SiO_2	Li_2O	Al_2O_3	MgO	ZnO	B_2O_3	TiO_2 [a]	P_2O_5 [a]
Li_2O-Al_2O_3-SiO_2 system	74	4	16				6	
MgO-Al_2O_3-SiO_2 system	65		19	9			7	
Li_2O-MgO-SiO_2 system	73	11		7		6		3
Li_2O-ZnO-SiO_2 system	58	23			16			3

[a] Nucleating agents.

fully controlled heat treatment, over 90% of the material crystallizes. The average crystallite grain size is characteristically between 0.1 and 1 μm. A small amount of residual glassy phase remains at the grain boundaries, helping to create a pore-free microstructure. As will be seen in Sec. 4.1, this typical glass–ceramic microstructure lends itself to superior mechanical impact resistance. The characteristic compositions of typical glass–ceramics shown in Table 4 are associated with low-thermal-expansion-coefficient materials and resulting superior thermal shock resistance, a topic discussed further in Sec. 4.4.

The benefits of the uniformly fine-grained microstructures of glass–ceramics can be ascribed indirectly to the compositions in Table 4. One should note that TiO_2 and P_2O_5 are nucleating agents. A fine dispersion of these components provides a high density of heterogeneous nucleation sites for the glass devitrification process.

The most important commercial glass–ceramic system in Table 4 is the Li_2O-Al_2O_3-SiO_2 system. The low thermal expansion coefficient is produced by the presence of crystallites of β-spodumene ($Li_2O \cdot Al_2O_3 \cdot 4SiO_2$) with a small expansion coefficient; or β-eucryptite ($Li_2O \cdot Al_2O_3 \cdot SiO_2$), which actually has a negative expansion coefficient.

2.5 Ceramic Composite Systems

Ceramic composites can be subdivided into two categories, viz., traditional cermets, in which ceramic and metallic phases are dispersed on the microscopic scale, and the relatively recent development of ceramic–matrix composites (CMCs), in which various dispersed phases are used to improve the mechanical behavior of structural ceramic materials.

2.5.1 Cermets. Ceramic–metal composite systems, known as cermets, became the source of intense research during and just following World War II for the purpose of developing materials incorporating the most desirable characteristics of both ceramics and metals (Tinklepaugh and Crandall, 1960). A special focus was the substitution for critical alloys in aircraft engines. Although largely unsuccessful for that purpose, the general combination of ceramic and metallic components on a microstructural scale has been the basis of numerous, useful materials for cutting tools, nuclear fuels, and electronic devices (Upadhyaya, 1984). Some typical cermets are listed in Table 5.

2.5.2 Ceramic–Matrix Composites. Ceramic–matrix composites (CMCs) are relatively recent developments in the area of advanced materials (see COMPOSITE MATERIALS). A primary driving force for their development is superior high-temperature resistance, e.g., high-efficiency engine designs (Lemkey *et al.*, 1988). Some typical ceramic–matrix composite systems are given in Table 6. As will be discussed in Sec. 4.1.3, a key focus of research on CMCs is their potential for improved fracture toughness. CMCs fall into two categories: fiber-reinforced and particulate- and whisker-containing. The fiber-reinforced configuration

represents a more challenging processing technology, but with the possibility of non-catastrophic failure if mechanical behavior is fiber-dominated. (In regard to the mechanical failure of engineered materials, the term "catastrophic" implies rapid failure without significant prior warning. In the case of fiber-reinforced CMCs, fiber pull-out is a time-consuming mechanism that provides this prior warning.) To date, the mechanical advantages of fiber-reinforced CMCs have been limited to relatively low-temperature applications. Particulate and whisker CMCs are easier to process but tend to fail catastrophically by a matrix-controlled mechanism. It is useful to note that many properties of composite systems can be described as averages of the properties of the individual component phases. It is equally important to note, however, that the specific nature of the "average" is a sensitive function of the microstructural geometry of the composite and the nature of the fiber–matrix interface. The interfacial issue is discussed further in Sec. 4.1.3.

3. CERAMIC PROCESSING

As noted at the outset, ceramic materials represent some of our most ancient as well as some of our most advanced materials. As a result, this discussion of ceramic processing will be divided into a section dealing with traditional methods and another dealing with recent technologies needed to develop the more modern materials. It is important to appreciate that such a discussion is due to the general effect of processing on materials properties. For example, properties as diverse as both mechanical strength and optical transparency can be seriously degraded by residual porosity, a common feature of traditional ceramic products.

3.1 Traditional Methods

Ceramic processing is both an ancient art and a relatively young applied science (Reed, 1988). The processing technology for ceramic materials is generally affected by the combined characteristics of mechanical brittleness and relatively high melting points. For example, fusion casting is similar to metal casting but is limited in application by high melting points. Some low-porosity refractories are formed in this way, but at a relatively high cost. More common for traditional clayware ceramics is slip casting. This room-temperature casting involves a "slip," or clay–water mixture poured into a porous mold. Water absorption by the mold produces a relatively rigid powder that can be removed from the mold. After a drying step in which the remaining absorbed water is driven off at moderate temperatures, a structurally viable product is produced by firing at elevated temperatures (typically above 1000 °C). Much of the strength of the fired piece is due to solid-state diffusion. Various phase transformations can also accompany the firing step, especially the production of glassy phases in many silicates. Sintering, defined as the bonding of powder particles by solid-state diffusion, is a component of the firing step following slip casting. The production of many nonsilicate oxide ceramics and nonoxide ceramics is done directly by the sintering of a pressed powder compact. The typically high melting points of these materials make sintering a widespread processing technique.

3.2 Recent Advances

Hot pressing is basically sintering under an applied mechanical load. Similarly, hot isostatic pressing (or "HIPing") is sintering under an applied, isostatic pressure from an inert gas. These technologies are increasingly popular for advanced ceramics, especially in providing fully dense products with superior mechanical properties. Sol–gel processing is among the most rapidly developing technologies for ceramic processing. The method provides the formation of uniform, fine particulates of high purity at relatively low temperatures. Such powders can subsequently be sintered to high density with correspondingly good mechanical properties. The essential feature is the formation of an organometallic solution. The dispersed-phase "sol" is then converted into a rigid "gel" which, in turn, is reduced to a final composition by various thermal treatments. In chemical-vapor deposition (see CVD), a source material is vaporized and thermally decomposed or reacted with a gas or vapor phase to produce a reaction product deposited onto a substrate. The CVD process corresponds to a molecular-scale buildup of a thin-film configuration. It has the capability of forming high-density, uniform films on complex-shaped surfaces. Substantial work is being done on the development of a wide variety of novel processing techniques for ceramic materials. As an example, self-propagating high-temperature synthesis (SHS) uses a highly exothermic energy of reaction to produce the necessary sintering temperature for the final ceramic product (Munir, 1988). Once initiated, a combustion wave can pass through a powder, providing both a chemical reaction and the densification of the compact. A simple example is the formation of titanium nitride by the reaction between titanium powder and nitrogen gas.

4. MECHANICAL PROPERTIES

The various mechanical properties discussed in this section are not an exhaustive listing but do represent the major factors in selecting a durable material for structural applications under a variety of service conditions.

4.1 Brittle Fracture

Perhaps the most distinctive characteristic of traditional ceramics is their tendency to exhibit brittle fracture (Evans, 1984). Such failure with the absence of significant ductility has represented a primary obstacle to be overcome in the application of the newer structural ceramics. In the sections that follow, the specific discussion of fracture is preceded by treatment of the elastic constants associated with the deformation prior to failure. The discussion of fracture strength is followed by the equally important topic of fracture toughness, the key property associated with the resistance of the material to flaw-induced failure (Ashby and Jones, 1980). This important factor in the application of structural ceramics comes from the general subject of fracture mechanics.

4.1.1 Elastic Constants. Unlike the cases for relatively ductile metals and polymers, the deformation of ceramics is generally elastic in nature up to the point of fracture. The mechanical behavior of a structural ceramic in this regime can be adequately characterized by two elastic constants, the elastic (or Young's) modulus and Poisson's ratio. The linear relationship between the applied stress σ and the resulting strain ϵ is given by Hooke's law:

$$\sigma = E\epsilon, \tag{1}$$

where E is the elastic (or Young's) modulus. Values of the modulus of elasticity for a variety of ceramics are given in Table 7. Poisson's ratio ν is defined as the negative of the contraction perpendicular to the extension caused by a tensile stress. Specifically,

$$\nu = -\epsilon_x/\epsilon_z, \tag{2}$$

where the strain in the x direction is perpendicular to that in the z direction, the direction of the tensile stress. Values of Poisson's ratio are given in Table 7.

4.1.2 Fracture Strength. The fracture strength can be defined simply as the tensile stress value at which fracture suddenly occurs following the elastic deformation of the ceramic. As a practical matter, a more reproducible fracture strength is obtained in a bending mode than in pure tension. For simple three-point bending, the flexural strength, FS (or modulus of rupture, MOR) is given by

$$\mathrm{FS} = \mathrm{MOR} = 3FL/(2bh^2), \tag{3}$$

where F is the force applied to a rectangular-bar-shaped specimen, L the separation distance between the two lower supports (each of which provides a reaction force, $F/2$), b the width of the specimen, and h the height. Typical values of FS or MOR are given in Table 8.

Table 7. Modulus of elasticity and Poisson's ratio for some ceramics.

	E (MPa)	v

Bonded silicon carbide (~20% porosity)	340×10^3	
Hot-pressed boron carbide (~5% porosity)	290×10^3	
Hot-pressed boron nitride (~5% porosity)	83×10^3	

Source: Kingery, Bowen, and Uhlmann (1976), and data from Smothers (1985, 1986).

The magnitudes of the values in Table 8 correspond to those for tensile strength, as the failure mode in bending is tensile (along the outermost edge of the sample opposite the applied force). It is important to note that, for ceramics, the magnitude of fracture strength in a compressive mode is often substantially higher than in tension. Differences as much as an order of magnitude can be appreciated from the simple Griffith crack model. Assuming the presence of elliptical cracks at the surface and/or in the interior of the material, the Griffith model predicts the amount of stress concentration at a given crack tip to be

$$\sigma_m/\sigma \cong 2(c/\rho)^{1/2}, \qquad (4)$$

where σ_m is the highest stress at the tip of such a crack, σ the applied tensile stress, c the crack length, and ρ the radius of the crack tip. As the crack tip radius can be on the order of an interatomic spacing, the stress intensification can be quite large. A compressive load tends to close, not open, the Griffith flaws and consequently does not diminish the inherent strength of the material.

4.1.3 Fracture Mechanics. The term *fracture mechanics* refers to the general analysis

of failure of structural materials with preexisting flaws. The most widely used single parameter from this field is the fracture toughness K_{IC}, the critical value of the stress–intensity factor at a crack tip necessary to produce catastrophic failure. In general, the value of fracture toughness is given by

$$K_{IC}=Y\sigma_f(\pi a)^{1/2}, \qquad (5)$$

where Y is a dimensionless geometry factor on the order of 1, σ_f is the overall applied stress at failure, and a is the length of a surface crack (or one-half the length of an internal crack). It should be noted that K_{IC} is associated with plane-strain conditions, and that the subscript I refers to "mode I" (or uniaxial tensile) loading and the subscript C to critical (or catastrophic) failure. The similarity to the Griffith crack model equation is obvious. The fracture-toughness expression of Eq. (5) is, however, not limited to purely brittle materials. In fact, one of the primary uses of fracture-toughness data for structural ceramics is the comparison with values for the common structural metals. Typical values of fracture toughness for a variety of ceramic materials are given in Table 9.

One should note that, for traditional ceramics, K_{IC} is typically ≤ 5 MPa $m^{1/2}$. In contrast to these relatively low values, typical aluminum alloys have K_{IC} values of between 25 and 45 MPa $m^{1/2}$ and pressure-vessel steels have values on the order of 170 MPa $m^{1/2}$. Values of 5 MPa $m^{1/2}$ for Al_2O_3 and Si_3N_4 are associated with careful processing, e.g., the elimination of residual porosity by hot pressing or hot isostatic pressing. Such resulting fracture toughness values represent substantial improvement over the values of ≤ 1 MPa $m^{1/2}$ for many conventionally sintered ceramics.

In order to make structural ceramics more competitive for applications traditionally dominated by metallic materials, K_{IC} values greater than 5 MPa $m^{1/2}$ are needed. One technique has involved the purposeful introduction of microcracks which serve the purpose of blunting the tip of an advancing crack. The Griffith expression [Eq. (4)] indicates that the larger effective tip radius dramatically reduces the local stress at the crack tip. The value of 9 MPa $m^{1/2}$ for partially stabilized zirconia (PSZ) in Table 9 is due to another microstructural mechanism known as transformation toughening and illustrated in Fig. 1. In this case, improved toughness is due to second-phase particles of tetragonal zirconia in a matrix of cubic zirconia. A propagating crack creates a local stress field that induces a transformation of tetragonal zirconia particles to the monoclinic structure in that vicinity. The slightly larger specific volume of the monoclinic phase causes an effective compressive load locally and, in turn, the "squeezing" of the crack shut.

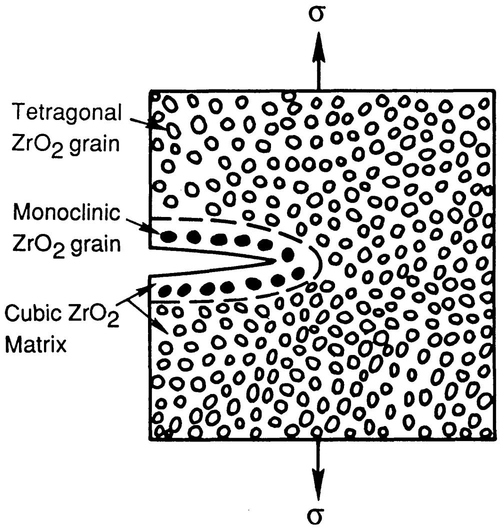

FIG. 1. Transformation toughening of partially stabilized zirconia (PSZ) involves the stress-induced transformation of tetragonal grains to the monoclinic structure, which has a larger specific volume. The result is a local volume expansion at the crack tip, squeezing the crack shut.

As noted in Sec. 2.5.2, many of the material properties of composite systems can be predicted as averages of the properties of the individual components (see COMPOSITE MATERIALS). For this property averaging to be in effect, however, the dispersed and matrix phases must be adequately bonded together. For example, the interface between the matrix and a discontinuous fiber-reinforcing phase must be strong enough to transmit a mechanical load from one phase to the other. In ductile–matrix composites, a high interfacial strength is desirable to maximize the overall composite strength, as failure generally originates in or along the reinforcing fibers. In ceramic–matrix composites, however, failure generally originates in the matrix phase. In order to maximize the fracture toughness of these materials, it is desirable to have a relatively weak interfacial bond allowing fibers to pull out. A crack initiated in the matrix can then be deflected along the fiber–matrix interface. Figure 2 illustrates the mechanism of fiber pull-out for improving fracture toughness. As can be seen in Table 9, some of the fiber-reinforced ceramic–matrix composites have fracture-toughness values approaching those of some conventional metallic alloys.

4.2 Static Fatigue

Analogous to the "fatigue" of metals (loss of strength over time due to cyclic loading), ceramics can display a loss of strength over time but without cyclic loading. This static fatigue is the result of crack growth due to chemical reaction with the environment. The classic example is crack extension in silicates by the breaking of Si–O bonds by reaction with H_2O molecules from atmospheric moisture. The mechanism involving reaction with atmospheric moisture confines this effect to the vicinity of room temperature.

4.3 Creep Deformation

Creep can be defined as plastic deformation occurring at a relatively high temperature (above about one-half the absolute melting point) under constant load over a long time period (see RHEOLOGY). A schematic creep curve is shown in Fig. 3. After the initial elastic deformation at $t \cong 0$, there are three stages of creep deformation: the primary stage characterized by a decreasing strain rate, the secondary stage corresponding to a constant strain rate, and the final (tertiary) stage in which the strain rate increases. The secondary-stage (steady-state) strain rate is a useful parameter to characterize the overall creep behavior of the ceramic and represents a balance between the increased ductility mechanisms of the primary stage and the increased resistance to deformation in the tertiary stage.

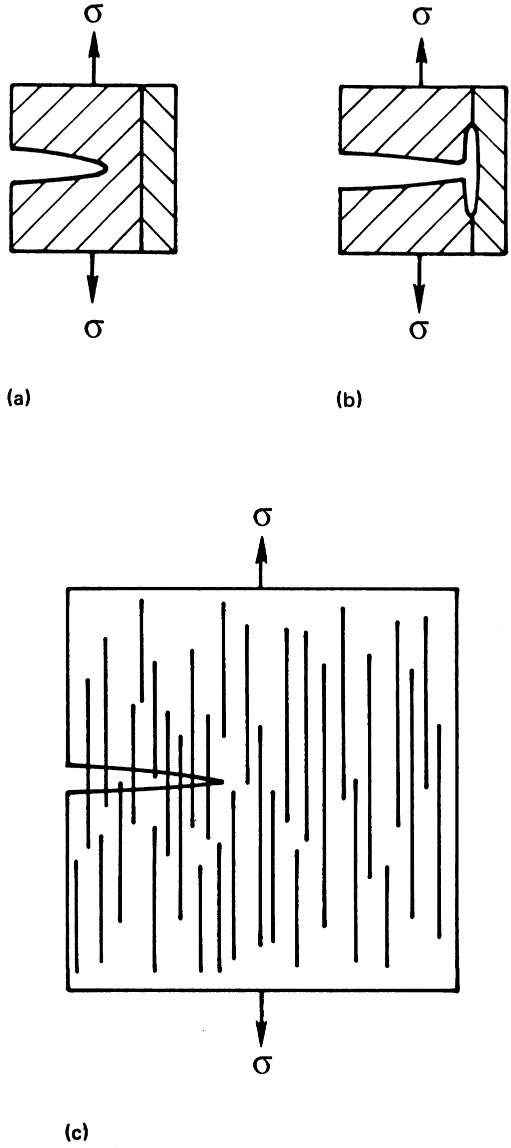

FIG. 2. For a close-up view of a ceramic-matrix composite, (a) a matrix crack approaching a fiber is (b) deflected along the fiber-matrix interface. For the overall composite, (c) the increased crack path length due to fiber pull-out significantly improves fracture toughness.

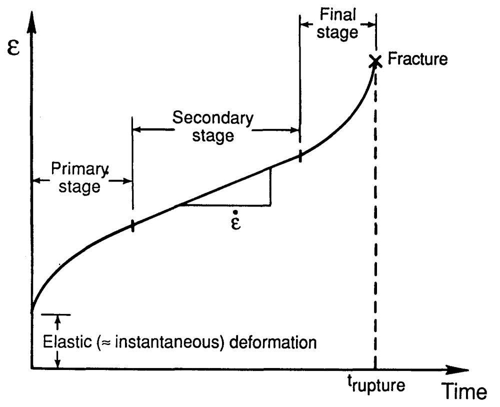

FIG. 3. Creep curve indicating the plastic strain occurring over time for a ceramic stressed at high temperatures (above about one-half the absolute melting point).

Another key parameter for characterizing creep behavior is the overall time to creep rupture.

Diffusional mechanisms (e.g., dislocation climb) are often less important in the creep deformation of ceramics than in metals, largely because of the greater complexity of diffusion in ceramic compounds. As a result, grain-boundary sliding (see GRAIN BOUNDARIES) frequently plays a dominant role in the creep of ceramics. In some relatively impure refractory ceramics, a substantial silicate glassy phase may form at the grain boundary, allowing for a creep mechanism of grain-boundary sliding by viscous deformation of the glassy phase. Such deformation is generally undesirable for a material intended for high-temperature structural applications.

The general dependence of the steady-state creep rate ($\dot{\epsilon}$) on both stress (σ) and absolute temperature (T) can be expressed as

$$\dot{\epsilon}=C\sigma^{n}e^{-Q/RT}, \qquad (6)$$

where C is a constant, n a constant typically between 3 and 8, Q the activation energy for the creep deformation mechanism, and R the universal gas constant. The preexponential term in Eq. (6) is essentially temperature independent, and the presence of the σ^n term gives the name "power-law" creep to the overall expression. Creep-rate data for some common ceramics at a fixed temperature are given in Table 10.

4.4 Thermal Shock

The routine use of structural ceramics at elevated temperatures in combination with inherent brittleness creates special concern about thermal shock, defined as fracture (partial or complete) as a result of a temperature change (usually sudden cooling). The mechanism of thermal shock involves two more fundamental thermal properties:

1. thermal expansion and
2. thermal conductivity.

The linear coefficient of thermal expansion α is given by

$$\alpha=(1/L)dL/dT, \qquad (7)$$

with L being specimen length and T temperature. The thermal conductivity k is defined by Fourier's law of heat conduction:

$$k=-\frac{dQ/dt}{A(dT/dx)}, \qquad (8)$$

where dQ/dT is the rate of heat transfer across an area A due to a temperature gradient dT/dx. Thermal expansion and thermal conductivity data for various ceramics are given in Table 11.

Figure 4 illustrates schematically a common mechanism of thermal shock for structural ceramics. The rapid cooling of the surface of a slab of material initially at an elevated temperature leads to surface tensile stresses. With the inevitable presence of Griffith flaws at the surface, this surface tensile stress creates the potential for brittle fracture.

The ability of a given structural ceramic to withstand a given temperature change depends on a complex combination of thermal expansion, thermal conductivity, overall geometry, and the inherent brittleness of the material.

4.5 Viscoelastic Deformation of Glassy Phases

As noted in the discussion of creep deformation, glassy grain-boundary phases in otherwise crystalline ceramics can play a critical role in mechanical behavior (Shackelford, 1987). A key parameter in describing the mechanical deformation of a glassy phase is the glass transition temperature T_g, defined as the temperature below which the material tends to behave as a true glass (a rigid solid) and above which the material tends to behave as a supercooled liquid (see GLASSES). Below T_g, the glass exhibits elastic deformation, and above T_g, the supercooled liquid exhibits viscous deformation. It should be noted that, unlike the melting point, T_g represents a narrow transition temperature range rather than a single temperature.

There are two viscosity levels that are used to define characteristic temperatures in the viscous deformation range in traditional glass-making technology. These can be useful reference points for determining the deformation behavior of a secondary glassy phase. The annealing point is the temperature at which the viscosity is equal to $10^{13.4}$ P, where P stands for the unit poise [$=1$ g/(cm s) $=0.1$ Pa s]. The practical significance of the annealing point is that internal stresses can be relieved in about 15 min at this viscosity level. The glass transition temperature occurs around the annealing point. The softening point is the

temperature at which the viscosity is equal to $10^{7.6}$ P, a value at which the material is easily deformable. Commercial glass compositions are formed into product shapes in a viscosity range near this point. The annealing point represents a temperature at which a glassy phase can begin to have a deleterious effect on the mechanical behavior of a structural ceramic, and the softening point represents a temperature at which the mechanical behavior can be seriously degraded. Table 12 gives values of the annealing point and softening point for various glassy phase compositions.

5. OPTICAL PROPERTIES

Traditional ceramic products, such as the pottery and whitewares of Sec. 2.1, are classic examples of opaque materials. It is important to note, however, that on an atomic scale these materials are often inherently transparent. Their opacity is the result of light scattering mechanisms associated with microscopic-scale structure. Following a discussion of refraction and reflection in microstructurally transparent materials, the mechanism of opacity in porous materials will be described. It is important to note that many applications of structural ceramics depend upon their optical properties, specifically their ability to refract, reflect, or transmit visible light (Kingery, Bowen, and Uhlmann, 1976). Although we may associate traditional ceramics with opacity, optical transmission is possible by the elimination of light-scattering porosity. The transparency of contemporary window glass results from the absence of such porosity. Both ceramic and glass materials are inherently good transmitters of visible light. The degree of transmission is a microstructural issue. Many of the advances in ceramic processing described in Sec. 3.2 have been driven by the superior optical quality derived from fine-grained, pore-free microstructures.

5.1 Refraction

The refraction of light by a transmitting ceramic is given by the refractive index n, equal to the ratio of the speed of light in vacuum to that in the transmitting medium. Table 13 gives values of n for typical ceramics and glassy phases. One may note that typical values are in the vicinity of 1.5 to 2.0.

5.2 Reflection

The technological importance of reflection involves two factors:

1. the fraction of light reflected at the ceramic surface and
2. the nature of the reflection in relation to the average surface topography.

The fraction of light reflected at a ceramic surface is given by the reflectance R and is a simple function of the index of refraction by Fresnel's formula (see ELECTROMAGNETIC RADIATION; ELECTROMAGNETIC WAVE PROPAGATION):

$$R=\left(\frac{n-1}{n+1}\right)^2 . \tag{9}$$

Eq. (9) is strictly valid for normal incidence but is a good approximation over a range of incidence angles. Clearly, Eq. (9) indicates that high-n materials are of high reflectivity or "glossy" in appearance.

Table 13. Refractive index for various ceramics.

Materials	Average refractive index
Quartz (SiO_2)	1.55
Mullite ($3Al_2O_3 \cdot 2SiO_2$)	1.64

Incident light
Specular reflection
Diffuse reflection
Average surface
True surface topography

FIG. 5. Specular reflection occurs relative to the "average" surface, and diffuse reflection occurs relative to locally nonparallel surface elements.

The general appearance of a given material is strongly affected by the relative amounts of specular reflection (defined as reflection relative to the "average" surface) and diffuse reflection (defined as relative to local surface irregularity). Figure 5 illustrates schematically these two types of reflection. Microscopically smooth surfaces tend to provide a high degree of specular reflection (another contributor to "glossy" appearance) and "rough" surfaces tend to provide a high degree of diffuse reflection.

5.3 Transmission

As discussed in the two preceeding sections, the overall quality of the optical behavior of a given ceramic depends upon the combination of reflection and refraction of light, as summarized in Fig. 6. The angle of reflection equals the angle of incidence θ_i, and the angle of refraction θ_r is related to the angle of incidence by the index of refraction, i.e.,

$$n = (\sin\theta_i)/(\sin\theta_r). \tag{10}$$

In general, the refraction of light on the microscopic scale leads to the scattering of light and a loss of image transmission quality, as indicated in Fig. 7, which illustrates how scattering can occur at a single pore. Transparency can be defined as the ability to transmit a clear image in a pore-free material. Translucency means that a diffuse image is transmitted, and opacity means total loss of image transmission.

In addition to the scattering effects described above, color is an important optical property based on a true absorption mechanism, viz., the selective absorption of certain wavelength ranges within the visible spectrum due to electron transitions in transition-

metal ions. The transmitted color is the resulting combination of the wavelength ranges not absorbed. Colors provided by various metal ions are summarized in Table 14.

6. ELECTRICAL PROPERTIES

Until 1986, a discussion of the electrical properties of ceramics primarily involved characteristic insulating behavior and related dielectric properties (Kingery, Bowen, and Uhlmann, 1976). Since that time, the discussion necessarily includes the superconducting behavior of a select family of oxides (Strongin *et al.*, 1987).

6.1 Conductivity of Traditional Ceramics

In general, the electrical conductivity (see INSULATORS AND SEMICONDUCTORS, CONDUCTIVITY IN), σ, of any material is the sum of the contributions of both negative and positive charge carriers, viz.,

$$\sigma = n_n q_n \mu_n + n_p q_p \mu_p, \tag{11}$$

where n is the density of charge carriers, q the charge carried by each, and μ the carrier mobility. The subscripts n and p refer to negative and positive carriers, respectively. For typical ceramics, the conductivity can be due to electrons, electron holes, or ions. In any case, the magnitude of conductivity in these solids with typically strong ionic and covalent bond character is quite low, e.g., in the range of 10^{-10} to 10^{-13} Ω^{-1} m^{-1}. Exceptions to this rule of thumb include ZnO semiconducting "varistors" (providing overvoltage protection for sensitive equipment) and "fast-ion" conducting Naβ-Al_2O_3, a candidate for high-energy-density battery applications (Buchanan, 1986). The ultimate exception to the rule is given in the next section.

6.2. Superconducting Ceramics

For a select group of materials known as superconductors, the electrical resistivity drops to zero at a critical temperature T_c. The discovery in 1986 that a $(La,Ba)_2CuO_4$ ceramic exhibited a critical temperature T_c of 35 K (more than 10 K higher than the previous record for a Nb_3Ge alloy) stimulated an unprecedented interest in ceramic materials (Strongin *et al.*, 1987) (see HIGH-TEMPERATURE SUPERCONDUCTIVITY). In 1987, $YBa_2Cu_3O_7$ (the 1-2-3 superconductor, named after the ratio of cations) was found to have a T_c of 95 K, well above the temperature of liquid nitrogen (77 K). By 1988, a Tl-Ca-Ba-Cu-O ceramic was found that exhibited a T_c of 125 K. Considerable evidence has been found for superconducting behavior in limited regions of samples of other ceramic oxides at even higher temperatures. The possibility of a room-temperature superconductor is, of course, a source of considerable interest.

The mechanism for superconductivity in metals is well established, viz., the "Cooper pairs" of electrons of opposite spin. Although superconductivity in high-T_c superconductors also involves paired electrons, the nature of the conduction mechanism is not as well understood. Specifically, electron pairing does not seem to result from the same type of synchronization with lattice vibrations. What has become apparent is that copper–oxygen planes in the crystal structure are the pathways for the supercurrent. In the 1-2-3 superconductor, that current is carried by electron holes. Other ceramic oxides have been developed in which the current is carried by electrons, not holes.

In either case, the promise of superconductors produced by the dramatic increase in T_c has encountered an obstacle in the form of another important material property, viz., the critical current density, defined as the current flow at which the material stops being superconducting. Metallic superconductors used in applications such as magnets in large-scale particle accelerators have critical current densities on the order of 10^{10} A/m^2. Such magnitudes have been produced in thin films of ceramic superconductors, but bulk samples typically give values about one-hundreth that size. Unfortunately, the limitation in current density becomes more severe for increasing values of T_c. The diminished critical current density is caused by the penetration of the surrounding magnetic field into the material, creating an effective resistance due to the interaction between the current and mobile magnetic flux lines. The problem does not exist in metallic superconductors because the magnetic flux lines are not mobile at such low temperatures. Above the commercially important temperature of 77 K, the effect (known as "flux lattice melting") becomes significant and is increasingly so with further increases in temperature. As a practical consequence, T_c values above that of the 1-2-3 material may be of little benefit. Even for this material, immobilization of magnetic flux lines may require a thin-film configuration or some special form of microstructural control. (In general, a primary challenge in the commercial development of high-T_c superconductors is the fabrication of usable product shapes from the inherently brittle ceramics.)

As the applications of superconductors generally involve their magnetic behavior, a further discussion of these materials will be given in Sec. 7.2.

6.3 Dielectrics

A parallel-plate capacitor is composed of an insulator (dielectric) between two conducting electrodes (see DIELECTRIC PROPERTIES OF INSULATORS). The charge density D built up in the insulator is proportional to the electric field strength E, according to the relation

$$D=\epsilon_0 \kappa E, \tag{12}$$

where ϵ_0 is the electric permittivity of a vacuum and κ the dielectric constant, representing the factor by which the capacitance of the system is increased by inserting the dielectric in place of a vacuum. For a given dielectric, there is a limiting voltage gradient, termed the dielectric strength, at which an appreciable current flow (or "breakdown") occurs and the dielectric fails. Representative values of dielectric constant and dielectric strength for various ceramics are given in Table 15.

Table 15. Dielectric constant and dielectric strength for various ceramics.

Material	Dielectric constant[a] κ	Dielectric strength[b] (kV/mm)

6.4 Ferroelectrics and Piezoelectrics

The nature of ferroelectric and piezoelectric behavior in ceramics can be conveniently represented by barium titanate, $BaTiO_3$. Above 120 °C, $BaTiO_3$ has the cubic crystal structure of the mineral perovskite, $CaTiO_3$. Upon cooling below 120 °C, $BaTiO_3$ undergoes a phase transformation to a tetragonal modification, as shown in Fig. 8.

Below the critical temperature (T_c) of 120 °C, $BaTiO_3$ is ferroelectric. This behavior is directly related to the asymmetric nature of the tetragonal structure shown in Fig. 8(b). The offset between the overall center of positive charge for the cation distribution and the overall center of negative charge for the anion distribution amounts to a permanent electrical dipole in the tetragonal $BaTiO_3$ unit cell. This dipole structure allows for a large polarization of the material in response to an applied electrical field. The specific nature of the polarization (P)–electric field (E) relationship is shown in Fig. 9.

The origin for the P-E axis system (in which zero polarization occurs under zero applied field) corresponds to a balance of equal volumes of oppositely oriented domains in a random microstructure. The domains can be defined as microscopic-scale crystallite regions with substantial polarization corresponding to the crystal structure of Fig. 8(b). Under an applied field, unit-cell dipole orientations roughly parallel to the applied field direction

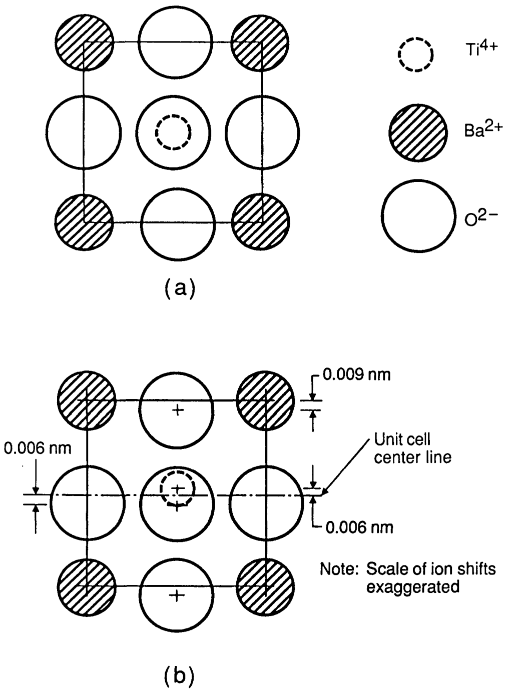

FIG. 8. (a) Front view of the cubic $BaTiO_3$ structure. (b) Below 120 °C, a tetragonal modification of the structure occurs. The net result is an upward shift of cations and a downward shift of anions.

are favored, and such orientations "grow" at the expense of other, less favorably oriented ones. The specific mechanism of domain-wall motion is simply the small shift of ion positions within unit cells, resulting in the net change of orientation of the tetragonal *c* axis. Such domain-wall motion results in the sharp rise in polarization for low-field application, termed spontaneous polarization (curved dashed line in Fig. 9). The straight dashed line from the origin represents the modest amount of polarization (induced dipole) that would occur in a paraelectric material, e.g., the distortion of the symmetrical cubic structure under the applied field. The solid line in Fig. 9 summarizes the hysteresis loop that results when the electrical field is repeatedly cycled. Key parameters that quantify the hysteresis loop are the saturation polarization P_s, the polarization due to maximum domain growth and determined by extrapolating to zero field; the remanent polarization P_r, the polarization remaining upon field removal; and the coercive field E_c, the field necessary to reduce the polarization to zero. Remanent polarization is due to the fact that simply removing the field does not return the domain structure to equal volumes of opposing polarization. The coercive field is needed to achieve this result.

The characteristic hysteresis loop gives ferroelectricity its name by analogy to the similar shape of the induction (*B*)–magnetic field (*H*) plots for ferromagnetic materials (Fig. 10). As the prefix "ferro-" implies, ferromagnetic materials generally contain iron, although ferroelectrics rarely contain iron as a significant constituent.

The most common applications of ferroelectrics stem from a closely related phenomenon, piezoelectricity. The prefix "piezo" comes from the Greek word for pressure, indicating that piezoelectrics give an electrical response to mechanical pressure application. Conversely, electrical signals make them pressure generators. Both functions are directly related to the asymmetric crystal structure of Fig. 8(b). The piezoelectric effect (in which an applied stress produces a measurable voltage across the material) is the result of the crystallographic dipole dimensions being affected by the stress-induced distortion of the ionic positions within a given unit cell. Similarly, the reverse piezoelectric effect involves a thickness change in the material due to a change in the magnitude of the polarization, in turn

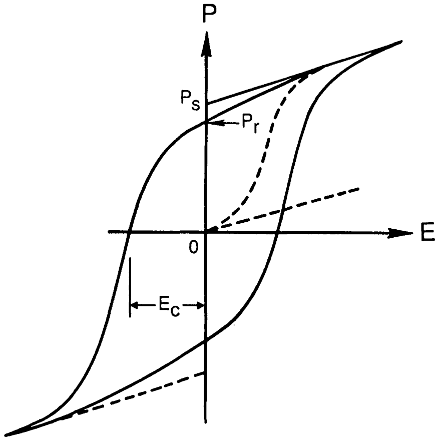

FIG. 9. A ferroelectric hysteresis loop is the result of an alternating electric field. A dashed line indicates the initial spontaneous polarization. Saturization polarization (P_s) is the result of maximum domain growth (extrapolated back to zero field). Upon actual field removal, some remanent polarization (P_r) remains. A coercive field (E_c) is required to reach zero polarization (equal volumes of opposing domains).

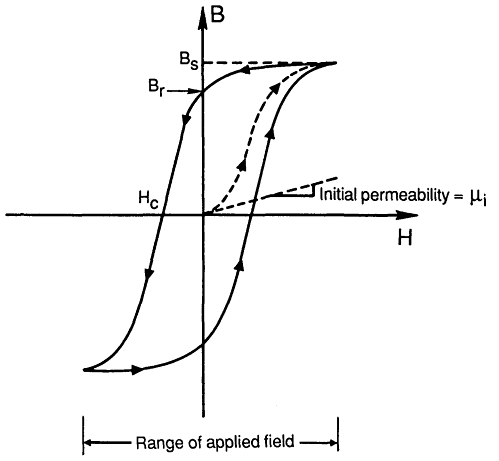

FIG. 10. The *B-H* plot hysteresis loop for a ferromagnetic material indicates a large rise in *B* during initial magnetization (shown by the dashed line). The induction reaches a large, "saturation" value (B_s) upon application of sufficient field strength. Much of that induction is retained upon removal of the field (B_r = remanent induction). A coercive field (H_c) is required to reduce the induction to zero.

caused by an applied voltage. By constraining the thickness change, the applied voltage produces a mechanical stress. A common application for a piezoelectric transducer is as an ultrasonic transmitter/receiver (see PIEZOELECTRIC DEVICES). In this case, voltage oscillations in the megahertz range produce (or sense) ultrasonic waves of that frequency.

The functioning of a piezoelectric transducer is dependent on a common crystallographic orientation throughout the material. A straightforward means of ensuring this is with a single crystal. Quartz (SiO_2) is an example and was widely used as a piezoelectric transducer after World War II. $BaTiO_3$ has a higher piezoelectric coupling coefficient k (= fraction of mechanical energy converted to electrical energy) than does SiO_2. The k value for $BaTiO_3$ is approximately 0.5 compared to 0.1 for quartz. As $BaTiO_3$ cannot be conveniently manufactured in single-crystal form, the material is processed in a powder form, and individual particles are aligned in a single crystallographic orientation under a strong electrical field. The powder is then sintered. The resulting polycrystalline material is said to be electrically poled. During the 1950s, this technology allowed $BaTiO_3$ to become the predominant piezoelectric transducer material. In the 1960s, the solid solution $Pb(Ti,Zr)O_3$, or PZT, became more widely used because of a substantially higher T_c (commonly in excess of 200 °C). In the 1970s, the addition of La_2O_3 in solid solution with PZT produced an optically transparent material, PLZT, which has found application as a high-frequency electro-optic shutter (Buchanan, 1986).

7. MAGNETIC PROPERTIES

As with electrical properties, the discussion of the magnetic behavior of ceramics has changed fundamentally since 1986. Before that time, the discussion concentrated primarily on the nature of ferrimagnetism (Buchanan, 1986). Since 1986, the magnetic behavior of the ceramic superconductors must be included (see MAGNETIC MATERIALS).

7.1 Ferrimagnetism

In general, we can define an induction **B** as a vector quantity whose magnitude is the flux density surrounding a magnetic field source. The induction is related to the magnetic field strength **H** by

$$\mathbf{B}=\mu\mathbf{H}, \tag{13}$$

where μ is the permeability of the solid within the magnetic field.

As noted in Sec. 6.4, ferromagnetic materials, such as pure iron, exhibit a hysteresis loop in the plot of induction B versus magnetic field strength H. Figure 10 is the magnetic analog for the ferroelectric hysteresis loop of Fig. 9, and, as pointed out in Sec. 6.4, serves as the source of the term "ferroelectric." The mechanism for ferromagnetism is fully analogous to that for ferroelectricity, viz., the saturation induction B_s is the result of complete domain growth, the remanent induction B_r is the value of induction remaining upon removal of the field, and the coercive field H_c is that needed to reduce the induction to zero. In this magnetic system, the domain is a region of aligned electron spins. The magnetic moment due to electron spin is given in units of the Bohr magneton μ_B, which has a value of 9.27×10^{-24} A m^2. A nonzero net magnetic moment is the result of unpaired electron spins that are present in materials such as the transition metals (e.g., Fe).

Table 16. Magnetic moment of various transition-metal ions.

Ion	Moment (μ_B)[a]
Mn^{2+}	5
Fe^{2+}	4
Fe^{3+}	5
Co^{2+}	3
Ni^{2+}	2
Cu^{2+}	1

[a] $\mu_B = 1$ Bohr magneton$=9.27\times10^{-24}$ A·m^2.

Traditional magnetic ceramics have a magnetic hysteresis loop similar to that in Fig. 10, but their crystal structure leads to some antiparallel spin pairing, causing the net magnetic moment to be less than that possible in metals. This similar phenomenon is distinguished from ferromagnetism by the slightly different spelling ferrimagnetism. The historical model of a magnetic material is magnetite, Fe_3O_4, in which one-third of the iron ions are in the Fe^{2+} charged state and two-thirds in the Fe^{3+} state. The trivalent ions are equally distributed between tetrahedral (fourfold coordination) and octahedral (six-fold coordination) sites, and their magnetic moments are antiparallel, leading to the cancellation of their contribution to the net magnetic moment of the crystal. The net moment is, then, provided solely by the divalent ions. The number of Bohr magnetons contributed by various transition-metal ions is summarized in Table 16. There are eight divalent ions per unit cell in magnetite, giving a predicted magnetic moment of $32\mu_B$, in good agreement with the experimental value of saturation induction.

The dominant examples of commercial ceramic magnets are the ferrites, which have the same crystal structure as magnetite (the so-called "inverse spinel" structure). A list of representative commercial ferrites is given in Table 17. Another group of magnetic ceramics is the garnets, based on the crystal structure of the natural gem garnet, $Al_2Mg_3Si_3O_{12}$. Yttrium iron garnet (YIG) is an example. Both ferrites and garnets are soft magnets, i.e., have a relatively small area within the hysteresis loop. The magnetoplumbites are, conversely, hard magnets with a characteristically high coercive field. These hexagonal materials with the composition $M_{0.6}Fe_2O_3$ (M =divalent cation) find applications as inexpensive permanent magnets. Another hard magnetic material is γ-Fe_2O_3, widely used as a fine-grained film in recording tape and both flexible and rigid computer disks.

7.2 Superconducting Magnets

As discussed in Sec. 6.2, ceramic superconductors have been available since 1986 (Strongin *et al.*, 1987). As pointed out in the discussion of their electrical properties, the encouraging rise in critical temperature for these materials has been contrasted with the discouraging limitation of critical current density. There is a third, major materials property for superconductors, viz., the critical magnetic field above which the material stops being superconducting. Unlike the critical current density, the critical magnetic field increases along with critical temperature for the high-T_c materials. Unfortunately, the limited current density (due to magnetic field penetration) remains as a primary obstacle, especially for large-scale applications such as power transmission and transportation. As pointed out earlier, the most promising applications

Table 17. Some commerical ferrite compositions.

Name	Composition	Comments
Magnesium ferrite	$MgFe_2O_4$	
Magnesium–zinc ferrite	$Mg_xZn_{1-x}Fe_2O_4$	$0<x<1$
Manganese ferrite	$MnFe_2O_4$	
Manganese-iron ferrite	$Mn_xFe_{3-x}O_4$	$0<x<3$
Manganese-zinc ferrite	$Mn_xZn_{1-x}Fe_2O_4$	$0<x<1$
Nickel ferrite	$NiFe_2O_4$	
Lithium ferrite	$Li_{0.5}Fe_{2.5}O_4$	Li^+ occurs in combination with Fe^{3+}, producing a configuration $(Li_{0.5}Fe_{0.5})^{2+}Fe_2{}^{3+}O_4$

of these new materials appear to be in thin-film devices, such as Josephson junctions.

GLOSSARY

Ferrimagnetism: As with ferromagnetism, the phenomenon of a sharp rise in induction with applied magnetic field. Distinguished from ferromagnetism by the presence of antiparallel spin pairing.

Ferroelectric: Material that exhibits a sharp rise in polarization under an applied electrical field.

Fracture toughness: Critical value of the stress–intensity factor at a crack tip necessary to produce catastrophic failure.

Piezoelectric: Material that produces a measurable voltage as a result of an applied stress (the piezoelectric effect) and undergoes a thickness change due to a change in applied voltage (the reverse piezoelectric effect).

Refractory: High-temperature-resistant material.

Sintering: Bonding of powder particles by solid-state diffusion.

Sol–Gel Processing: Technique for forming ceramics of high density at a relatively low temperature by means of an organometallic solution.

Transformation Toughening: Mechanism for enhanced fracture toughness involving a stress-induced phase transformation.

Vitreous: Noncrystalline or glassy phase.

INTRODUCTION

Daily experience shows that for many systems small changes in the initial conditions lead to small changes in the outcome. If we turn the steering wheel by a small angle the course of our car will only gradually deviate from its previous route. But there are other cases: For a coin standing on end, a slight touch will suffice to make it fall and to determine the side on which it will fall. In recent years it has become clear that sensitive dependence on initial conditions is not exceptional but typical of many systems and leads to chaotic, i.e., irregular, behavior in time.

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

In the following we shall consider systems whose time dependence is deterministic, i.e., there exists a prescription in terms of either difference or differential equations for calculating their future behavior from given initial conditions. One could assume naively that deterministic motion is rather regular and far from being chaotic because successive states evolve continuously from each other. But it was already discovered at the turn of the century by the mathematician Poincaré (1892) that certain mechanical systems could display chaotic motion. Unfortunately, this was considered by many physicists as a mere curiosity, and it took another 70 years until in 1963 the meteorologist E. N. Lorenz found that even a simple set of three differential equations which describe in a crude sense the flow of air in the earth's atmosphere, i.e., the problem of weather forecasting, can lead to completely irregular trajectories. Mainly through the availability of high speed computers it has now become clear that chaotic behavior is abundant in nature (see Table 1) and has far-reaching consequences in many branches of science.

The observed chaotic behavior in time is due neither to external sources of noise (there are none in Lorenz's equations) nor to an infinite number of degrees of freedom (Lorenz's system has only three degrees of freedom) nor to the uncertainty associated with quantum mechanics (Lorenz's system is purely classical). The actual source of irregularity is the nonlinearities in the equations of motion which amplify small but practically unavoidable errors in the initial conditions so strongly that the long-time behavior of the system becomes erratic and unpredictable.

Table 1. Some nonlinear systems which display deterministic chaos.

Biological models for population dynamics
Stimulated heart cells

Lorenz called this sensitive dependence on initial conditions the butterfly effect because the outcome of his equations, which describe the flow of air in the earth's atmosphere, could be changed by a butterfly flapping its wings.

Thus the question arises whether the appearance of chaotic motion implies the end of predictability for most nonlinear systems or whether one can still learn something from a chaotic signal (Ford, 1983). As we will seen in the following, fortunately the latter is the case; however, one has to pose the right questions.

The approach taken here is to review the general characteristics of chaotic systems and then to classify and quantify their behavior in more detail. We begin with a historical introduction followed by more a general introduction to nonlinear dynamical systems. Next we introduce the concept of a strange attractor and review different routes by which a dynamical system could develop chaotic behavior if one external control parameter is changed. The remaining sections are devoted to the occurrence of chaos in classical systems and the behavior of quantum systems whose classical counterpart displays chaos. We conclude with several applications of chaotic motion analysis and an outlook on further developments.

1. HISTORY

Chaos was first discovered in mechanical systems by the great French mathematician H. Poincaré (1892), who was stunned by the complexity of trajectories traced by three bodies interacting by gravitational forces (the classical three-body problem). About sixty years later Kolmogorov (1954), Arnol'd (1963), and Moser (1973) proved, in what is now called the KAM theorem, that motion in classical mechanics is neither completely regular nor completely irregular, but that the type of trajectory depends sensitively on the initial conditions. Another breakthrough came when, in 1963, E. N. Lorenz found the first example of chaos in dissipative systems. In contrast to systems of classical mechanics where energy is conserved, in dissipative systems energy is dissipated by friction, and motion is kept up only by external driving forces. A typical dissipative system is a damped pendulum which is driven by an external torque. Lorenz's discovery not only enlarged the number of systems which could display chaos but also opened the door for the discovery of qualitatively new phenomena, like universal routes to chaos and strange attractors.

In the 1970s Ruelle and Takens (1971) and Newhouse *et al.* (1978) suggested a transition to chaotic motion which was radically different from an earlier proposal by Landau (1944). Landau considered "turbulence in time" as the limit of an infinite sequence of instabilities (Hopf bifurcations) each of which creates a new basic frequency, such that the motion becomes more and more complicated. However Ruelle, Takens, and Newhouse showed that after only two instabilities the trajectory could move onto a so-called strange attractor displaying chaotic motion. A strange attractor is a generalization of simple attractors such as fixed points or limit cycles and allows for a classification of chaotic systems.

A more recent route to chaos has been found by Grossmann and Thomae (1977), Feigenbaum (1978), and Coullet and Tresser (1978). They considered a simple nonlinear difference equation (logistic equation) that has been used to describe the time evolution of populations in biology, and found that the population oscillated between distinct values (fixed points) whose number doubles again and again if an external parameter is increased. This continues until the number of (unstable) fixed points becomes infinite at a finite parameter value where the time variation of the population becomes irregular. Feigenbaum (1978) has shown, and this was a major achievement, that these results are not restricted to this special model, but are in fact universal and hold for a large variety of physical, chemical, and biological systems.

Almost in parallel to this discovery, Manneville and Pomeau (1979) found a third route to chaos via intermittency. Intermittency means that a signal which behaves regularly (or laminarly) in time becomes interrupted by statistically distributed periods of irregular motion (intermittent bursts). The average number of these bursts increases with the variation of an external control parameter until the motion becomes completely chaotic.

These discoveries triggered an explosion of theoretical and experimental research, part of which will be reported in the following sections.

2. NONLINEAR DYNAMICAL SYSTEMS

Nonlinear dynamical systems are generally described by first-order differential equations

$$\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x}, \lambda_1, \lambda_2, \ldots); \quad \mathbf{x} = (x_1, \ldots, x_d) \tag{1}$$

(the overdot denotes time derivative) which are autonomous, i.e., **F** does not contain the time explicitly, and nonlinear, i.e., **F** is a nonlinear function of the variables $x_1, \ldots, x_d$. These equations can lead to chaotic behavior in time if one or several external control parameters λ_1, $\lambda_2, \ldots$ are varied.

2.1 Examples

In Table 2 we describe two examples of systems which display deterministic chaos and comment on the methods by which chaos could be detected experimentally.

2.1.1 Periodically Driven Pendulum. The equation of motion for the angle θ of the pendulum shown in the upper part of Table 2 contains a friction term $\gamma\dot{\theta}$, a periodic driving torque $A\cos(\omega t)$, and the characteristic nonlinearity $\sin\theta$. The dot denotes the time derivative and ω is the frequency of the driving force. By introducing new variables x, y, z, the equation of motion of the driven pendulum can be brought into the canonical form of Eq. (1). The external control parameters are A and ω, and for special values of both, the time dependence of the angle simply "looks" chaotic as shown in the right column of Table 2.

2.1.2 Bénard Experiment. In this experiment a fluid layer in a "matchbox" is heated from below in a gravitational field. The heated fluid at the bottom rises to the top and cold liquid descends but both motions are opposed by viscous forces. For small temperature differences ΔT viscosity wins, the liquid remains at rest, and heat is transported by heat conduction. This state becomes unstable for larger values of ΔT, and a state of stationary convection rolls develops which is in turn unstable and leads to chaotic motion in time if ΔT is further increased. Here ΔT is the control parameter and chaotic motion is detected in the power spectrum

$$p(\omega) = |x(\omega)|^2, \tag{2}$$

Table 2. Detection of chaos in simple systems.

System	Equation of Motion	Indication
Pendulum 	$\ddot{\theta}+\gamma\dot{\theta}+g\sin\theta=A\cos\omega t$ $x=\theta,\ y=\dot{\theta},\ z=\omega t$ $\dot{x}=y$ $\dot{y}=-\gamma y-g\sin x+A\cos z$ $\dot{z}=\omega$	 Signal
Bénard experiment 	$\dot{x}=-\sigma x+\sigma y$ $\dot{y}=rx-y-xz$ $\dot{z}=xy-bz$	 Power Spectrum

where $x(\omega)$ is the Fourier transform of the fluid velocity $x(t)$:

$$x(\omega)=\lim_{T\to\infty}\int_0^T dt\, e^{i\omega t}x(t). \tag{3}$$

For regular motion $p(\omega)$ consists of discrete lines indicating distinct basic frequencies with which the system oscillates, whereas chaotic motion which is completely aperiodic is indicated by a broad continuum in $p(\omega)$ which extends to very low frequencies.

2.2 Lorenz Equations

The Bénard experiment can be crudely described by the following famous equations of motion which were first derived by Lorenz (1961) to describe meteorological phenomena:

$$\begin{aligned}\dot{x}&=-\sigma x+\sigma y,\\ \dot{y}&=-xz+rx-y,\\ \dot{z}&=xy-bz.\end{aligned} \tag{4}$$

A derivation of these equations from the Navier–Stokes equation for fluid motion is beyond the scope of this contribution and we will merely comment on the physical meaning of the different variables. The variable x in Eq. (4) is proportional to the circulatory fluid flow velocity, y characterizes the temperature difference between ascending and descending fluid elements, and z describes the deviation of the vertical temperature profile from its equilibrium value. The variables σ and b are dimensionless constants which characterize the system, and r is proportional to the temperature difference ΔT which is the control parameter. Again the Lorenz equations are of the form of Eq. (1).

2.3 Poincaré Section

The natural space in which the time behavior of a dynamical system could be visualized is phase space, which is spanned by the variables

$$\mathbf{x}(t)=[x_1(t),\ldots,x_d(t)] \tag{5}$$

that describe the state of the system. Figure 1 shows a two-dimensional projection of the phase-space variable

$$x_1(t)=\theta(t),\quad x_2(t)=\dot{\theta}(t),\quad x_3(t)=\omega t \tag{6}$$

for a damped driven pendulum. We distinguish the following different attractors, i.e., bounded regions in phase space to which the trajectory becomes attracted in the course of time:

- Fixed point: The trajectory comes finally to rest in a point in phase space, $\theta=0$, $\dot{\theta}=0$, if the pendulum swings back to its resting position with decreasing angle and angular velocity $\dot{\theta}$.
- Limit cycle: The trajectory becomes at-

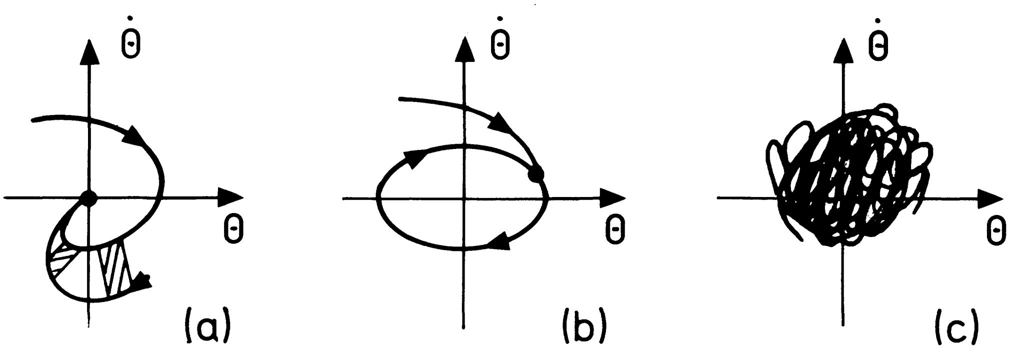

FIG. 1. Schematical drawing of different attractors which could occur in the phase space of a driven pendulum: (a) fixed point; (b) limit cycle; (c) strange attractor.

tracted to a simple closed loop in phase space if the pendulum is externally driven in such a way that the external torque compensates friction, and stabilizes regular pendulum motion, without leading to turnovers.

- Strange attractor: The trajectory performs irregular motion in a bounded region of phase, i.e., on a so-called strange attractor. This is because the driving torque is strong enough to generate turnovers of the pendulum. At the summit $\theta=\pi/2$ a tiny touch is enough to determine whether the angle moves to the right or left, i.e., one sees at least qualitatively that we have there sensitive dependence on initial conditions which leads to error amplification and finally to chaotic motion because at each turnover the pendulum passes the point $\theta=\pi/2$ again and again, i.e., we have so-called "backfolding" which amplifies errors enormously and makes the system unpredictable.

Following a method introduced already by Poincaré we have plotted in Fig. 2 the points in which the trajectory cuts the x axis. We see that a limit cycle corresponds to a single point, a two-cycle to two points, and chaotic motion to a sequence of successive points $x_0, x_1, x_2, \ldots$. This method to study the trajectories of a d-dimensional flow described by Eq. (1) by cutting it with a $(d-1)$-dimensional hyperplane is called Poincaré section, and it is often applied to visualize three-dimensional flows in the two-dimensional plane.

2.4 Mechanism for Chaos

If in Fig. 2 the sequence of points is irregular, we know that the system displays chaos, because these points belong to a trajectory. It is therefore possible and convenient to visualize the basic mechanism for chaotic motion via a one-dimensional map

$$x_{n+1}=f(x_n), \quad n=0,1,2,\ldots \tag{7}$$

which generates a sequence of chaotic points. In order to do so the map should have the

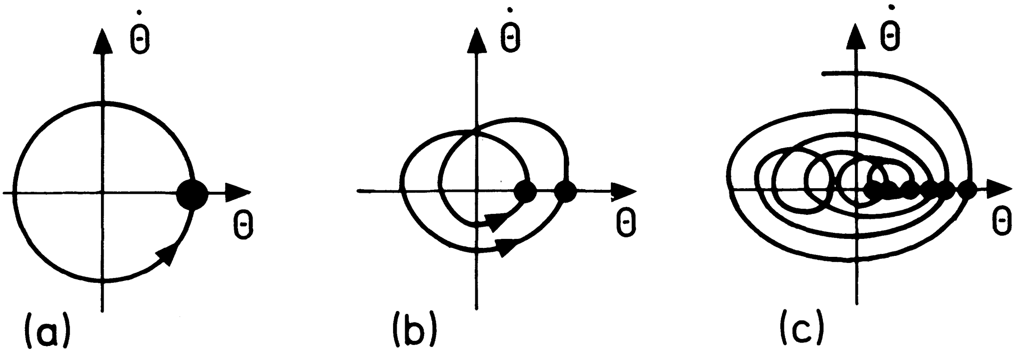

FIG. 2. Poincaré section of trajectories with an axis. (a) Limit cycle; (b) two-cycle; (c) chaos. Successive crossing points are denoted by x_n, $x_{n+1}, \ldots$. Note that there is only one crossing point for a circle.

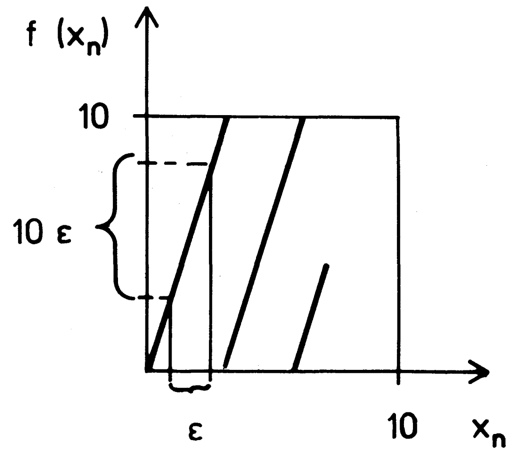

FIG. 3. The map $x_{n+1}=(10x_n)\,\mathrm{mod}10$.

property of error amplification and backfolding that are needed to generate chaos.

Figure 3 shows that the map

$$x_{n+1}=(10x_n)\mathrm{mod}10, \quad n=0,1,2,..., \tag{8}$$

amplifies an error ϵ by a factor of 10 and folds the iterates back to the interval [0, 10]. If we apply this map to an irrational number, say π, we obtain the following sequence of iterates:

$$\begin{aligned} x_0&=\pi &&=3.14159...,\\ x_1&=(31.4159...)\mathrm{mod}10 &&=1.4159...,\\ x_2&=(14.159...)\mathrm{mod}10 &&=4.159..., \end{aligned} \tag{9}$$

i.e., we see that the map shifts the sequence of decimals to the left and cuts off all but one digit before the decimal point. In this fashion it "pumps" the irregular sequence of decimals of π in front of the decimal point and makes them visible. This is all that a chaotic system does: It makes the chaos which exists already in the data of the initial conditions (x_0 for our example) macroscopically visible. If we assume for example that x_0 is a measured variable which is known up to three digits after the decimal point, we could write

$$x_0=a_0\cdot a_1a_2a_3???, \tag{10}$$

where the question marks indicate the unknown decimals. After four iterations with our map from Fig. 3 we obtain

$$x_4=?.???, \tag{11}$$

i.e., the fourth iterate is completely unknown; we cannot make any prediction about it; the system displays chaos.

3. STRANGE ATTRACTORS AND THEIR CHARACTERIZATION

3.1 Attractors of Dynamical Systems

Attractors of dissipative dynamical systems are bounded regions in phase space to which the trajectory becomes attracted in the course of time. The simplest attractor is a fixed point on which the trajectory comes to rest. More complicated attractors are limit cycles, or tori, on which the trajectory spirals around. In dissipative chaotic systems the trajectory often moves onto a so-called strange attractor, a concept that was introduced by Newhouse *et al.* (1978). We will explain its properties by way of an example.

3.1.1 Lorenz Attractor. The trajectory which is generated by Eq. (4) of the Lorenz model which has been explained in Sec. 2.2, i.e.,

$$\begin{aligned} \dot{x}&=-\sigma x+\sigma y,\\ \dot{y}&=-xz+rx-y,\\ \dot{z}&=xy-bz, \end{aligned} \tag{12}$$

leads for $r=28$, $\sigma=10$, $b=8/3$, and $\mathbf{x}(t=0)=[0,0.1,0]$ to the trajectory shown in Fig. 4. One sees that

1. the motion is confined to a bounded region in phase space;
2. the motion is erratic, i.e., the trajectory makes a few loops to the right, then a few more to the left, etc.

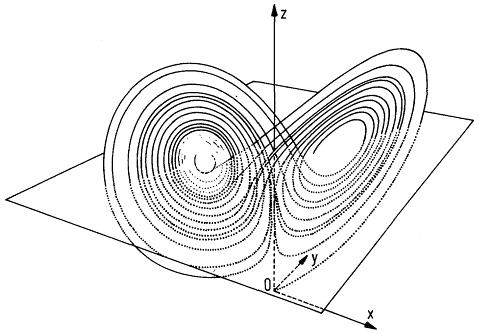

FIG. 4. The Lorenz attractor, after a computer calculation by Lanford (1977).

Numerical simulations show that there exists also a sensitive dependence on initial conditions, i.e., if instead of $\mathbf{x}(0)=[0,0.1,0]$ an adjacent initial condition is chosen, the new solution soon deviates from the old one and the numbers of right and left loops become different.

Since volume elements in phase space of dissipative systems shrink (see Fig. 1), the volume of the attracting bounded region contracts to zero. This means that the flow of the three-dimensional Lorenz system generates a set of points whose dimension is less than three. One might think that the dimension of the object spanned by the trajectory should then be two or one. However, there is no chaotic motion in systems of two dimensions or less. The fact that there are no trajectory crossings (otherwise a specific initial condition could lead to different trajectories) restricts the attractors in two dimensions to limit cycles or fixed points. The solution to this problem is that the attractor of the Lorenz system has a dimension (more precisely a Hausdorff dimension, defined in Sec. 3.2.2) which is noninteger and lies between 2 and 3; its precise value is $D=2.06$. This means that the attractor of the Lorenz system is indeed an object which deserves the name strange attractor. The general definition of a strange attractor is as follows:

1. It is an attractor, i.e., a bounded region of phase space to which all sufficiently close trajectories from the so-called basin of attraction are attracted asymptotically for long enough times. The basin of attraction is the collection of all points in phase space whose trajectories move in the limit of infinite time onto the attractor (see Fig. 5). Furthermore, the attractor itself should be indecomposable; i.e., the trajectory should visit every point on the attractor in the course of time. A collection of isolated fixed points is not a single attractor.
2. The property which makes the attractor strange is the sensitive dependence on the initial conditions; i.e., despite the contraction in volume, distances between points on the attractor need not shrink in all directions, and points which are arbitrarily close initially become exponentially separated at the attractor for sufficiently long times.

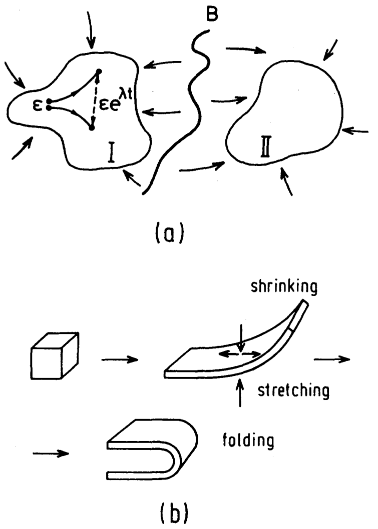

FIG. 5. (a) Two strange attractors I and II with different basins of attraction separated by a boundary *B*. (b) Deformation of a volume element on a strange attractor with increasing time.

All strange attractors that have been found up to now have fractional Hausdorff dimensions.

A strange attractor arises typically when the flow contracts the volume element in some directions, but stretches it along the others. To remain confined to a bounded domain, the volume element is folded at the same time. By analogy to the broken linear maps in Sec. 2 Eq. (7), this stretching and backfolding produces a chaotic motion of the trajectory at the strange attractor (see Fig. 5).

3.2 Characterization of Chaotic Motion

Let us now consider the question of how chaotic motion on a strange attractor could be characterized in more detail. There are in fact two essential quantities which can be computed locally for every point on the attractor:

1. the local density of points, or, more precisely, the local dimensionality, and
2. the local Liapunov exponents which measure the local instability, i.e., how fast and in what directions adjacent trajectories which start locally will diverge in the course of time.

By averaging these quantities over long times, i.e., over the whole attractor, one obtains several global numbers by which the attractor can be described.

3.2.1 Liapunov Exponents. For chaotic systems the difference between nearby trajectories $\epsilon(0)$ separates exponentially in time, i.e., $\epsilon(t)=\epsilon(0)e^{\lambda t}$. The averaged rates of separations in different directions of a dimensional phase space are the Liapunov exponents $\lambda_1,\ldots,\lambda_d$ shown in Fig. 6.

This leads for chaotic systems that are described by autonomous differential equations

$$\mathbf{x}=\mathbf{f}(\mathbf{x}) \tag{13}$$

to the following expression for the Liapunov exponents λ_i:

$$\lambda_i=\text{modulus of an eigenvalue of } \Lambda \tag{14}$$

where the matrix Λ is given by

$$\Lambda=\lim_{t\to\infty}\frac{1}{t}\log\left[\hat{T}\int_0^t M(t')dt'\right].$$

Here $M(t)$ is the matrix

$$M_{ij}(t)=\frac{\partial f_i(\mathbf{x})}{\partial x_j};\quad \mathbf{x}=\mathbf{x}[t,\mathbf{x}(0)] \tag{15}$$

and $\hat{T}$ orders the matrices $M(t)$ according to increasing times.

Figure 7 shows the largest Liapunov exponent $\lambda_{\max}$ of the Lorenz model for $\sigma=10$, $b=8/3$, as a function of the parameter r. Note that $\lambda_{\max}$ varies widely with the control parameter and becomes zero very often. This means that Lorenz model only displays chaos $\lambda_{\max}>0$ for specific values of r and chaotic regions are densely interwoven in parameter space with nonchaotic regions $\lambda_{\max}\leqslant 0$.

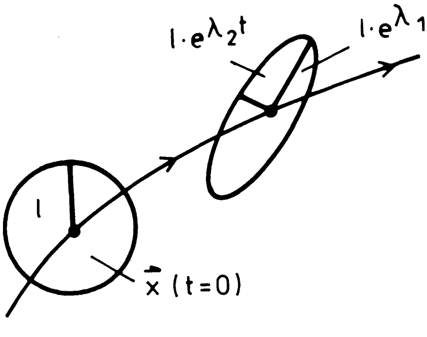

FIG. 6. Deformation of a sphere on a strange attractor in phase space as a function of time. The surface of the sphere consists of trajectory points.

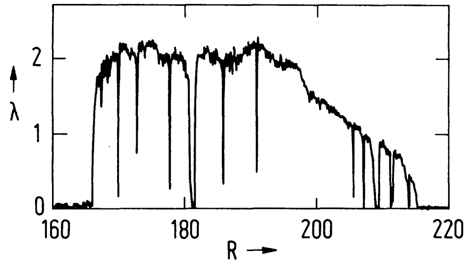

FIG. 7. The largest Liapunov exponent of the Lorenz model [Eqs. (4) for $\sigma=10$, $b=8/3$] as a function of the parameter $r=R$ (after K. Schmidt, private communication).

3.2.2 Hausdorff Dimension. Another important quality by which a strange attractor can be characterized is its fractal or Hausdorff dimension. The Hausdorff dimension D of a set of points is defined as follows: If for a set of points in d dimensions the number $N(l)$ of d-spheres of diameter l needed to cover the set increases like

$$N(l)\propto l^{-D}\quad\text{for } l\to 0 \tag{16}$$

then D is called the Hausdorff dimension of the set. A typical set of points with a noninteger Hausdorff dimension is the Cantor set shown in Fig. 8.

3.2.3 Spectrum of Attractor Dimensions. In order to characterize attractors that have a very inhomogeneous density in phase space, the notion of a Hausdorff dimension has been generalized to a spectrum $\rho(\alpha)$ of local dimensions α. The definition of a local dimension is explained in Fig. 9. The distribution $\rho(\alpha)$ of α's is obtained by measuring α for a large set of points on the attractor. One often plots instead of $\rho(\alpha)$ the function

$$f(\alpha)=\lim_{l\to 0}\frac{\log\rho(\alpha)}{\log l} \tag{17}$$

which for many strange attractors has the characteristic shape shown in Fig. 9. It can be shown that the value $\alpha_{\max}$ where $\rho(\alpha)$ [and $f(\alpha)$] have their maximum gives just the Hausdorff dimension of the attractor, i.e., $\alpha_{\max}=D$.

4. ROUTES TO CHAOS

It has been found experimentally effective for many systems to reduce the description of their dynamics to one- or two-dimensional maps by performing Poincaré sections. It has also been observed that only some general features of these maps, such as the existence of a single maximum, determine how chaos emerges if an external control parameter is tuned. Various routes to chaos have been found which differ in the way in which the signal behaves before becoming completely chaotic. Interestingly enough, all these routes have been verified experimentally, and they show a fascinating universal behavior which means that basic properties such as critical exponents near the transition to chaos depend only on some global features of the map, such that many physical systems (a whole class) display the same behavior at the transition to chaos. The beauty of nature reveals itself only after asking the right questions, and it seems that for dynamical systems the question about universal features at the transition to chaos has led to the discovery of a beautiful unifying pattern behind different phenomena. In the following we will discuss the three most prominent routes, although more routes have been found.

FIG. 9. (a) Definition of local dimensions α. Consider a small sphere of radius l around a point on the attractor. (b) The number of points Z which remain in the sphere for $l \to 0$ scales like $Z(l \to 0) \propto l^{\alpha}$. (c) The distribution of α's which is obtained by measuring α for a large set of points on the attractor is $p(\alpha) \propto l^{f(\alpha)}$.

4.1 Period Doubling Route

This route to chaos was discovered by studying the sequence of points generated by the logistic map

$$x_{n+1} = f(x_n) = r x_n (1 - x_n) \tag{18}$$

shown in Fig. 10. This map was already introduced by P. F. Verhulst in 1845 to simulate the

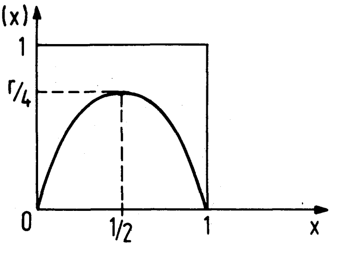

FIG. 10. The quadratic map $f(x)$ [Eq. (18)] on the unit interval.

growth of a population in a closed area. The number x_{n+1} of individuals of a species is proportional to the number in the previous year x_n and to the remaining area which is diminished proportionally to x_n, i.e., $x_{n+1}=rx_n(1-x_n)$, where the parameter r depends, e.g., on the fertility.

4.1.1 Universality and Feigenbaum Constants. In order to provide an overview over the dynamic behavior of the logistic map from Eq. (18), its iterates $x_0, x_1, \ldots, x_n$ and its Liapunov exponent

$$\lambda=\lim_{n\to\infty}\frac{1}{n}\sum_{i=1}^{n}\log|f'(x_n)|$$

are plotted in Fig. 11. We distinguish a period-doubling regime for $1\leqslant r\leqslant r_\infty$ where the iterates move for $r<r_1$ to a fixed point, for $r_1<r<r_2$ to a cycle of period two, for $r_2<r<r_3$ to a cycle of period $4=2^2$, etc., until at r_∞ the cycle period becomes infinite. In this regime the Liapunov exponent is almost always negative and only becomes zero at the bifurcation points r_n where a cycle changes from period $2^{n-1}$to 2^n. The distances of the bifurcation points r_n to the accumulation point $r_\infty=3.569\,9456$ shrink geometrically as

$$r_n=r_\infty-\text{const}\times\delta^{-n} \quad \text{for } n\gg 1, \tag{19}$$

and the distances d_n of the point of a 2^n-cycle that is closest to the cycle point $x=\frac{1}{2}$ (see Fig. 12) have constant ratios:

$$d_n/d_{n+1}=-\alpha \quad \text{for } n\gg 1. \tag{20}$$

The so-called Feigenbaum constants δ and α have the values

$$\delta=4.669\,201\,6091\ldots.$$

$$\alpha=2.502\,907\,8750\ldots. \tag{21}$$

For $r_\infty<r<4$ the Liapunov exponent is mostly positive, indicating chaotic behavior that is interrupted by nonchaotic periodic windows. Although one can also find universal behavior in this region, the most important finding is that for $r_\infty<r<4$ chaotic and regular behavior are strongly intermingled on the

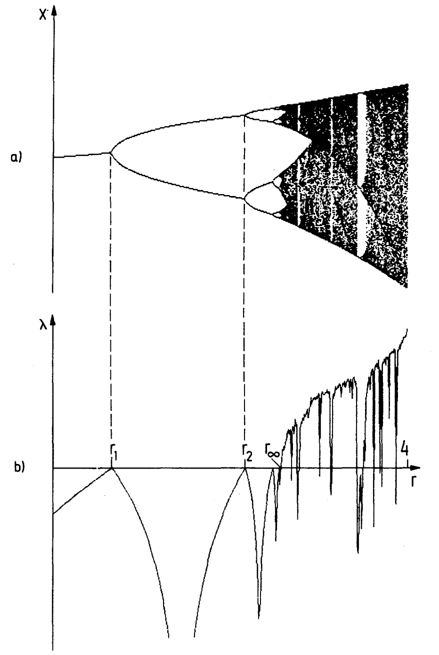

FIG. 11. (a) Iterates of the logistic map, (b) Liapunov exponent λ (after W. Desnizza, private communication).

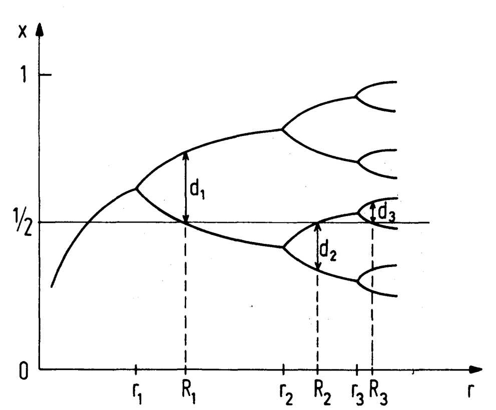

FIG. 12. Distances d_n of the fixed points closest to $x=1/2$ for superstable 2^n-cycles (schematically). Note that $x=1/2$ is an element of the cycle.

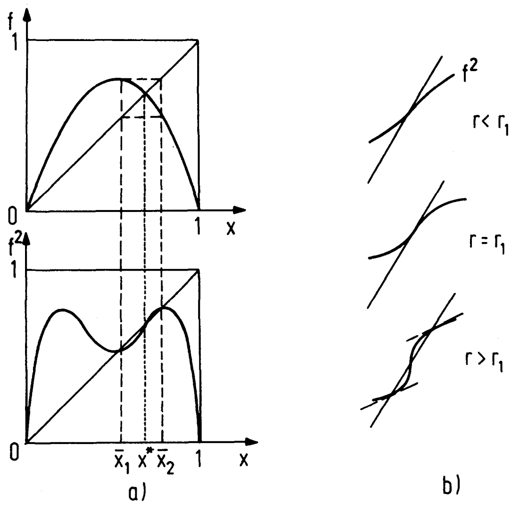

FIG. 13. (a) $f(x)$ and $f^2(x)=f[f(x)]$ for $r>r_1$. (b) Generation of two new stable fixed points in f^2 via a pitchfork bifurcation. (The bifurcation diagram looks like a pitchfork; see Table 4.)

parameter axis and the set of r values has a finite length for both types of behavior.

4.1.2 Pitchfork Bifurcation and Functional Fixed-Point Equation. The elementary mechanism which leads to period doubling is the pitchfork bifurcation shown in Fig. 13. Here a fixed point x^* of $f(x)$, i.e., $f(x^*)=x^*$, becomes unstable in favor of a cycle of period two. The points x_1 and x_2 of the two-cycle follow each other in time, i.e., $x_2=f(x_1)$ and $x_1=f(x_2)$. Since after two iterations the two-cycle closes we have $f(f(x_1))=x_1$ and $f(f(x_2))=x_2$, i.e., the elements of the two-cycle are fixed points of the second iterate $f^2(x)=f(f(x))$. This means that for the two-cycle, $f^2(x)$ plays the same role as $f(x)$ plays for a single fixed point, and so on, for the points of the 2^n-cycle are fixed points of $f^{2^n}(x)$. A comparison shows that the rescaled second iterate $(-\alpha)f^2(x/(-\alpha))$ at r_2 looks similar to the first iterate $f(x)$ at r_1, i.e., we have $(-\alpha)f^2_{r_2}(x/(-\alpha))\approx f_{r_2}(x)$ where the index denotes the values of r in $f_r(x)=rx(1-x)$. Although the details are beyond the scope of this article, it should be noted that this self-similarity has been used by Feigenbaum to relate α rigorously to the fixed-point function $g(x)$ of the so-called doubling operator T:

$$Tg(x)=-\alpha g(g(x/-\alpha))=g(x). \qquad (22)$$

This fixed-point equation can be solved by expanding $g(x)$ into a power series around $x=0.5$, and Feigenbaum (1978) obtained

$$\begin{aligned} g(x)=1&-1.527\,63(x-0.5)^2\\ &+0.104\,815(x-0.5)^4\\ &+0.026\,7057(x-0.5)^6\ldots\,. \end{aligned}$$

It follows from Eq. (22) that for a normalized solution with $g(0)=1$ the Feigenbaum constant α is given by

$$\alpha=1/g(1)=2.502\,807\,876\ldots\,. \qquad (23)$$

This rather elegant relation of the Feigenbaum constant α to a special value of the general fixed-point equation (22) establishes the universality of α because its value depends only on the boundary conditions for the solution of Eq. (22), i.e., on the order of the maximum of $g(x)$ (quadratic, quartic, etc.) at $x=0.5$.

The other Feigenbaum constant δ is the largest eigenvalue of the linearized doubling operator $L\{h(x)\}$. It can be computed from the eigenvalue equation

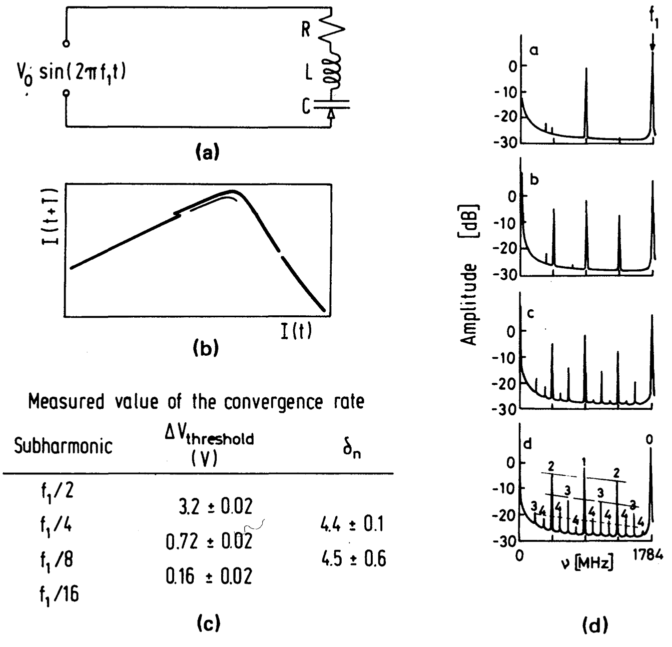
$$\begin{aligned} L\{h(x)\}=&-\alpha\{g'[g(x/-\alpha)]h(-x/\alpha)\\ &+h[g(-x/\alpha)]\}=\delta h(x). \qquad (24) \end{aligned}$$

Since the eigenfunction $h(x)$ and the eigenvalue δ depend, according to Eq. (24), only on the universal quantities $g(x)$ and α, it follows that δ itself also has a universal character.

4.1.3 Experimental Observation of Period Doubling. The period-doubling route has been discovered in many experiments. A typical example is shown in Fig. 14. Here the nonlinear element is the capacitor diode whose voltage-charge relation is nonlinear. Since at each doubling of the period of the signal its frequency is reduced to one half, one sees an increasing number of low-frequency peaks in Fig. 14.

4.2 Intermittency

The intermittency route to chaos is characterized by the appearance of a signal which alternates randomly between long regular phases and relatively short irregular bursts. A typical example for an intermittent signal is shown in Fig. 15. With increasing control parameter the lengths of the laminar regions shrink and the chaotic regimes become longer



Measured value of the convergence rate

Subharmonic	$\Delta V_{\text{threshold}}$ (V)	δ_n
$f_1/2$		
	3.2 ± 0.02

(After Linsay, 1981.)

and longer. This offers a continuous route from regular to chaotic motion.

4.2.1 Mechanism for Intermittency. A mechanism for the intermittency route in terms of one-dimensional Poincaré maps has first been given by Manneville and Pomeau (1979). Infinitely long laminar regions correspond to period-one cycle oscillations, i.e., a fixed point in the Poincaré map. If the control parameter is increased this fixed point becomes unstable. Because there are three ways in which a fixed point can become unstable, Pomeau and Manneville distinguished three types of intermittency (I, II, III) shown in Table 3. In all three cases the signal leaves the unstable fixed point only slowly, i.e., there is a sort of memory of the fixed point which leads to the typical regular laminar signals that increase slowly with time n. Above a certain value of the laminar signal the motion becomes chaotic until the signal becomes reinjected to the vicinity of the unstable fixed point, where it becomes again laminar. The theory of Pomeau and Manneville explains only the characteristic behavior in the laminar region, e.g., how the mean length $\langle l \rangle$ of these regions, averaged over long time scales, varies with the control parameter; but it makes no statements about the chaotic regime. The different scaling behavior together with the

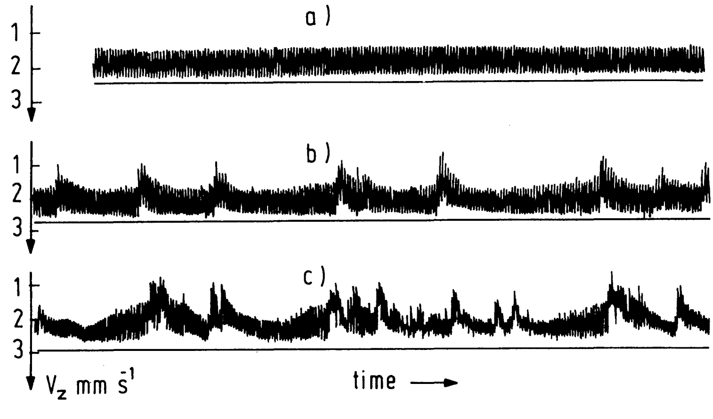

FIG. 15. Intermittency for a Bénard experiment: time dependence of the vertical velocity component measured in the middle of a Bénard cell. It changes with increasing Rayleigh number from periodic motion (a) via intermittent motion (b) to chaos (c) (after Bergé *et al.*,1980).

Table 3. Characteristic properties of different types of intermittency. The different types of intermittency can be distinguished by their Poincaré maps, their forms of the laminar signal, and their distributions $P(l)$ of laminar lengths.

Type	Poincaré map	Laminar Signal	Distribution $P(l)$
I	 $x_{n+1}=x_n+x_n^2+\epsilon$	 increases monotonically	II	 $r_{n+1}=(1+\epsilon)r_n+ur_n^3$ $\theta_{n+1}=\theta_n+\Omega$	 spirals	III	 $x_{n+1} = -(1+\epsilon)x_n - ux_n^3$	 alternates	
distribution $P(l)$ of laminar lengths is also shown in Table 3.

4.2.2 Experimental Observation of Intermittency. Figure 16 shows that the intermittency route can be seen in the same experimental setup which displays period doubling (see Fig. 14), albeit for different values of the control parameter.

4.3 Ruelle–Takens–Newhouse Route

This route to chaos can be visualized most easily by displaying the Fourier spectrum of the signal. Figure 17 shows the power spectrum of the fluid velocity at a special point in a Bénard cell (see Table 2). With increasing temperature difference the following states are observed:

1. periodic movement with one frequency and its harmonics,
2. quasiperiodic motion with two incommensurate frequencies, and their linear combinations,
3. nonperiodic chaotic motion with some sharp lines,
4. chaos.

This experiment was in fact performed after Newhouse, Ruelle, and Takens (1979) suggested this route to chaos. Its characteristic features are as follows. As the external control parameter is changed the system undergoes first two Hopf bifurcations which are characterized by the facts that first a fixed point becomes unstable in favor of a limit cycle on which the trajectory moves with a frequency ω_1. The second Hopf bifurcation generates

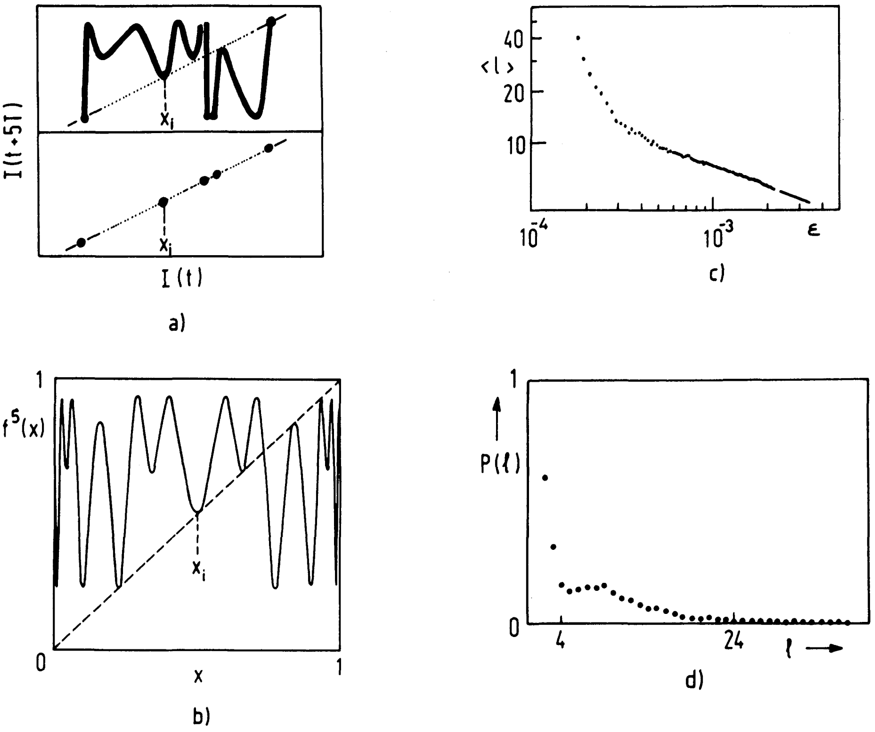

FIG. 16. Intermittency in the nonlinear RCL oscillator: (a) $I(t+5T)$ vs $I(t)$ which corresponds to the fifth iterate of the logistic map at tangency which is shown in (b). (c) The measured averaged length of the laminar regions scales like $\langle l \rangle \propto \epsilon^{-0.43}$ (where $\epsilon \sim V_0 - V_c$) [V_0 is the external control parameter and V_c is its value at the critical point where $I(t+5T)$ vs $I(t)$ is at tangency with the bisector], which is in reasonable agreement with the prediction of Manneville and Pomeau, $\langle l \rangle \propto \epsilon^{-0.5}$. (d) $P(l)$ vs laminar lengths l (in units of 5 T) for $\epsilon = 2.5 \times 10^{-4}$. (After Jeffries and Péres, 1982.)

another frequency ω_2 (which is generally incommensurate with ω_1, i.e., the ratio ω_2/ω_1 is irrational), and the trajectory moves on a torus (see Fig. 18). Further increase of the control parameter yields a "three-torus" with three independent frequencies, which, however, decays with finite probability onto a strange attractor. This breakup of the torus can be visualized in the experimentally observed Poincaré section shown in Fig. 19.

4.4 Comparison of Three Routes to Chaos

Table 4 summarizes the three different routes to chaos which we have discussed up to now. In the bifurcation diagram the behavior of stable (s) and unstable (u) solutions is shown as a function of the control parameter r.

This table, however, should only be considered as a first approximation to the true variety of transition scenarios. While it is natural to focus on common features, it would be premature to make sweeping generalizations about routes to chaos, and it should be emphasized that the range of dynamical behavior observed is quite large.

5. EXPERIMENTS AND APPLICATIONS

Having observed a seemingly chaotic signal $x(t)$, one wants to know what information it contains about the strange attractor.

5.1 Reconstruction of the Attractor from a Measured Time Series

Before one can extract the relevant variables λ_i and $f(\alpha)$ mentioned above in Sec. 3.2, one must in the first place reconstruct the trajectory $\mathbf{x}(t)$ of the system in phase space. This problem has been solved by Takens

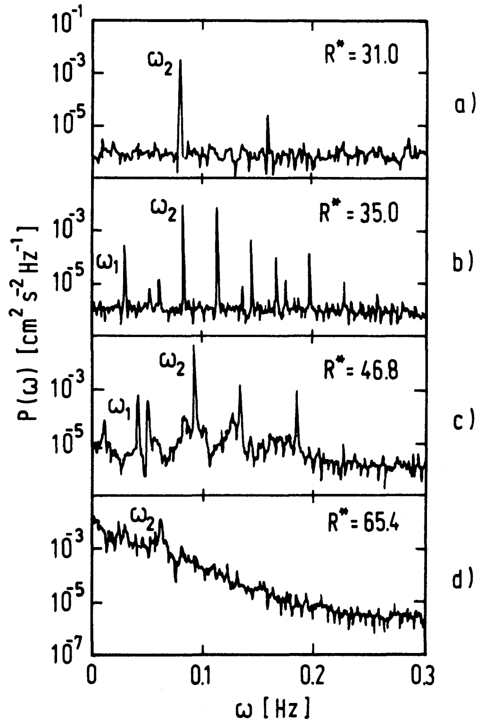

FIG. 17. Power spectrum of the convection current for a Bénard experiment (after Swinney and Gollub, 1978). With increasing (relative) Rayleigh number $R^* = R/R_c$ (where R_c is the critical value of the Rayleigh number, above which convective rolls develop in a Bénard cell), the following states are observed: (a) periodic movement with one frequency and its harmonics, (b) quasi-periodic motion with two incommensurate frequencies and their linear combinations, (c) nonperiodic chaotic motion with some sharp lines, (d) chaos.

(1981), and we illustrate his method by means of a simple example. Suppose that the true trajectory is a circle, i.e.,

$$\mathbf{x}(t) = [x_1(t), x_2(t)] = (\sin t, \cos t), \tag{25}$$

where the parameter t denotes time in dimensionless units. If we had only measured the variable $x_1(t) = \sin t$ we could reconstruct the second component $x_2(t)$ of the vector $\mathbf{x}(t)$ in phase space by performing a phase shift in $x_1(t)$, i.e.,

$$x_2(t) = \cos t = \sin(t + \pi/2) = x_1(t + \tau);$$

$$\tau = \pi/2 \tag{26}$$

Takens has shown that this method works also for the reconstruction of vectors in higher dimensional phase space, i.e.,

$$[x_1(t) \ldots x_m(t)]$$
$$= \{x_1(t), x_1(t+\tau) \ldots x_1[t+(m-1)\tau]\}, \tag{27}$$

yielding a strange attractor which has the same topological features as the "true" attractor (but it need not "look" the same).

Figure 20 shows a reconstruction of (a projection of) the Rössler attractor (Rössler, 1976), which is generated by the system

$$\begin{aligned} \dot{x} &= -y, \\ \dot{y} &= x + ay, \\ \dot{z} &= b + z(x - c), \end{aligned} \tag{28}$$

from about 6×10^5 points for different choices of the delay time τ. Although for an infinite amount of noise-free data, τ could be chosen almost arbitrarily (Takens, 1981), it can be seen from Fig. 20 that for a finite time series the quality of the reconstruction depends on τ. If τ is too small, $x(t)$ and $x(t+\tau)$ become practically indistinguishable and one obtains a linear dependence that is not present for the coordinates of the real trajectory. It is, therefore, reasonable to choose the decay time of the autocorrelation function $C(t)$ of the signal x_n for τ:

$$C(t) = \lim_{N \to \infty} \frac{1}{N} \sum_{n=1}^{N-1} x_n x_{n+1} \equiv \langle x_0 x_t \rangle, \tag{29}$$

$$C(t) \approx \tfrac{1}{2} C(0),$$

which ensures that $x(t)$ and $x(t+\tau)$ become linearly independent; but other choices for τ have also been proposed (Fraser and Swinney, 1986).

5.2 Correlation Integral

Having reconstructed $\mathbf{x}(t)$ one could proceed to calculate the spectrum of dimension and the Liapunov exponents as indicated in Sec. 3. But for the calculation of fractal dimensions there exists the problem that in order to compute $p(l) \sim l^{\alpha}$ one has to cover the whole attractor with little spheres of diameter l and then count how the number of points in them change with l. In order to avoid counting the many empty boxes Grassberger and Procaccia (1983) introduced the correlation integral as a rather elegant method to compute fractal dimensions, and it has found wide application. The correlation integral $C(l)$ measures the probability of finding two points of an attractor in a box of size l:

$$
\begin{aligned}
\sum_i p_i^2 &= \text{the probability that two points of the attractor lie within a cell } l^d \\
&\simeq \text{the probability that two points at the attractor are separated} \\
&\quad\ \text{by a distance smaller than } l \\
&= \lim_{N\to\infty} \frac{1}{N^2}\{\text{number of pairs } ij \text{ whose distance } |\mathbf{x}_i - \mathbf{x}_j| \text{ is less than } l\} \\
&= \lim_{N\to\infty} \frac{1}{N^2} \sum_{ij} \theta\,(l - |\mathbf{x}_i - \mathbf{x}_j|) = C(l) = \text{correlation integral.}
\end{aligned}
\tag{30}
$$

Here $\theta(z)$ denotes the step function with $\theta(z>0)=1$ and $\theta(z<0)=0$.

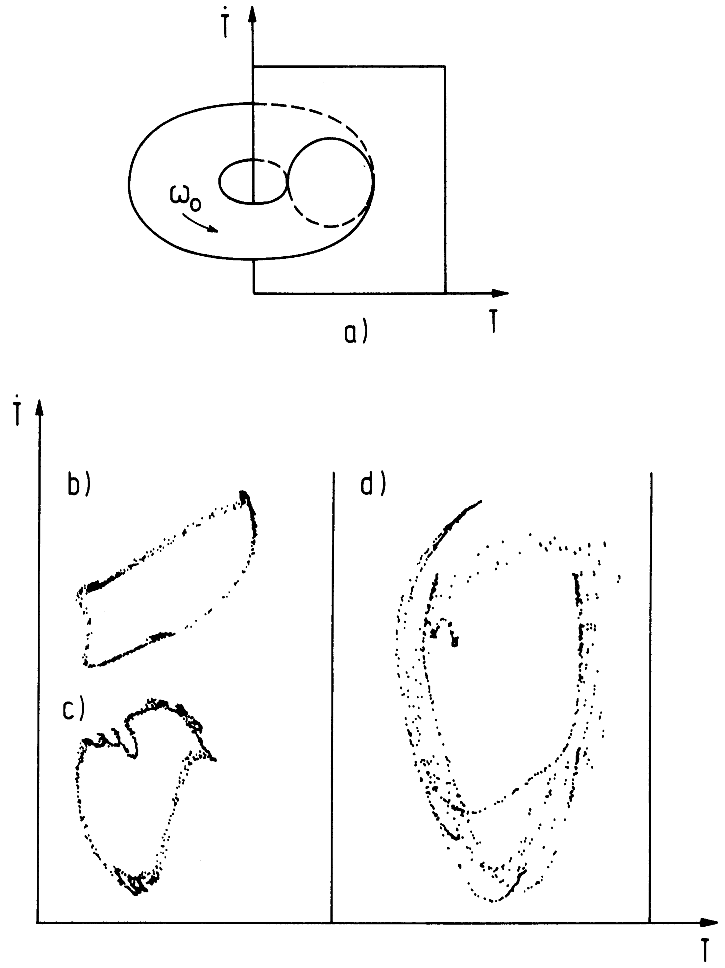

FIG. 19. Poincaré sections for the Bénard experiment: (a) schematic section through torus; (b)–(d) experiments showing with increasing Rayleigh number a transition from quasiperiodic motion (b) to substructures indicating the destruction of the torus (c) and then to a strange attractor (d). (After Dubois, Bergé and Croquett, 1982.)

Since the probabilities p_i scale like $p_i \sim l^{\alpha_i}$, where α_i are the local dimensions, it can be shown that the correlation integral scales like

$$C(l) \sim l^{-D_2} \quad \text{for } l \to 0, \tag{31}$$

where the correlation dimension D_2 yields a lower bound to the Hausdorff dimension D, i.e., $D_2 \leqslant D$.

5.3 Applications

5.3.1 Lorenz Model. Figure 21 shows how Takens's reconstruction works together with the correlation integral method to yield from about 10^4 points the correlation dimension D_2 for the Lorenz attractor.

5.3.2 Taylor Instability. Another example where Takens's method works has been observed experimentally in Taylor instability. The Taylor instability occurs in a fluid layer between an inner cylinder rotating with an angular velocity Ω and a stationary outer cylinder (see Fig. 22). For small Ω, angular momentum fed to the inner cylinder is transported outside by viscosity. Above a critical angular velocity Ω_c', this state becomes unstable, and momentum is transported by annular convection cells. At still higher Ω's, periodic and multiply periodic oscillations of these

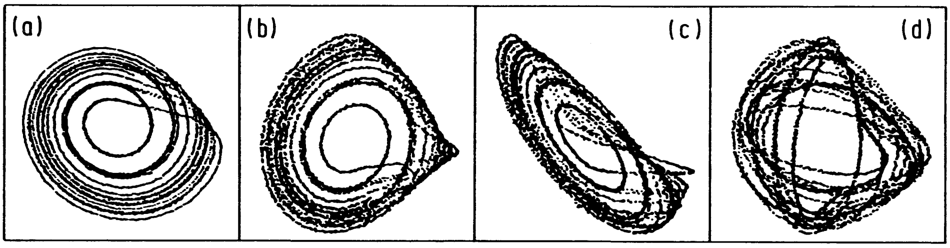

FIG. 20. Reconstruction of the Rössler attractor for $a=0.15$, $b=0.20$, $c=10.0$, $x_0=(10.0, 0, 0)$ from a time series: (a) x, y coordinates of the "true" attractor obtained by numerical integration of Eq. (27); (b), (c), (d) reconstructions for $\tau=0.23$, 0.39, 3.26, measured in units of the average orbital time, respectively. (After Fraser and Swinney, 1986.)

occur which merge into chaos after two Hopf bifurcations.

The following results in Fig. 23 have been obtained by reconstructing the phase space for a Taylor experiment from a series of the radial velocity measured at a special point in the Taylor cylinder

$\{v(t_k),\ldots,v(t_k+m\tau)\}$ with $t_k=k\tau_0$,

$k=0,1,2,\ldots$ $(\tau_0<\tau)$:

1. The Poincaré section shows the breakup of a torus.
2. The largest Liapunov exponent λ (obtained from separation of nearby orbits in five-dimensional phase space) becomes positive for $\Omega>\Omega^*$. This proves experimentally the existence of a strange attractor.
3. The Hausdorff dimension D and D_2 increase slowly with Ω/Ω_c. This shows that there are only a few relevant degrees of freedom even at Ω values that are 30% above the critical value $\Omega^*\approx 12\Omega_c$ at the onset of chaos.

5.3.3 Medical Data.

Figure 24 shows the logarithm of the correlation integral $C(l)$ as a function of $\log l$ and phase-space dimension n as computed from data points of a magnetoencephalogram for (a) a normal and (b) an epileptic patient. The correlation dimension, which is given by the average slope of these curves, is smaller for the epileptic patient. This is a first hint of more regular brain waves which have a higher tendency to culminate

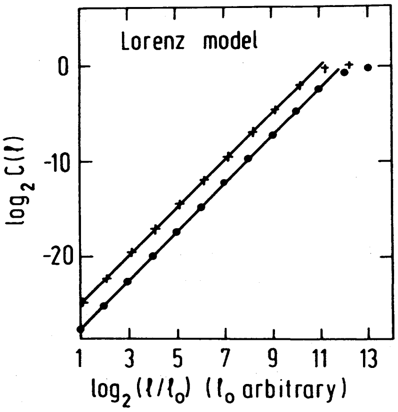

FIG. 21. $\log C(l)$ vs $\log l$ for the Lorenz model. The lower line is obtained directly from the three-dimensional time series $\{x(t_i), y(t_i), z(t_i)\}$, whereas the upper line originates from the reconstructed series $\zeta(t_i)=\{x(t_i), x(t_i+\tau), x(t_i+2\tau)\}$. The slopes of both curves are the same, i.e., the correlation dimension $D_2=2.05$ obtained by both methods is the same, as stated above (Grassberger and Procaccia, 1983).

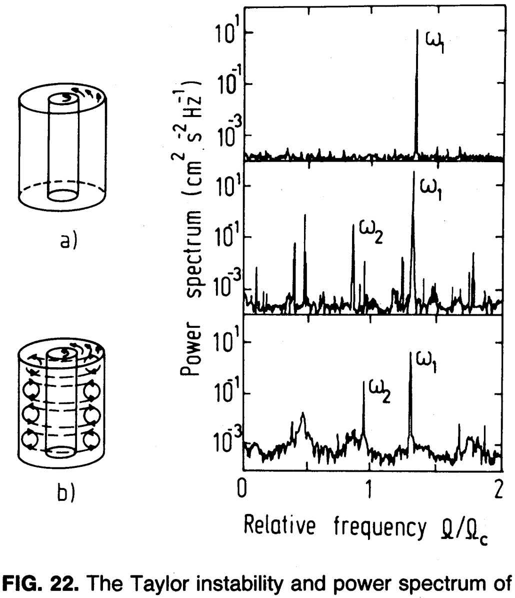

FIG. 22. The Taylor instability and power spectrum of the radial velocity measured at a point in the Taylor cylinder (after Swinney and Gollub, 1978).

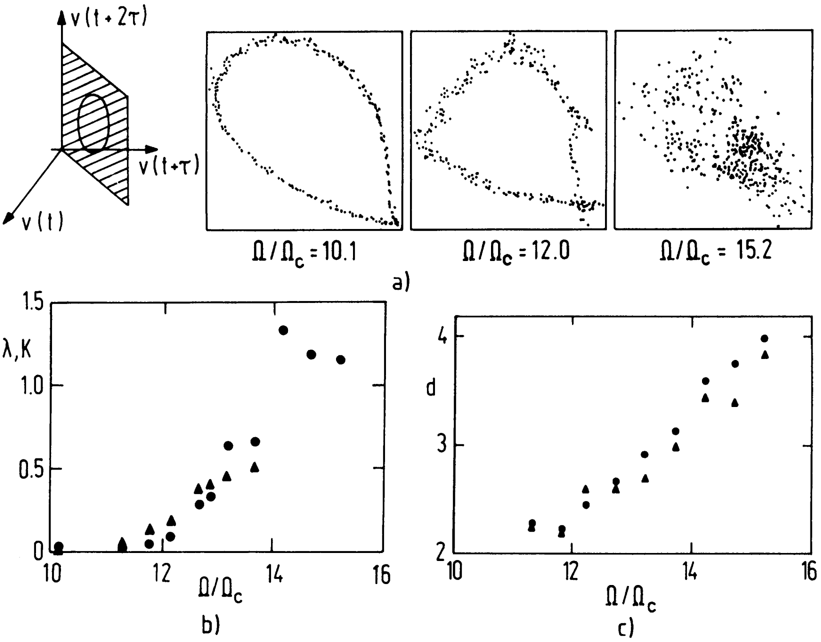

FIG. 23. Experimental properties of a strange attractor which occurs in a Taylor experiment: (a) Plane of the Poincaré section and break up of the torus with increasing Ω. (b) K-entropy (▲) and largest Liapunov exponent (●) vs Ω/Ω_c. (c) Hausdorff dimension D (●) and correlation dimension D_2 (▲) vs Ω/Ω_c. (After Brandstäter *et al.*, 1983.)

in regular bursts of an epileptic seizure than in a normal patient with more irregular neural activity. This last example shows that rather esoteric looking measures of chaos have quite practical medical applications.

6. CONSERVATIVE SYSTEMS

Conservative systems differ from dissipative systems by the fact that volume elements in phase space are conserved. Figure 25 shows the different behavior of trajectories in phase space in the vicinity of a fixed point for both types of dynamical systems. Conservative systems encompass all dynamical systems of classical mechanics, i.e., their time evolution is governed by Hamilton's equation for the coordinates **q** and momenta **p**:

$$\dot{q}_i=\frac{\partial H}{\partial p_i},\quad \dot{p}_i=-\frac{\partial H}{\partial q_i},\quad i=1,\ldots,d, \tag{32}$$

and $H=H(\mathbf{p},\mathbf{q})$ is the Hamilton function which specifies the energy E of the system. The simplest example for a conservative system is a harmonic oscillator, whose Hamilton function reads (after proper normalization)

$$H=\tfrac{1}{2}(p^2+\omega^2q^2), \tag{33}$$

where ω is the oscillator frequency. The corresponding trajectories in phase space are ellipses (since $H=E=$const.) as shown in Fig. 25(b).

The fact that volumes do not change in conservative systems implies immediately that they display (in contrast to dissipative systems) no attracting regions in phase space, i.e., no attracting fixed points, no attracting limit cycles, and no strange attractors. Nevertheless, in conservative systems one also finds chaotic regions in phase space, but they are not attractive and can be densely interwoven with regular regions.

For some time attention has shifted from the calculation of individual orbits to consid-

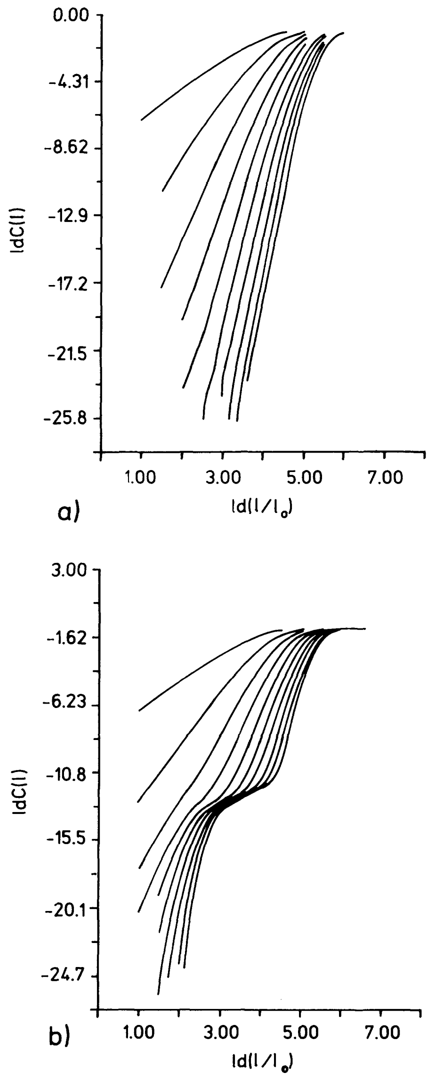

FIG. 24. Correlation integral $C(l)$ vs $\log(l)$ for (a) a normal subject and (b) an epileptic patient based on data from magnetoencephalograms. (After Saermark *et al.*, 1988.)

eration of the qualitative properties of families of orbits as shown in Fig. 26.

6.1 Integrable Systems

A conservative system is called integrable if one can find a transformation of the coordinates **q** and momenta **p** such that in the new variables $\boldsymbol{\theta}$, **I** the equations of motion can be integrated as

$$I_i = \text{const}_i,$$

$$\theta_i = \omega_i t + \delta_i, \quad i = 1 \ldots n, \tag{34}$$

i.e., the motion in phase space can be described by angular variables on a torus as shown in Fig. 27. In the following, we will confine ourselves to systems with $n=2$ degrees of freedom, but most results can be extended $n>2$. Figure 27 shows the motion of an integrable system with two degrees of freedom (i.e., with a four-dimensional phase space) on a torus. Closed orbits occur only if

$$n\Delta\theta_2 = 2\pi m, \text{ i.e., } \omega_2/\omega_1 = m/n = \text{rational};$$

$$m,n = 1,2,3\ldots . \tag{35}$$

For irrational frequency ratios, the orbit never repeats itself but approaches every point on the two-dimensional manifold infinitesimally closely in the course of time. In other words, the emotion is ergodic on the torus.

6.2 Kolmogorov–Arnol'd–Moser Theorem

The Kolmogorov–Arnol'd–Moser theorem states that under certain technical conditions the motion of an integrable system which is perturbed externally remains stable. This theorem is important, for example, for such questions as the stability of the solar system or the stability of trajectories in a particle accelerator in the long time limit. More precisely the Kolmogorov–Arnol'd–Moser (KAM) theorem makes a statement about the dynamical behavior which occurs if an integrable system whose frequency ratio ω_1/ω_2 is close to an irrational value is perturbed. The theorem states that under certain technical conditions, those tori whose motion is sufficiently irrational that

$$\omega_1/\omega_2 - m/s > K(\epsilon)/s^{2.5}, \tag{36}$$

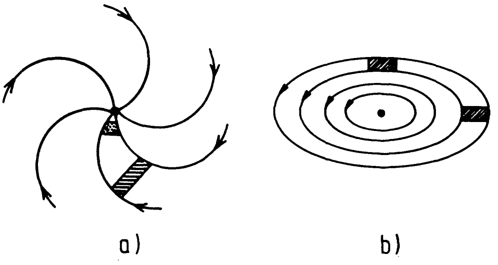

FIG. 25. (a) In dissipative systems trajectories are attracted to a fixed point, and volume shrinks. (b) In conservative systems the points rotate around an elliptic fixed point; volume is conserved.

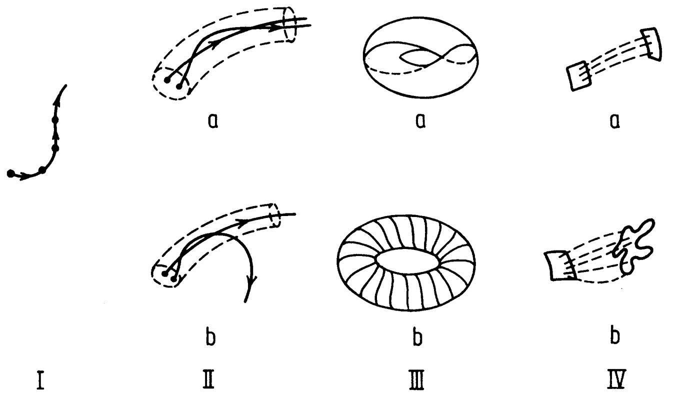

FIG. 26. Problems of increasing globality in classical mechanics. I. Step by step integration of the equations of motion. II.(a) Local stability; (b) Local instability. III. Topological nature of complete trajectories: (a) Periodic motion on a torus; (b) Motion on a torus with irrational frequency ratios. IV. Types of flow in phase space: (a) nonmixing; (b) mixing. (After Balescu, 1975.)

where m and s are mutually prime integers, are stable under a perturbation whose strength is proportional to ϵ. $K(\epsilon)$ is a constant with $K(\epsilon \to 0) = 0$. It is important to note that the set of initial conditions for which Eq. (36) holds has a finite volume in phase space, i.e., there is a finite probability that the motion remains stable under perturbation.

6.3 Coexistence of Regular and Irregular Motion

If ω_1/ω_2 is rational, the original torus decomposes into smaller and smaller tori. Some of these newly created tori are again stable according to the KAM theorem. But between the stable tori there appear unstable fixed points. Figure 28 shows that, near a hyperbolic fixed point H, the motion becomes unstable and orbits are driven away from it, in contrast to the stable rotational motion around an elliptic fixed point.

The stable (W_s) and unstable (W_u) lines which lead to or emanate from H behave highly irregularly since

1. they cannot intersect themselves (otherwise the motion on a trajectory in phase space would not be unique for a given set of initial conditions);
2. but W_u can intersect W_s at a so-called homoclinic point (see Fig. 29).

According to the so called Lamba lemma [see, e.g., Guckenheimer and Holmes (1983), p. 248] the curves W_u and W_s form an extremely complex network which characterizes chaotic motion.

It is shown in Fig. 30 that stable and unstable regions are densely interwoven. So-called elliptic fixed points are stable and surrounded by stable KAM tori, whereas hyperbolic fixed points are unstable and in their vicinity the motion becomes chaotic.

Whereas for systems with two degrees of freedom the irregular orbits are trapped between stable KAM tori, this is no longer the case if the number of degrees of freedom exceeds two. Then so-called Arnol'd diffusion (Arnol'd, 1964) of trajectories occurs between tori as shown in Fig. 31.

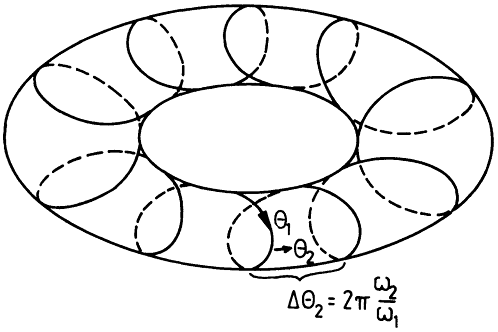

FIG. 27. Torus in phase space.

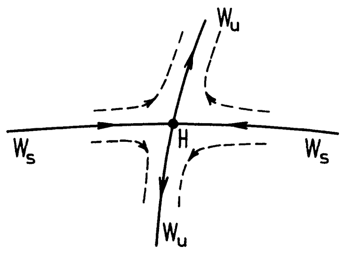

FIG. 28. Hyperbolic fixed point H with stable (W_s) and unstable (W_u) lines.

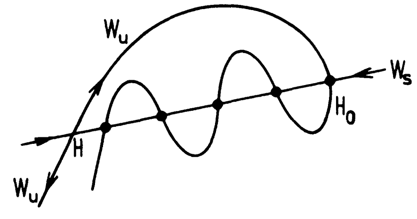

FIG. 29. Homoclinic points H_0 are the intersections of W_u and W_s.

6.4 Unstable Planetary Motion

An example of the coexistence of regular and irregular trajectories in a Hamiltonian system is given by the motion of an asteroid around the sun perturbed by Jupiter. This three-body problem is nonintegrable, and according to Eq. (36) we expect that the asteroid motion becomes unstable if the ratio of the unperturbed frequency of the asteroid motion ω and the angular frequency of Jupiter ω_J becomes rational. Figure 32 illustrates that, in fact, gaps occur in the asteroid distribution f for rational ω/ω_J. On the other hand, the existence of stable asteroid orbits ($f \neq 0$) can be considered as a confirmation of the KAM theorem.

7. CHAOS IN QUANTUM SYSTEMS?

The existence of chaotic motion in classical conservative systems naturally leads to the question of how this irregularity manifests itself in the corresponding quantum systems. In a broader context, one might inquire about the nature of the solutions to the wave equations that arise, e.g., in plasma physics, optics, or acoustics, whose ray trajectories, e.g., in geometric optics, are stochastic.

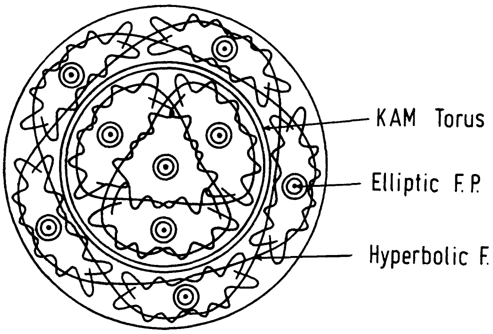

FIG. 30. Regular and irregular motion in the phase space of a nonintegrable system.

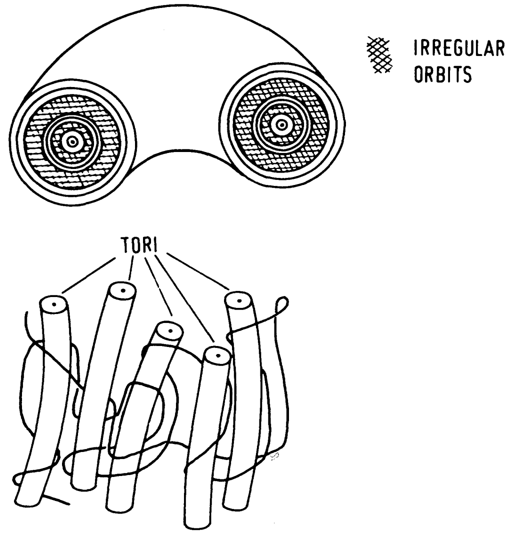

FIG. 31. Arnol'd diffusion for Hamiltonian systems with more than two degrees of freedom (schematically).

The question about the behavior of quantum systems whose classical limit exhibits chaos has been posed since the early days of quantum mechanics (Einstein, 1917) because it raises the problem of how to quantize a system which executes nonperiodic motion. At that time, periodic systems were quantized via the Bohr-Sommerfeld quantization rule $\oint p\, dq = nh$, where h is Planck's constant and $\oint$ denotes integration over a closed trajectory, which occurs for periodic motion. Since the discovery and the establishment of wave mechanics, we know how to proceed if we wish to learn about the time evolution of any quantum system: solve the time-dependent Schrödinger equation

$$\hat{H}\psi = -\frac{\hbar}{i}\frac{\partial}{\partial t}\psi, \qquad (37)$$

where $\hat{H}$ is the Hamilton operator of the system, ψ is its wave function, and $\hbar = h/2\pi$.

7.1 Classical versus Quantum Systems

In order to develop some intuition for the changes which will arise if we pass from a classically chaotic system to its quantum mechanical version, we recall several major differences between classical and quantum systems:

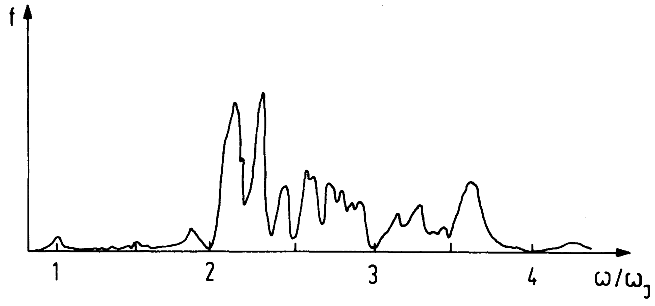

FIG. 32. Fraction f of asteroids in the belt between Mars and Jupiter as a function of ω/ω_J. (After Berry, 1978.)

1. In contrast to classical mechanics (where a statistical description is only necessary if the system becomes chaotic in time), quantum mechanics allows only statistical predictions. Although the Schrödinger equation is linear in ψ and can, e.g., be solved exactly for a harmonic oscillator with the result that ψ depends regularly on time (i.e., there is no chaotic time behavior), this does not mean that the motion is completely deterministic, since $|\psi(\mathbf{x}, t)|^2$ is only the probability density to find an electron at a space-time point $(\mathbf{x}, t)$.
2. Because of Heisenberg's uncertainty principle

   $$\Delta p \Delta q > \hbar/2 \tag{38}$$

   there are no trajectories in quantum mechanics [if one measures q with precision Δq, one disturbs the momentum p by Δp according to Eq. (38)]. Therefore, the characterization of chaos based on the exponentially fast separation of nearby trajectories becomes useless for quantum systems.
3. The uncertainty principle Eq. (38) implies also that points in $2n$-dimensional phase space within a volume $\hbar^n$ cannot be distinguished, i.e., the phase space becomes coarse grained. This means that regions in phase space in which the motion is classically chaotic (see Fig. 31), but which have volumes smaller than $\hbar^n$, are not "seen" in quantum mechanics; and for the corresponding quantum system, we expect a regular behavior in time. Thus the finite value of Planck's constant tends to suppress chaos. On the other hand, the limit $\hbar \to 0$ becomes difficult (for quantum systems which have a classical counterpart which displays chaos) because if $\hbar$ becomes smaller, more irregular structures will appear.

7.2 A Quantum Particle in a Stadium

Although it was made plausible in the previous section that the finite value of Planck's constant tends to suppress chaos, one nevertheless expects some difference between a quantum system having a classical counterpart that displays chaos and a quantum version of an integrable classical system having regular trajectories. To cast some light on this problem, McDonald and Kaufmann (1979) calculated numerically the wave functions and spectra of a free particle in a stadium (i.e., a rectangular region of length R which is closed at two opposite ends by semicircles with radius a) and in a circular disk by solving the Schrödinger equation for a free particle in two dimensions,

$$\nabla^2\psi = E\psi, \tag{39}$$

with the boundary condition $\psi(x, y) = 0$ at the "walls."

In the classical limit most (not all) trajectories of a free moving particle in a stadium (but not in a circle) are chaotic because the curved boundary reflects the particle in such a way that nearby trajectories separate exponentially in time. The results of McDonald and Kaufmann for the quantum situation are summarized as follows (see Fig. 33):

1. The eigenfunctions of the stadium problem show irregular nodal curves [where $\psi(x, y) = 0$] in contrast to the regular curves for the circle.
2. The distribution $N(\Delta E)$ of the eigenvalue spacings ΔE for the circle shows a maximum at $\Delta E = 0$, i.e., there is a high probability of level degeneracies, and one finds level clustering. It has been proved by Berry and Tabor (1977) that for integrable systems $N(\Delta E) \propto \exp(-\Delta E \times \text{const})$. For the stadium $N(\Delta E)$ has a maximum at $\Delta E \neq 0$,

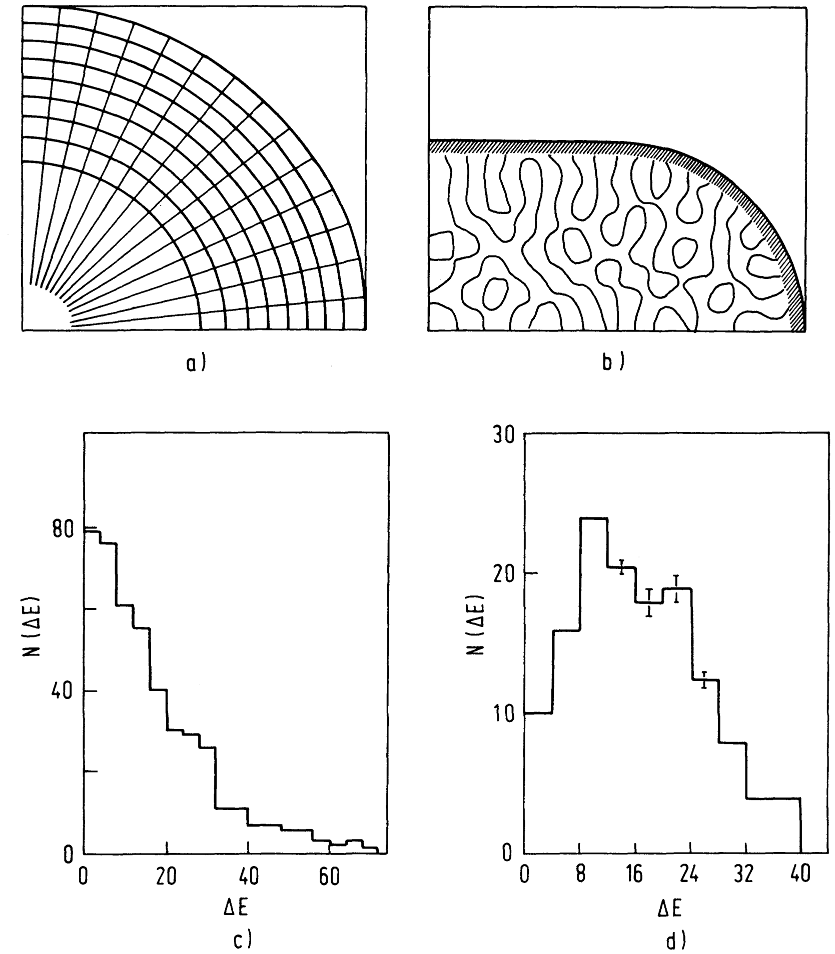

FIG. 33. Nodal curves [$\psi(x,y)=0$] for one quadrant of the (odd-odd parity) eigenfunctions (a) in a disk and (b) in a stadium (with dimensions $R=a$). Distribution $N(\Delta E)$ of (odd-odd parity) energy level spacings (c) for a circular boundary and (d) for a stadium boundary. (After McDonald and Kaufmann, 1979.) Note that $\Delta E=E_{j+1}-E_j$ is the spacing between neighboring levels; j increases with energy.

i.e., there is level repulsion. This level repulsion seems to be a characteristic feature of quantum systems whose classical limit shows chaos. It is related to the fact that no symmetries exist in these systems, i.e., there are no degeneracies (and no selection rules which prevent mutual interaction of the levels) such that $\lim_{\Delta E\to 0}(N(\Delta E))=0$. Several theoretical explanations for this phenomenon have been offered, and an interesting connection to random matrix theory (which is used to explain level repulsion in nuclear spectra) has been suggested (Berry, 1983).

The stationary Schrödinger equation in two dimensions is formally equivalent to the equation for the eigenfrequencies of a flat microwave resonator. This has recently been used by Stöckmann and Stein (1990) to confirm the computations shown in Fig. 33 by a microwave experiment.

7.3 Explicitly Time-Dependent Quantum Systems

Let us finally mention that the investigation of quantum chaos is not only of academic interest. Besides the stationary problems mentioned above, there exists also the large class of explicitly time-dependent systems such as atoms or molecules in a time-dependent radiation field. An understanding of, for example, the quantum ionization behavior of these systems which are again not integrable classically is of uttermost interest for laser chemistry.

8. OUTLOOK

Let us now take a glance at future possible developments by indicating several topics not dealt with in previous sections.

First of all, there is the problem of chaotic motion in spatially coupled nonlinear systems, such as coupled heart cells, chemical reactions (Vidal and Pacault, 1984) where the diffusion term is included [i.e., $\mathbf{c}=\mathbf{F}(\mathbf{c})+k\nabla^2\mathbf{c}$ instead of Eq. (1)], and the Navier–Stokes equations which could describe the motion of a turbulent fluid in time and space (Ruelle, 1983). Some pertinent questions are: How do these nonlinear oscillators influence each other? Do they synchronize? Does there exist something like spatial chaos? What is the influence of spatial motion on temporal chaos? What are the dimensions of strange attractors if one approaches fully developed turbulence?

Another major area is the question of the chaotic behavior of quantum systems with dissipation, such as lasers of Josephson junctions. It is also interesting to note that in quantum systems with many particles the question of chaos is related to the fundamental problem of the "arrow of time" (Misra and Prigogine, 1980).

This list is, of course, by no means complete. From the mathematical point of view, the very nature of a random number is still an issue of interest (De Long, 1970), and we have not discussed the possible role that the close coexistence of chaos and regular motion could play for the formation of structures in biology (Hess and Markus, 1984). It should also be noted that cellular automata (i.e., discrete approximations to partial differential equations in which all variables—time, space, and the signal—only take integer values) promise to become an important tool for answering many of the questions mentioned above (Wolfram, 1985).

The major conclusion, however, should be clear: Since nature is nonlinear, one has always to reckon with chaos.

GLOSSARY

Bifurcation: A dynamical system loses as a function of an external control parameter its stability and moves to one or several new stable states.

Critical Exponent: Near a transition from order to chaos tuned by a control parameter r, a measurable quantity x displays a power-law behavior $x \propto (r - r_c)^{\alpha}$ where α is the critical exponent and r_c is the transition point.

Ergodicity: The motion of a dynamical system in phase space is called ergodic if the trajectory covers a finite region of phase space densely. For ergodic systems time averages over dynamical variables can be replaced by phase-space averages.

Hopf Bifurcation: A fixed point becomes unstable in favor of a limit cycle if a control parameter is increased. The radius of the limit cycle increases smoothly from zero with the control parameter, whereas the frequency of the limit cycle jumps to a finite value at the transition point, i.e., each Hopf bifurcation introduces a new frequency into the system.

Navier–Stokes Equations: Spatio-temporal differential equations which determine the velocity profile of a liquid as a function of external pressure and boundary conditions.

INTRODUCTION

The science of materials analysis and characterization is an integral part of the procedure of developing new materials. More accurate, more precise, and faster response instruments and methodologies are always being sought to aid in the understanding of material behavior and in the development of new materials themselves.

In recent years advances in computer hardware and software, electronic circuitry, sensing devices, vacuum systems, and many other technologies have manifested themselves in the development of analytical instrumentation beyond the wildest dreams of scientists

digital Encyclopedia of Applied Physics

only one generation ago. Again, in recent years, significant advances have been made in materials development. Novel polymers with enhanced mechanical, chemical, electrical, high-temperature, and barrier properties have been developed. Light, composite plastics have found their way into the aerospace, automotive, and housing-construction industries. Great strides have also been made in the development of metals and metal alloys, with improved mechanical, magnetic, fatigue and corrosion resistance properties. New ceramic materials with excellent high temperature properties and improved strength and toughness are also beginning to appear in commerce. Dramatic breakthroughs in new superconducting materials have also been made and the biosciences have made dramatic strides in the last two decades.

In this article a variety of instruments, techniques, and methodologies will be described which have played a major role in the development and commercialization of new polymers, biomaterials, metals, and ceramics. Each methodology will be described in order to acquaint the reader with the principles of the technique, sample requirements, and how it is applied to characterization and analysis. Where possible, specific examples and in some cases the limitations of the techniques will be discussed. Since the article is limited in its scope, it will not be possible to go into extensive depth in any particular technique. However, references will be cited where the reader will be able to follow up in more detail on any of the subjects described.

The sections are written in such a manner as to familiarize a novice with the first principles of each technique and how that technique is applied to materials analysis and characterization. The more experienced investigator can use the article as a quick review with an opportunity to examine the techniques in more depth through utilization of the numerous reference citations.

Anyone who practices in the field of characterization and analysis understands that most problems involve a multidisciplinary approach in order to provide the most efficient solutions. Therefore, while each technique will be described in a "stand alone" manner, in reality a combination of many techniques is used in materials characterization and analyses.

1. MICROSCOPY

Optical microscopy is one of the oldest characterization tools known. In many cases it is one of the first examinations made on a material, since it is an extension of what the human eye itself sees. However, the resolution in optical microscopy is limited by the wavelength of light. Greater magnification can only be achieved by electron microscopy and newer techniques such as scanning tunneling and atomic force microscopy. The latter two techniques, as well as other "surface microscopic" techniques, will be covered in Sec. 6.

1.1 Optical Microscopy and Image Analysis

The optical microscope obtains information about a material either through transmitted or reflected light (see OPTICAL MICROSCOPY). Magnification from 10× to 1400× can be achieved with modern optical microscopes. The limit of resolution is about 0.2 μm or the order of the wavelength of visible light. Cameras can be adapted to light microscopes which will allow for permanent storage of images; or, in the case of video cameras, real-life observations can be made by groups of people at the same time. Cameras are usually equipped with polarizing devices and bright-field, dark-field, and temperature control units which allow observations on specimens from -20 to 350 °C. Temperature studies are extremely useful in determining phase transitions in materials, the most common of which is the melting point.

Transmission optical microscopy is used to examine thin (of the order of microns) specimens which can be prepared in a variety of ways. Polymer films or fibers, powders, biological or thin petrographic sections, dispersions, and emulsions are all routinely examined. Reflected-light microscopy is used primarily on flat specimens. Polished and etched metallurgical or ceramic samples are studied for the nature and variability of grain sizes in the specimens.

All microscopic techniques lend themselves to image analysis. A real microscopic image or a photograph can be scanned with a video camera. The camera scans the image and generates an analog signal. The variation in the signal voltage corresponds to intensity variations in the photograph or sample being

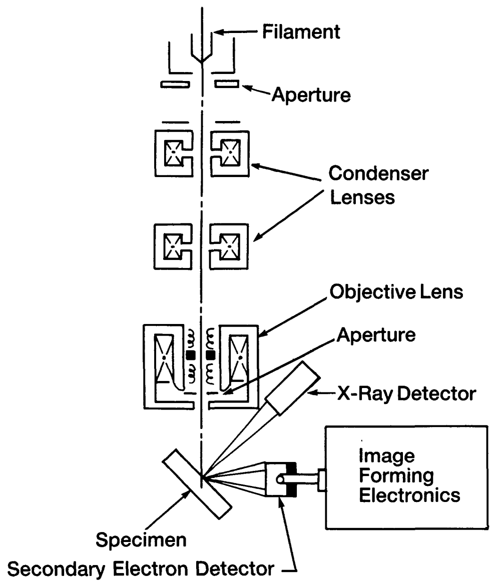

FIG. 1. Schematic drawing of a combined scanning electron microscope–microprobe analyzer.

scanned. The data can then be used to calculate particle sizes and shapes or any structural elements in the material which exhibit intensity variability.

1.2 Scanning Electron Microscopy/Electron Probe Microanalysis

All solid materials can be studied by scanning electron microscopy (SEM). Sample sizes are normally limited to < 10 cm. Information about surfaces or the surface topography is usually obtained by SEM techniques since the depth of field is far greater than that achieved in either optical or transmission electron microscopy (TEM). Resolution is about 3 nm, or about two orders of magnitude greater than with the optical microscope and one order of magnitude less than with TEM (see ELECTRON MICROSCOPY.)

In Fig. 1 is given a schematic diagram of an SEM with an electron probe microanalysis (EPMA) attachment. The EPMA attachment is indicated as the x-ray detector. The higher resolution of an SEM as compared to an optical microscope is achieved by use of an electron beam, generated by a heated filament and focused in a vacuum chamber by electromagnetic lenses. The beam is rastered over the specimen in synchronism with the beam of a cathode-ray-tube display screen. The brightness of the cathode-ray tube is modulated by the signal from a scintillator which in turn has collected electrons that have been scattered from the sample surface. The result is an image on the cathode-ray tube which represents the surface topography of the specimen.

In Fig. 2 is an SEM image of the fracture face of an optical fiber. Note the small (~1 μm) impurity inclusion which is responsible for the failure of the fiber.

When materials are bombarded by high-energy electrons (10 keV–50 eV) such as those generated in SEM, x-ray fluorescence radiation is produced by the elements in the specimen being bombarded. The elements are subsequently identified and their concentrations measured by distinguishing characteristic x-ray wavelengths. Detectors equipped with analyzing crystals can be used to detect the characteristic wavelengths based on the use of

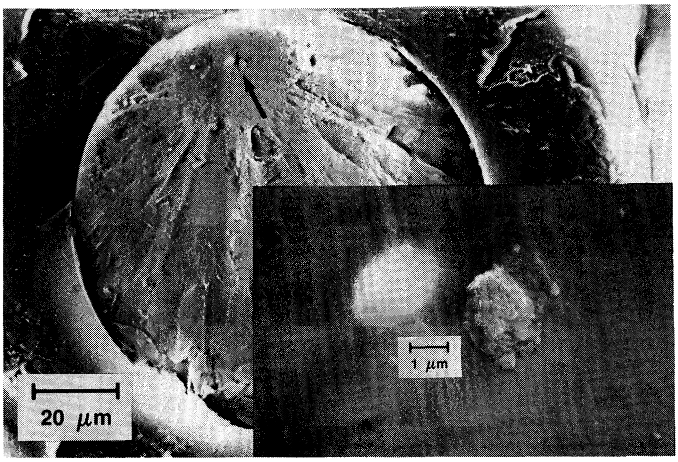

FIG. 2. Optical fiber fracture face showing inclusions responsible for failure.

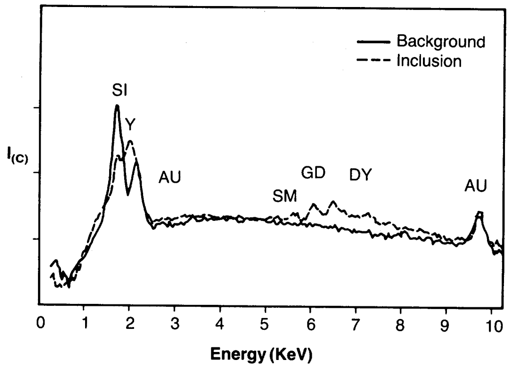

FIG. 3. Energy-dispersive x-ray spectra indicating that the inclusions shown in Fig. 2 consist of rare earth elements, and are probably in the form of complex oxides.

Bragg's law. Energy-dispersive detectors can also be used, giving a signal amplitude which is proportional to the quantum energy of the radiation and can be separated out by a suitable electronic gate. When an energy-dispersive detector is used, the intensity of the x-ray signal is plotted as a function of the energy. In Fig. 3 are EPMA energy-dispersive x-ray spectra of the elemental composition of the optical fiber (shown in Fig. 2) background and the inclusion. Note that the inclusion contains the elements Y, Sm, Gd, and Dy and is most likely a mixed oxide of the compounds.

The SEM and EPMA techniques are applied to a wide variety of materials. For example, they have been used to study the distribution of glass fibers in glass-polymer composites, the microstructure of ceramics, the nature of small spot impurities in electronic materials, the nature of fracture surfaces in composites, and the magnetic domain structures in amorphous metals.

1.3 Transmission Electron Microscopy

High resolution transmission electron microscopy (TEM) instruments have resolutions finer than 0.2 nm. Sample specimens are usually <3 mm in diameter and <0.2 μm in thickness. In TEM a collimated beam of high-energy electrons (100–400 keV) in a vacuum chamber is allowed to pass through a thin specimen. The transmitted beam can be used to project an image of the specimen on a viewing screen or photographic plate. If the transmitted beam is allowed to raster and a scintillation detection system is used then a scanning transmission electron microscope (STEM) image is obtained. When the high-energy electron beam impinges on the specimen, some of the electrons are diffracted and can be imaged on a fluorescent screen. In this way information about the crystal and compositional structure of material can also be obtained.

Bright-field and dark-field TEM images are used to study the microstructures of ceramics, metal alloys and semiconductors. Diffracted electrons (see ELECTRON DIFFRACTION) can be imaged to create an electron diffraction pattern of the material. Such a pattern is characteristic of the crystal structure at the microscopic level. Information about the orientation of microstructural features can also be obtained from electron diffraction patterns. In Fig. 4 is shown a TEM micrograph and corresponding electron-diffraction pattern of a device used as a hetero interface in the semiconductor industry. It is produced by epitaxially depositing GaAlAs layers on a GaAs substrate. Note how TEM can provide a clear measure of thickness and thickness variation of the layers. Figure 5 shows the TEM micrograph of a

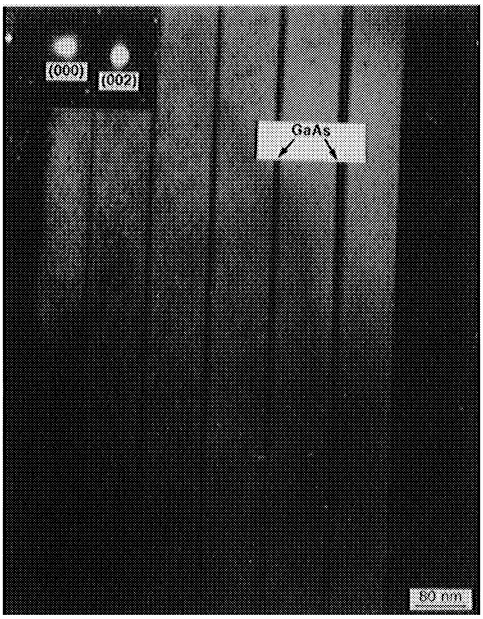

FIG. 4. Dark-field transmission electron micrograph of alternating layers of GaAs (dark)/GaAlAs (light) epilayers deposited by molecular beam epitaxy onto a GaAs substrate. Inset shows the corresponding electron diffraction pattern.

crystallized microstructure of a metal alloy. It consists of Mo/Fe/B precipitates in a Ni-rich matrix.

In general, TEM is used to study the morphology and microstructure of materials. It is used to obtain information about the particle size and particle size distribution of powders, the dispersion of one polymer phase in another, the nature of grain boundaries in metals, metal alloys, and ceramics, and the relative orientations of microstructural features.

2. SPECTROSCOPY

Some spectroscopies, similar to optical microscopy, represent some of the earliest techniques in the characterization and analysis of materials. Spectroscopic techniques can be divided into two categories. The molecular spectroscopies are those such as infrared, ultraviolet, visible, Raman, microwave, electron paramagnetic, and nuclear magnetic resonance spectroscopies which provide information about the structure of molecules. All of these spectroscopies are based on the interaction of electromagnetic radiation with molecules. The way in which the incident radiation is modified by a molecule gives specific information about the structure of the molecule (see MOLECULAR SPECTROSCOPY).

The second type of spectroscopy, atomic spectroscopy (*q.v.*), involves the breakdown of molecules in a material into their individual atoms with subsequent qualitative and quantitative analyses of the elemental contents of the material. These spectroscopies include atomic absorption (AA), emission spectrographic, flame emission, and inductively coupled plasma emission spectroscopies.

Mass spectrometry (see SPECTROMETERS, MASS) does not fall neatly into either of these categories. It can be used as both an elemental analytical technique and a molecular analytical technique. In most cases mass spectrometric analyses involves a partial breakdown of molecules through electron or ion impact and an analysis of the resulting mass fragments. A spark source can also be used on metals to provide elemental analysis. For organic materials analysis, information from mass-spectrometric techniques is similar to that obtained from the molecular spectroscopies since it provides knowledge about the molecular structure of materials. In the current work, mass spectrometry is included in the section on molecular spectroscopy since a wider number of applications appear in this context.

2.1 Molecular Spectroscopy

2.1.1 Infrared Spectroscopy Infrared (IR) spectroscopy is based on the fact that atoms in molecules vibrate at specific frequencies which are characteristic of the atoms involved, the nature of their bonding, and the nature of the molecule in general. Most of these frequencies occur in the 200- to 4000-cm^{-1} region of the spectrum, i.e., the infrared region. When infrared radiation is passed through an organic or inorganic substance, those specific incident frequencies that match the frequencies of the substance are absorbed. Therefore, if infrared frequencies are allowed to be passed through material and the resultant frequencies are scanned and detected individually, a plot of absorption intensity vs infrared frequency can be obtained. This plot is unique to a given material and can be used as a "fingerprint" of the material for identification purposes. Characteristic frequencies,

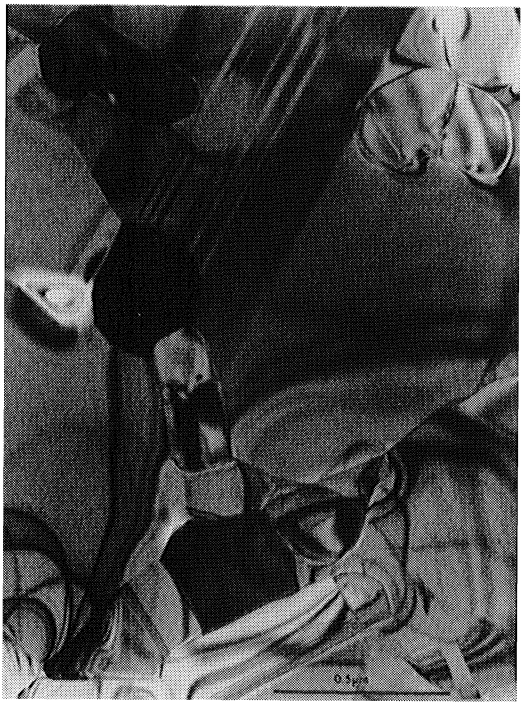

FIG. 5. Alloy 5006 microstructure showing Mo/Fe/B precipitates in a Ni-rich matrix.

usually expressed as "wave numbers" (cm^{-1}), can also give detailed information about the structural nature of the material. Quantitative measurements of the intensity can serve to give a measurement of the amount of a chemical species or amount of a compound present in a mixture. Samples are usually analyzed in the milligram range but samples as small as 50 pg can be analyzed with special techniques. Materials in the solid, liquid, or gaseous state can be analyzed. Infrared spectroscopy is used routinely to perform both quantitative and quantitative analyses on organics, inorganics, polymers, and biomaterials.

In polymers, functional groups, conformations, orientation, molecular weight, degradation, impurities, and many other characteristic features can be studied. Infrared spectroscopy has also been used to study the reaction kinetics of organic molecules, configurational structures, the nature of hydrogen bonding, and the nature of hydration in inorganics.

In Fig. 6 is given a series of spectra which illustrate an application of infrared spectroscopy to study the nature of thermal degradation in an organic fluoropolymer. When the material is heated in a vacuum at 300 °C, an absorption peak occurs which is indicative of cracking of the polymer chain with subsequent formation of a perfluorovinyl end group.The changes are quite different when the material is heated in the presence of oxygen as indicated in the bottom curve in Fig. 6. This type of information is useful in determining what happens to polymeric materials when they are subjected to degrading temperatures.

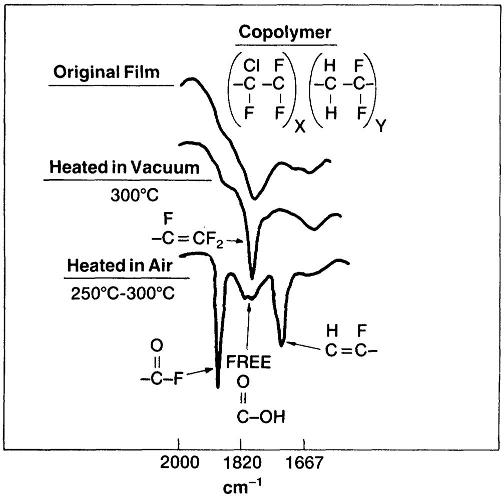

FIG. 6. Infrared spectra of thermally degraded halocarbon film.

2.1.2 Ultraviolet, Visible, and Near Infrared Spectroscopy. Spectroscopy in the broad region of the electromagnetic spectrum from about 2500 nm to <200 nm, which includes ultraviolet (UV), visible, and near-infrared (NIR) radiation, is used for both qualitative and quantitative analyses of organic, inorganic, and polymeric materials. Materials in the solid, liquid, or gaseous state can be analyzed. In some cases nanogram quantities of materials can be analyzed.

The UV region ($\sim$400 to 180 nm) and the visible region ($\sim$750 to 400 nm) provide information about the electronic transitions which occur in molecules. In particular, the techniques give information about the nature of conjugated double bonds or chromophoric groups in molecules. Generally speaking, the larger the region over which π-electron conjugation can occur, the longer the wavelength of the absorption and the more intense becomes the absorption. For example, simple alkenes absorb at about 200 nm while large dye molecules absorb very strongly in the visible region. Therefore UV–visible spectroscopy is particularly suited for analyzing aromatics and dyes at the ppm level. However, since the absorptions in the UV–visible region tend to be very broad, structural information is sometimes difficult to obtain.

The NIR region of the spectrum, like the infrared region, provides information about the molecular structure of materials based on an analysis of vibrational modes in a molecule. Absorption bands in the NIR usually arise from combinations and overtone bands which arise from fundamental vibrations in the infrared region of the spectrum. Therefore, the NIR absorptions are relatively weak compared to the IR regions. However, the region can be extremely useful for analyzing compounds containing hydrogen, since vibrations involving hydrogen atoms occur at high vibrational frequencies and extend into the near-infrared region of the electromagnetic spectrum. For example, the NIR region can be used to obtain information about bonded and unbonded -NH and -OH in compounds such as amines, amides, oximes, alcohols, and lactams.

2.1.3 Raman Spectroscopy. Raman spectroscopy, like infrared spectroscopy, can detect vibrational frequencies in a molecule. However, while infrared spectroscopy is an absorption phenomenon, Raman spectroscopy is a scattered-light phenomenon.

When an intense beam of light enters a sample, scattering can occur in all directions, with the frequency of the scattered light being the same as that of the incident light (ν_0). This effect is known as Rayleigh scattering. Another type of scattering that can occur simultaneously with the Rayleigh scattering is Raman scattering. It occurs at frequencies higher and lower than ν_0 and at much lower intensities. The differences $\Delta\nu$ between the incident and scattered frequencies are equal to the vibrational frequencies of the material. Therefore, Raman spectroscopy, like infrared provides information about the various functional groups in a molecule. However, since the selection rules governing the allowable vibrational transitions are different for the two techniques, some frequencies may be observed in the Raman spectrum which do not appear in the infrared and vice versa.

Raman spectra are usually obtained on solid or liquid materials. One advantage of Raman spectroscopy over infrared is that the spectra of materials in aqueous solutions, such as biological, organic, and inorganic compounds can be readily obtained. It is difficult to obtain usable spectra in the infrared since water absorbs too strongly, thus obscuring the spectra of dissolved species.

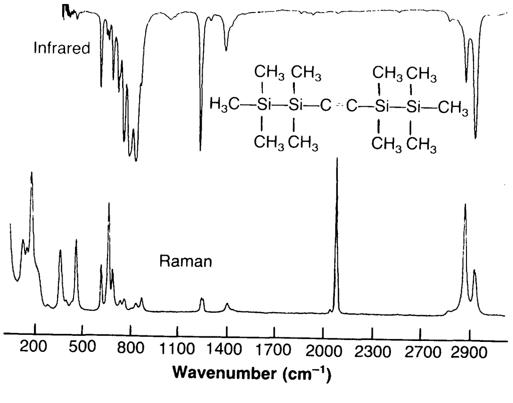

FIG. 7. Infrared and Raman spectra of bis(pentamethyldisilanyl) acetylene.

In Fig. 7 are given the infrared and Raman spectra of an organic silicone compound. The very intense infrared band at 1246 cm^{-1} is indicative of the CH_3 group on a Si atom, while the very intense band at 2092 cm^{-1} in the Raman spectra is indicative of the $-C{\equiv}C-$ group in the molecule. Note that this frequency is essentially nonexistent in the IR spectrum.

2.1.4 Nuclear Magnetic Resonance Spectroscopy. Nuclear magnetic resonance spectroscopy (NMR) (see MAGNETIC RESONANCE, NUCLEAR) is a much newer molecular structure technique than either infrared or Raman spectroscopy. However, in a relatively short time it has proven itself to be a major tool particularly in the structural analysis of organic, polymeric, and biological materials. In high-resolution NMR, structural analysis is accomplished on materials dissolved in suitable solvents. Concentrations greater than 1% are normally used.

When a material containing a nucleus with a magnetic moment is placed in a strong external magnetic field (H_0), the magnetic moment of the nucleus will begin precessing about H_0 with a frequency $\nu=\gamma H_{\text{eff}}/2\pi$, where γ is the gyromagnetic ratio of the nucleus and H_{eff} is the effective magnetic field which the nucleus "sees." When a strong radio-frequency pulse at a frequency close to ν and perpendicular to H_0 is applied, the angle of the magnetic moment with respect to H_0 will change, inducing a resonance signal which can be detected. Since H_{eff} is sensitive to the immediate environment of the nucleus in a molecule, nuclei in different environments will resonate at different frequencies. The difference between the frequency of a particular resonance peak and the frequency of a reference peak when divided by the frequency corresponding to the external magnetic field for the particular nucleus under study is called the "chemical shift." It is expressed in parts per million (ppm). Therefore, a plot of intensity of the signal as a function of chemical shift in ppm will give characteristic information about the functional groups and overall structure of a molecule.

Nuclei commonly studied in NMR are ^1H, ^{13}C, ^{19}F, ^{29}Si, and ^{31}P, although any nucleus with a magnetic moment can give rise to an

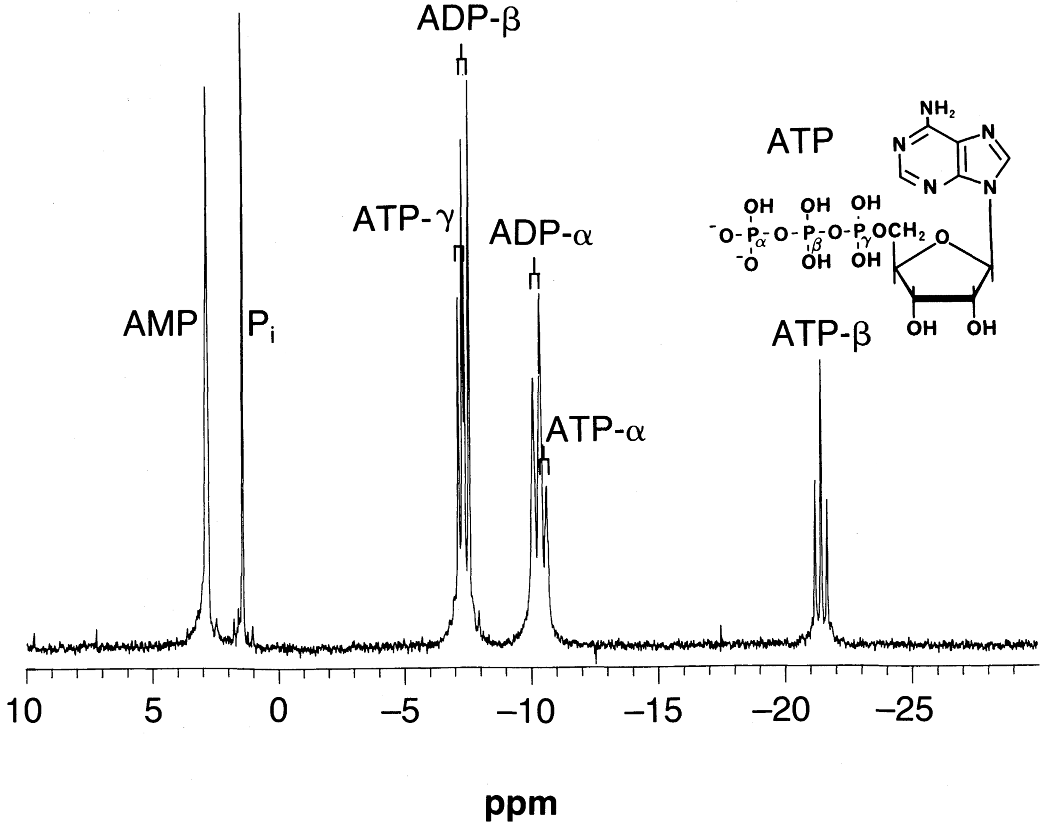

FIG. 8. ^{31}P, 162 MHz nuclear magnetic resonance spectrum of impure ATP.

NMR effect. In Fig. 8 is reproduced a ^{31}P NMR spectrum (ppm vs intensity) of adenosine triphosphate (ATP), an important component of living systems. Adenosine diphosphate (ADP), adenosine monophosphate (AMP), and inorganic phosphate are also detected in the particular sample studied. Resonance signals from the various types of phosphorus atoms are indicated. It has been more difficult to obtain detailed structural information on solids by NMR techniques. The basic principles which apply to solution NMR are applicable to solid-state NMR. However, while molecules are free to tumble and rotate in solution, which gives rise to very narrow lines, their restricted motion in solids can result in very broad noninformative spectra. The nuclei in a solid "see" the effects of the different local magnetic fields of adjacent nuclei. This causes broadening of the spectra. However, when the solid sample is rotated at very high speeds (>200 000 rpm) and at an angle of 54° 44′ (the magic angle), the solid-state interaction effects can be largely reduced and relatively narrower line spectra can be obtained. This technique, together with improvement in instrument performance, has enabled solid-state NMR to yield a wealth of new information.

Solid-state NMR has been successfully applied to the study of polymers, polymer blends, ceramics, and inorganic zeolites. In Fig. 9 is a solid-state ^{29}Si NMR spectrum of a zeolite. It clearly shows that the silicon atoms in the SiO_4 tetrahedra have different environments, i.e., different associations with the aluminum (Al) atoms in the zeolite.

2.1.5 Mass Spectrometry. Mass spectrometry is a structural technique which can be applied to the analysis of organic, organometallic, inorganic, and ionic compounds as well as polymers, ceramics, metals, and alloys. It is possible to obtain information on materials with molecular weights as high as

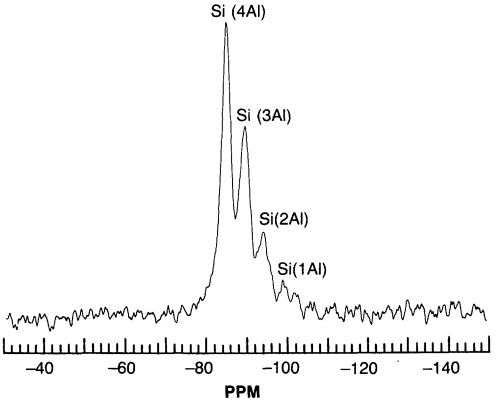

FIG. 9. ^{29}Si, 39.7 MHz solid-state nuclear magnetic resonance spectra of a zeolite.

10 000 g mol^{-1}. Liquid, gaseous, and solid samples can be analyzed.

The common mode of operation of a mass spectrometer is to produce gas-phase ions-from a sample which can then be separated according to their mass-to-charge ratio. Separations are made under high vacuum by means of electrical and magnetic fields. Gas-phase ions can be produced by using electron impact, chemical ionization, and fast-atom bombardment techniques. Other excitation techniques such as plasma discharge ionization and spark excitation are used for metals and ceramics analyses.

The most common applications of mass spectrometry are to determine elemental metal contents, to identify the structures of new materials, and to confirm the structures of known substances. Two examples are given. In Table 1 is given a computer printout of a high- resolution mass spectrum with mass measurements accurate to 0.1 millimass unit. One peak of the unknown compound had a measured mass of 251.1543 which is consistent with the empirical formula $C_{14}H_{21}NO_3$. These data along with other supporting data confirmed the organic structure as indicated. Another example involves a polymeric structure. An important piece of information in understanding the properties of polymeric materials is to know the molecular weight and molecular-weight distribution of the material. The flow characteristics, viscosity, solution properties, etc., depend on the molecular weight and molecular-weight distribution. In Fig. 10 is given the fast-atom-bombardment mass spectrum (FAB-MS) plotted as the intensity of detector response against the mass-to-charge ratio (m/z), for a polyether. In the FAB-MS technique, the surface of a liquid solution which contains the analyte is bombarded by a beam of energetic neutral atoms such as xenon. Secondary ions typical of the solvent and analyte are sputtered from the liquid surface and analyzed by the mass spectrometer. This technique is extremely useful for analyzing nonvolatile, thermally labile, and high molecular-weight compounds. From Fig. 10, both the average molecular weight and the distribution of molecular weights of the polyether can clearly be ascertained.

In many cases mass spectrometry is coupled with separation techniques such as gas or liquid chromatography. These combination techniques, GC-MS and LC-MS, have been demonstrated to be some of the most powerful methods for analysis, materials identification, and structure elucidation.

2.2 Atomic Spectroscopy

2.2.1 Atomic Absorption Spectroscopy. Atomic absorption (AA) spectroscopy is a technique for determining the concentration of metals in solution. It allows for analysis of only one element at a time. A solution of the metal to be quantitatively analyzed is first vaporized into a flame. An emission source containing the element to be analyzed emits radiation characteristic of the element which passes through the vaporized analyte element in the flame. Absorption of the specific radiation occurs which is related to the concentration of the analyte which has been vaporized into the flame. Vapor may also be formed by converting the metal to a volatile hydride as in the case of As or by cold vaporization as in the case of Hg. If a graphite furnace is used as the vaporization source, the method is known as flameless AA and the analysis is two orders of

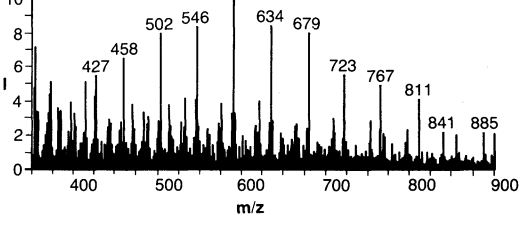

FIG. 10. Molecular-weight distribution of a commercial polyether sample by positive-ion fast-atom bombardment mass spectrometry.

```

magnitude more sensitive than when a flame is used. In Table 2 is given a comparison of the sensitivities of both flame and flameless AA techniques. These analyses are applied widely to metals, metal alloys, and trace metals in polymers and ceramic materials.

2.2.2 Inductively Coupled Plasma Spectroscopy. Inductively coupled plasma (ICP) spectroscopy, unlike AA, is an emission technique. Its chief advantage over AA is its ability to analyze many elements at one time. In ICP a solution of the analyte is atomized into a stream of a gas such as argon which passes through a radio frequency generator to create an argon plasma and excited atoms of the analyte. The excited atoms emit characteristic radiation specific to their atomic structures which in turn can be detected by photomultiplier tubes.

The limits of detection in ICP when photomultiplier tubes are used are similar to AA except for the refractory elements (e.g., boron, zirconium, and phosphorus) which are more readily determined by means of the hotter plasma source. When ICP is coupled with a mass spectrometer detection system (ICP-MS), detectabilities can be improved by several orders of magnitude. Again like AA, the method is used for trace metal analysis in polymers, metal matrixes, ceramics, and chemicals, and for determining composition of metal alloys.

2.2.3 Flame Emission and Emission Spectrographic Analysis. Flame emission spectroscopy involves excitation of atoms in a flame with subsequent emission of radiant energy specific to the elements in the flame. In emission spectrographic analyses excitation occurs through an electrical arc or a spark to produce emission from specific elements exposed to the arc or spark. In both cases the emitted frequencies from all the elements exposed are passed through a monochromator and then into a detection system which can be either photographic or electronic. Both methods allow for analysis of many elements simultaneously. However, problems in analysis can arise from overlapping frequencies when many elements are present. Arc or spark emission methods are less sensitive than AA techniques. The flame emission technique is particularly suited to the analysis of alkali and alkaline earth metals. In Table 3 are listed the detection limits for the flame method for alkali and alkaline earth metals.

Emission methods are useful for analysis of metals, elements in metal alloys, polymers, ceramics, clinical materials, and soils. In Table 4 are given the detection limits for metals by emission spectrography.

3. CHROMATOGRAPHY

Chromatography (*q.v.*) is an important part of the technology of the analysis and characterization of materials. It is the science of separating components in a mixture, identifying the components, and quantitatively measuring the amount of each component. Chromatographies are dynamic in nature. They consist of a flow of liquid or gas through a medium which has the ability to separate components and measure their concentrations with a suitable detector. Chromatography is a broad field and overlaps the field of separation sciences. However, only four types of chromatography will be covered in this section.

3.1 Gas Chromatography

Gas chromatography (GC) is used to analyze gases or those liquids and solids which can be heated to a volatile state without decomposition occurring.

Samples as small as one microliter can be analyzed at detection levels, in some cases as low as parts per billion.

In GC, a sample is vaporized into a stream of inert gas such as argon, nitrogen, or helium, and allowed to pass through a column containing a separation medium. As components in the gas are preferentially absorbed and desorbed from the separation medium or "packing," less tightly bound molecules will elute first from the column followed by those components which were more tightly bound. A variety of detectors such as thermal conductivity, flame ionization, and electron capture are commonly used to monitor the compounds as they elute from the column. The nature of the separation medium, length of the column, type of detector, flow rate of the gas, and column temperature can all be adjusted to effect the desired separations and level of detection of the components. In many cases, where a material is insufficiently volatile to be transported through a column, the material can be "derivatized" to form a more volatile species. In Fig. 11 is given a gas chromatogram of a mixture of amino acids which have been derivatized to give volatile components.

Gas chromatography is a major analytical tool in organic and bio-organic analyses, especially when used in conjunction with mass spectrometry. It is a key tool in the analysis of pollutants in our air, water, and soil. Gas chromatography is also relied upon heavily in determining impurities in plastics, especially when such impurities might migrate from food packaging plastics.

Table 3. Detection limits of alkali and alkaline earth metals by flame emission spectrometry.

Element	Limit (ppm)
Barium	0.03
Calcium	0.005
Cesium	0.005
Gallium	0.01
Indium	0.03
Lanthanum	0.1
Lithium	0.000 03
Potassium	0.001
Rubidium	0.002
Sodium	0.0001
Strontium	0.004

Table 4. Emission spectrographic detection limits.

Element	Limit (μg)	Element	Limit (μg)
Aluminum	0.05	Manganese	0.05
Barium	0.5	Molybdenum	0.05
Beryllium	0.002	Nickel	0.1
Boron	0.1	Palladium	0.02
Calcium	0.01	Silicon	0.2
Chromium	0.05	Silver	0.01
Cobalt	0.05	Tin	0.1
Copper	0.02	Titanium	0.02
Gold	0.2	Vanadium	0.05
Iron	0.1	Zirconium	0.05
Lead	0.2		

3.2 Liquid Chromatography

Liquid chromatography (LC) is particularly useful for analysis of liquids and solutions of solids when such materials cannot be analyzed by gas chromatography because of their thermal instability. Like gas chromatography, it can be coupled with mass spectrometry. Sensitivities are in the ppm range, sometimes extending to the ppb range. The carrier phase in LC is a liquid which is forced under pressure through a suitably packed column. Early column materials were silica and alumina. Other columns consist of a support material to which is bound a material in which the solute components have some degree of solubility. Separation is effected by a partitioning of solute molecules between the liquid mobile phase and the solid stationary phase. Detection systems are more limited than those available in gas chromatography. Ultraviolet absorption and index of refraction are two commonly used detection systems.

Liquid chromatography can be used for analysis of over 80% of known organic compounds, whereas gas chromatography is limited to analysis of only about 20%. Therefore, although gas chromatography is a very rapid and reliable analytical technique, it is limited in scope because of the requirement that samples be volatile. On the other hand, liquid chromatography is much more flexible and can lend itself to analysis of such nonvolatile species as macromolecules, ionic species, and biological and natural product materials.

3.3 Ion Chromatography

Ion chromatography (IC) is used for qualitative and quantitative analyses of ionic species in complex mixtures. Liquids and solids can be analyzed after dissolution in deionized water. Gases which produce ionic species in water can also be analyzed. Under some conditions ionic species can be detected and measured at the parts per billion level.

Ion exchange columns are used to effect the chromatographic separations with sodium bicarbonate/sodium carbonate as an eluent for anions and dilute nitric acid as an eluent for cations. An electrical conductivity detector is most commonly used while ultraviolet/visible and amperometric detectors can also be used.

It is possible to separate and analyze transition metals by forming complexes with acid such as oxalic, citric, tartaric, and isobutyric. The selectivity and sensitivity of the method is dependent on the type of metal, its oxidation state, the complexing agent, and the *p*H. In general, ion chromatography allows for the separation and detection of a wide variety of ionic species. Some of these are F^-, Br^- NO_3^-, SO_3^{-2}, SO_4^{-2}, PO_4^{-3}, AsO_4^{-3}, SeO_4^{-2}, the alkali and alkaline earth metals, transition and lanthanide metals, ammonium and low molecular weight amines, quaternary ammonium compounds, weak organic acids, aliphatic and aromatic sulfonic acids, carbohydrates, and amino acids. Ion chromatography has been extremely useful in determining ionic concentrations in pickling baths, plating baths, and electrolysis solutions.

3.4 Gel Permeation Chromatography

Gel permeation chromatography is a technique which separates molecules by size. It is particularly useful for determining the molecular weight and molecular-weight distributions of polymeric materials. Low-molecular-weight species such as oligomers and additives can also be separated and analyzed by gel permeation chromatographic techniques.

Size separation is accomplished by passing a solution of a solid or liquid polymer through a column containing a semiporous or gel-like packing. Cross-linked polystyrene gel or porous silica is commonly used as a packing material. Separation is effected when smaller molecules are trapped in the pores or openings in the gel structure and larger molecules pass more quickly around the pores through channels in the packing material. Since the packing materials can contain a distribution of pore sizes, the polymer molecules will likewise be separated into a distribution based on their sizes. Larger molecules will elute first since their paths have been least restricted, while the smaller, more readily trapped molecules will take a longer time to elute from the column. Refractive index detectors are most commonly used. However, ultraviolet absorption, infrared absorption, and light scattering detectors are also used.

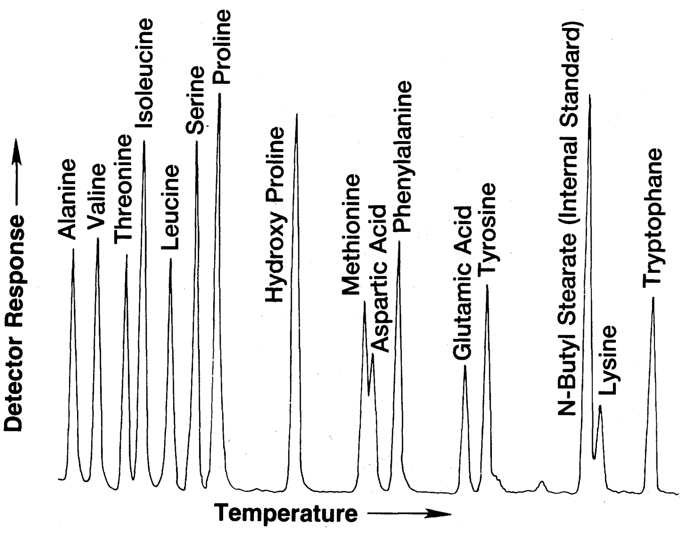

FIG. 11. Gas chromatogram of *n*-butyl esters of trifluoroacetylated amino acids.

In Fig. 12 are given the gel permeation chromatograms of two different styrene vinylbenzyl chloride copolymers. The elution times can be calibrated with molecular weights by first eluting polymers of known molecular weights. Note in the figure that the polymers are of different molecular weights. One polymer has a peak elution time of about 20 min corresponding to a peak molecular weight of about 700 000, while the other polymer has a peak elution time of about 23 min corresponding to a peak molecular weight of about 100 000. Some differences in the molecular-weight distributions of the polymers are also noted. The molecular weight and molecular-weight distribution are important properties of polymers which affect both their processibility and their end-use properties.

4. THERMAL ANALYSIS

Thermal analysis is a general term for a series of techniques all involving the measurement of changes which occur in materials when subjected to heat. The simplest of these is thermogravimetry (TG), which measures the weight change of a material as it is heated. In addition to TG there are other techniques which include differential scanning calorimetry (DSC), thermomechanical analysis (TMA), and dynamic mechanical analysis (DMA). Many other techniques such as thermal conductivity, dielectric thermal analysis, and dilatometry (which is a vital tool used by metallurgists for determining phase transitions), while also important in the characterization of materials, will not be included in the present article. The reader is referred to more general references for further detail and a discussion of these and other related subjects.

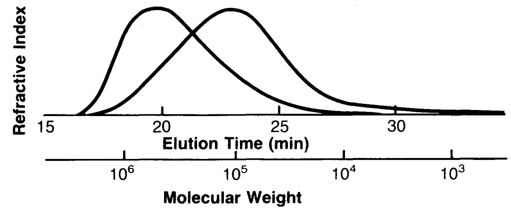

FIG. 12. Gel permeation chromatograms of styrene vinylbenzyl chloride copolymers.

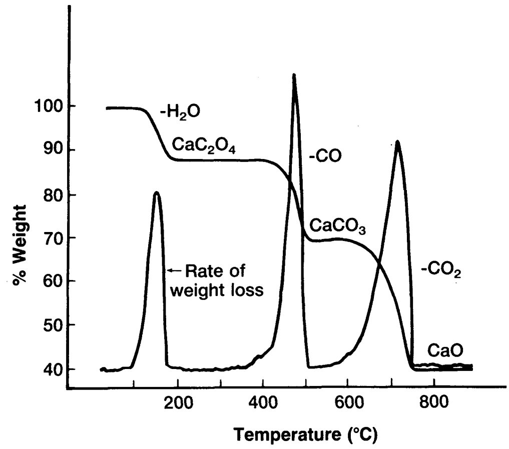

FIG. 13. Calcium oxalate monohydrate ($CaC_2O_4 \cdot H_2O$). TG in nitrogen (10 °C/min heating rate).

4.1 Thermogravimetry

Thermogravimetry (TG) is a technique to measure automatically the weight change as a material is heated either isothermally or in a programmed manner. The sample is placed on a very sensitive balance which is contained in an oven. Weight changes in the sample are recorded as the temperature of the oven is increased.

Thermogravimetry is particularly useful for understanding the thermal stability of materials. However, many other applications such as residue analysis, volatile contents, materials composition, and purity analysis are conducted on a routine basis. Materials such as polymers, metals, and ceramics can be heated in a variety of atmospheres (including vacuum and reactive gases) up to 2400 °C. If a TG instrument is coupled with a mass spectrometer, the composition of the volatiles emitted during degradation and volatilization can be detected. Sample amounts as small as 1 mg can be studied by this technique.

In Fig. 13 is given an example of a thermogravimetric analysis of a chemical compound, calcium oxalate monohydrate. The dehydration and decomposition is clearly seen to take place in three steps when the sample weight is plotted against the temperature of the sample at a heating rate of 10 °C/min. The last transition occurs about 700 °C, the final state of the sample at 800 °C being CaO.

If a magnet is placed around a sample which is suspended from a balance and if the sample is ferromagnetic, then a characteristic of the material called the Curie temperature can be obtained as the sample is heated. The Curie temperature defines a change in state of the material from ferromagnetic to paramagnetic. When a sample is originally placed above the magnetic field, an apparent weight gain is noted as the sample is pulled down into the magnetic field. At this point the instrument is set so that the observed weight is recorded as 100%. As the temperature is raised, the sample loses its ferromagnetism and an apparent "weight loss" begins to occur. In Fig. 14 is shown the "apparent" weight changes which occur as an amorphous metal alloy is heated up to temperatures of 900 °C. At about 400 °C, the Curie temperature, a sharp loss in apparent weight is noted. Other magnetic changes also occur in the material as devitrification or crystallization of the amorphous metal occurs at temperatures above 400 °C.

4.2 Differential Scanning Calorimetry

Differential scanning calorimetry (DSC) involves heating a sample along with a thermally inert reference material and measuring the relative heat changes that occur in the sample during the heating process. The most common heat change normally observed is the melting transition of a crystalline material which results in an absorption of heat or energy relative to the inert standard. It is observed as an endothermic peak in the thermogram. The reverse phenomenon, crystallization, which occurs upon cooling a crystallizable sample from the melt, manifests itself as a release of heat and is observed as an exothermic peak.

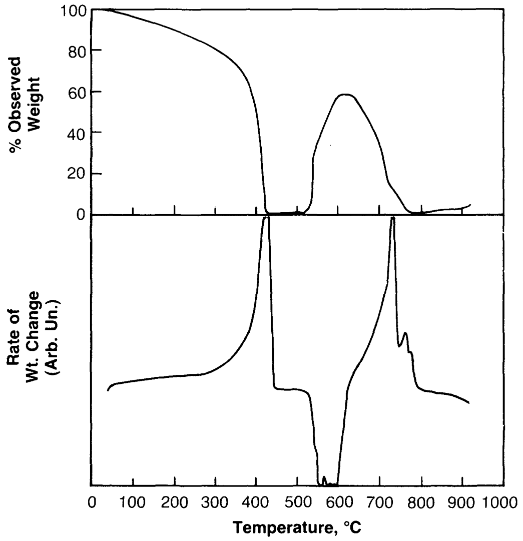

FIG. 14. Thermogravimetry of amorphous $Fe_{78}B_{17}Si_5$ in a magnetic field.

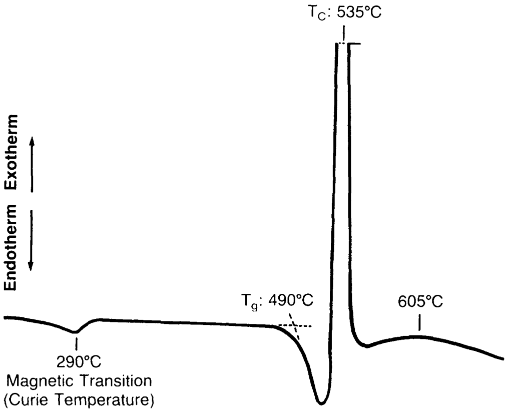

FIG. 15. Differential scanning calorimetric curve of an amorphous metal alloy heated in argon (20 °C/min heating rate).

Materials can undergo many other heat-sensitive changes which can be detectable by DSC. Loss of volatiles, the glass transition, multiple crystal phase transitions, degradation processes, melting of impurities, and melting of blends and alloys are other commonly observed phenomena of the DSC technique. All materials undergo changes when heated; therefore, the DSC technique is widely used and generally applicable.

In Fig. 15 is the thermogram of an amorphous metal alloy. The Curie temperature, previously described in the section on thermogravimetry, is accompanied by an endothermic heat change which occurs in this material at 290 °C. The temperature of the onset of large-scale molecular mobility, the glass transition temperature (T_g), is observed at 490 °C. Crystallization is evident with the sharp exotherm at 535 °C and the broader exotherm at 605 °C, indicating multiple or complex crystallization for this material.

The DSC technique is widely used in the characterization of polymers, composites, and blends. In Fig. 16 is given the thermogram of poly(ethylene terephthalate). The glass transition (T_g), crystallization (T_c), and melting (T_m) temperatures are all clearly indicated. In some cases the amount of heat absorbed during the melting process of a semicrystal-

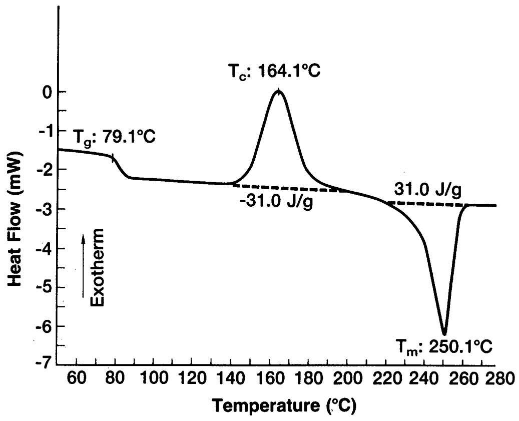

FIG. 16. Differential scanning calorimetry of poly(ethylene terephthalate) in argon (20 °C/min heating rate).

line polymer can be used as a measure of the crystallinity of the polymer when it is compared to the heat of fusion of the 100% crystalline material. However, care must be taken in this analysis since materials can crystallize during the heating process. In this case the melting endotherm does not represent the original crystallinity of the material.

4.3 Thermomechanical Analysis

Thermomechanical analysis (TMA) can give information, like dilatometry, about the dimensional changes which occur in a material when it is heated. Coefficients of expansion and shrinkage performance, two important characteristic of materials can readily be determined by TMA techniques.

Samples can be in the form of fibers, rods, plaques, bars, and even powders. In the TMA experiment, a sample is in contact with a rod-like probe whose motion can be detected as the sample is heated and undergoes contraction or expansion. The motion of the rod is detected and translated into an electrical signal by means of a linear variable differential transformer. The temperature range in TMA is from −150 to 1500 °C. The technique is used whenever information is needed about the dimensional stability of a material in a particular temperature range.

4.4 Dynamic Mechanical Analysis

The dynamic mechanical analysis technique provides information about the viscoelastic properties of materials as a function of temperature and time. A constant oscillating stress, at a frequency in the range of 0.01–200 Hz, is applied to the sample at strains of 0.03%–1.5% while the temperature is raised in a controlled manner. Samples are usually of the order of about 25 to 5000 μm thick and can be in the form of films, foils, sheets, or fibers.

A number of viscoelastic parameters can be obtained from DMA. One parameter is the dynamic (elastic) modulus (E') of a material. The dynamic modulus is an important measure of the stiffness of a polymer. It is important to know this parameter, e.g., for designing polymer-graphite composites. In Fig. 17 are given the plots of $\log E'$ as a function of temperature for graphite composites with three different polymer matrices. A second parameter, the dynamic loss (viscous) modulus E'' can also be obtained. The dissipation or damping factor, $\tan\delta = E''/E'$, is used as a measure of the damping characteristic of a material.

5. X-RAY ANALYSIS

There are a variety of techniques which utilize x rays to characterize and analyze materials. X-ray fluorescence spectroscopy (XRF) is a nondestructive qualitative and quantitative technique for elemental analysis. X-ray diffraction analysis (XRD) is used to determine the molecular structure of materials. These two techniques will be discussed in the following sections.

There are a variety of other x-ray techniques, such as x-ray absorption and small-angle x-ray scattering, which will not be included in the current article but which are

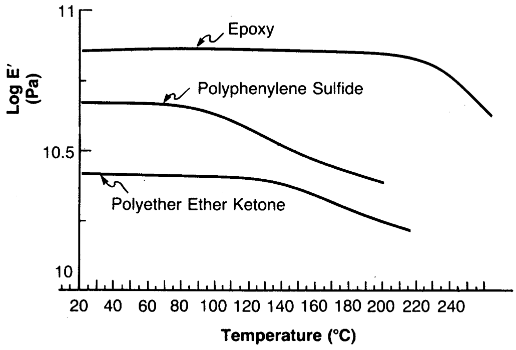

FIG. 17. Dynamic mechanical analysis of graphite fiber composites.

sufficiently important to be included as further reading in the references.

5.1 X-Ray Fluorescence Spectroscopy

X-ray fluorescence (XRF) (see INTERACTION OF SOLIDS WITH PARTICLES AND RADIATION) is a relatively simple, nondestructive technique for elemental analysis. Samples can be liquid or solid, and as little as milligram quantities is sufficient for analysis in many cases. The XRF technique is based on the principle that if a material is bombarded by a high-energy source, such as electrons or photons, some of the electrons in the atoms of the material will be ejected. As other electrons fill the vacated energy levels, quanta of radiation, characteristic of the atom, are emitted. Such quanta, in the form of x rays, can be detected by either a wavelength-dispersive x-ray fluorescence (WDXF) spectrometer or an energy-dispersive x-ray fluorescence (EDXF) spectrometer. In WDXF a crystal is used to separate the energies and a detector such as a scintillation counter is used to measure the intensity of the x rays as a function of energy, since different energies are associated with different wavelengths and thus different angles. In EDXF, a solid-state detector is used which has an inherent ability to separate the energies without any mechanical movement. The development of computers and accompanying software have been instrumental in improving the accuracy and precision of the data. The same techniques are applied at the microscopic level and are described in the section on electron probe microanalysis.

In Fig. 18 is given a plot of the lower limit of detection (LLD) as a function of atomic number for a WDXF detector and two different EDXF detectors. It is possible to detect and analyze all elements down to boron with the lower limit of detection, in some cases, down to several ppm.

5.2 X-Ray Diffraction Analysis

X-ray diffraction (*q.v.*) is one of the most important tools in characterizing the crystalline nature of materials. If a beam of monochromatic x radiation is directed at a crystalline material, then diffraction of the x-ray beam can occur. The relationship between the wavelength of the x-ray beam (λ), the angle of diffraction 2θ, and the distance between each set of atomic planes of the crystal lattice d is given by the well-known Bragg equation $n\lambda = 2d \sin\theta$, where n represents the order of diffraction. From this equation the interplanar distances can be calculated. By an analysis of the intensity of the x-ray scattering from the various crystalline planes, it is possible to reconstruct the total molecular structure of the crystalline material.

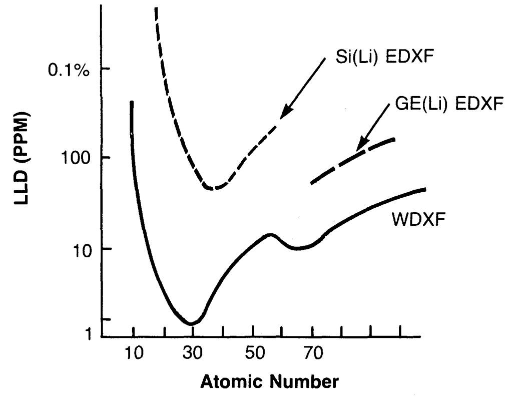

FIG. 18. Lower limits of detectability of elements with various x-ray fluorescence detectors.

For the purposes of the current article, x-ray diffraction analysis is divided into three areas: single-crystal analysis, powder diffraction techniques, and analysis of partially crystalline, partially oriented polymer materials. Single-crystal x-ray diffraction analysis is now a mature, well-defined methodology. Crystal structure of most metal alloys, inorganics, ceramics, and even complex organic and biochemical compounds can be determined in relatively short times (see CRYSTALLOGRAPHY). These techniques will not be described in this article but references are provided for further reading on the subject.

5.2.1 X-Ray Powder Diffraction. X-ray powder diffraction is used to obtain information about the structure, composition, purity, and state of polycrystalline materials. Materials to be analyzed can be powders, bulk solids, films, or ribbons. Sample sizes should be at least of the order of grams, although in some cases information can be obtained on milligram quantities. The powder x-ray pattern of a crystalline material, like its infrared spectra, can be used as a fingerprint, unique to that material alone. The Joint Committee on Powder Diffraction Standards has published the diffraction patterns of some 50 000 compounds. An unknown compound can be identified by comparing its interplanar spacings and intensities with those in the powder diffraction standards file. When elemental data on the material is added, such as that obtained from atomic absorption (AA) or emission or x-ray fluorescence (XRF) analysis, the number of patterns involved in the search can be reduced. The composition of compounds in mixtures of up to nine compounds can be determined for compounds present at concentrations greater than 1%. Computer methods have greatly facilitated these comparisons.

In Fig. 19 is given the powder diffraction pattern of an "unknown" inorganic material. A computer search reveals two stick diagrams, whose combined pattern matches the unknown. In this case the material in question is found to be a mixture of Al_2O_3 and AlN.

In addition to making identification of crystalline materials, powder diffraction techniques can also provide information on the crystallite size, the degree of crystal perfection, the degree of crystallinity in poorly crystallized metals and ceramics, and many other crystal state characteristics. In Fig. 20 is given the diffraction pattern of zirconia which has been partially stabilized with yttria. By use of an on-line least-squares program, the diffraction pattern has been deconvoluted to yield information about the various phases that are present.

5.2.2 X-Ray Diffraction of Polymers. X-ray diffraction analysis of polymers requires special attention because of the many unique features of polymers. Although there are many techniques such as IR, NMR, and DSC which can provide information about molecular ordering or crystallinity in polymers, XRD can be considered the definitive technique because it directly measures the three-dimensional relationship between molecules in polymeric crystals. XRD can provide information about the degree of crystallinity, crystallite sizes, degree of crystal perfection, orientation

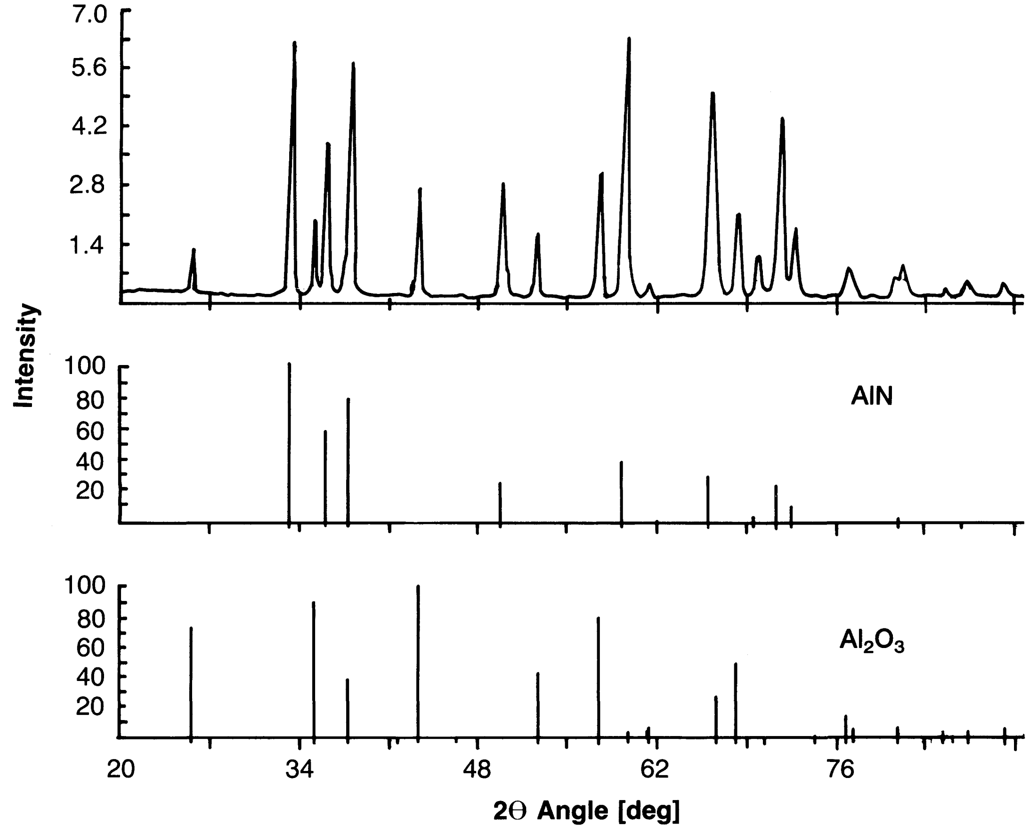

FIG. 19. Results of computer-assisted x-ray diffraction phase identification of a two-component system.

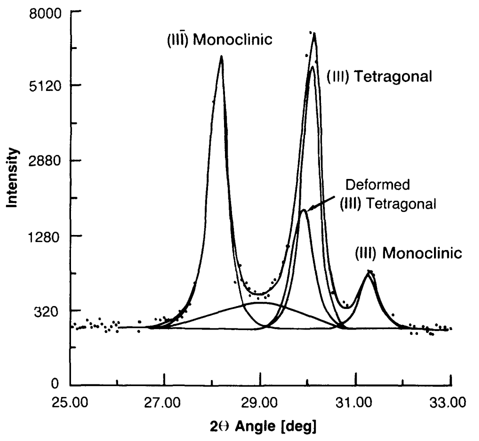

FIG. 20. Deconvolution of x-ray diffraction patterns of tetragonal and monoclinic phases in a $Zr(Y)O_2$ ceramic.

of the crystallites, and phase composition in polymorphic materials. Information has also been obtained in the amorphous state in both amorphous and semicrystalline polymers by XRD techniques. Materials to be examined by XRD can be in the form of fibers, films, plaques, pellets, powders, and even gels.

In Figs. 21(a) and 21(b) are given the diffraction patterns from an oriented fiber of Nylon 6. The photographic insert illustrates that the fiber is partially oriented and partially crystalline. By deconvolution of the patterns in Figs. 21(a) and 21(b), it is possible to determine the phase contents of the α and γ phases, the amount of amorphous phase (AM), the overall crystallinity, and the orientation of the different phases.

6. SURFACE ANALYSIS

The surface properties of materials play a large role in their performance. Oxidation and corrosion on metal surfaces can initiate bulk failure in the metal or metal alloy. Surface properties such as smoothness, adhesion, printability, wettability, friction, and wear are important for products such as molded plastics, plastic films, ceramics, and composite materials used in the automotive and aircraft industries. Surface properties of components are extremely important in the electronics and optical electronics fields. Since the importance of surface properties is clearly recognized, then attention must be focused on the means to measure and understand surface properties and surface phenomenon.

In this section a variety of surface analytical techniques will be described and their utilization discussed. Auger electron microscopy, x-ray photoelectron spectroscopy, Rutherford backscattering, electron energy-loss spectroscopy, secondary-ion mass spectrometry, scanning tunneling microscopy, atomic force microscopy, and electron diffraction techniques will be discussed. Again the reader is directed to additional readings since surface science is a broad field encompassing many techniques and disciplines, only some of which will be covered in this article.

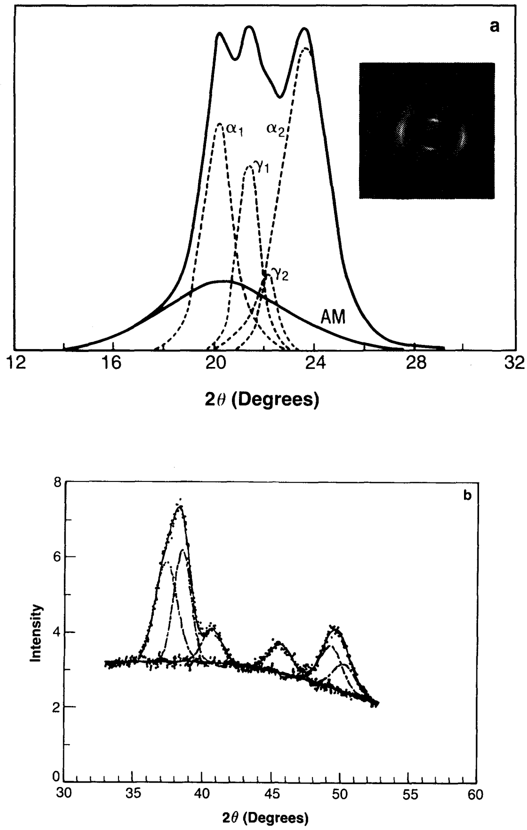

FIG. 21. Equatorial scan of an oriented nylon-6 fiber. (a) The pattern for 2θ from 15° to 30° resolved into α, γ, and amorphous components. The α form has two reflections at ~20.3° and ~23.5°; the γ has two reflections at ~21.3° and ~22.5°. (b) The higher angle equatorial scan of an α-rich fiber resolved into six individual reflections. Inset: The corresponding diffraction photograph of the fiber.

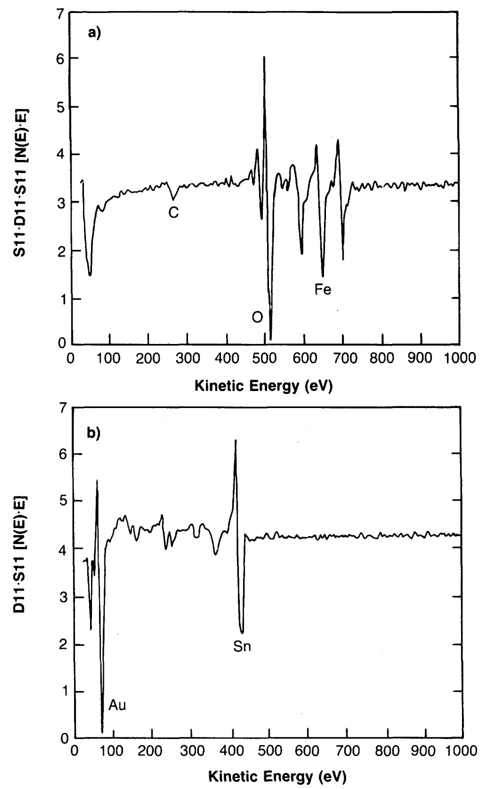

FIG. 22. Scanning Auger microanalysis of blue tarnish on a metal preform (a) initially and (b) after Ar ion sputtering.

6.1 Scanning Auger Microscopy

Scanning Auger microscopy (SAM) is a technique for determining the elemental composition of surfaces. Surfaces can be probed to depths of 1–5 nm, with spot analyses on the order of 100 nm. Sample sizes can range from a few millimeters up to about a square centimeter.

The source in an Auger spectrometer is a finely focused electron beam contained along with the sample in a high-vacuum chamber. When the electron beam impinges on a material, core-level electrons can be ejected from atoms in the material creating a core hole. An electron from a higher energy level can then fall into the core vacancy. The energy of this transition can be released by characteristic x rays or by the ejection of a second (Auger) electron. The Auger electron then passes into a detection system which determines the number of electrons and their kinetic energies. Metals and ceramics are readily analyzed by Auger microscopy; but the high-energy electron source causes degradation of polymeric materials, making analysis of these materials problematical by this method. Depth profiling can be accomplished by ion sputtering away the surface and determining the elemental composition at various sputtering times or depths into the sample.

One of the advantages of SAM over other surface techniques is its high spatial resolution. An example of this is shown in Figs. 22(a) and 22(b). The problem was to determine the cause of tarnishing of a Au/Sn alloy which was bonded to a Au-plated substrate containing iron. An Auger elemental scan of the tarnished area [Fig. 22(a)] revealed that C, O, and Fe were the only elements present on the surface. After argon-ion sputtering of the surface, the contaminants were removed and only a clear Au/Sn surface was revealed [Fig. 22(b)]. It was concluded that the tarnish was due to Fe which had migrated from the substrate to form an oxide layer of about 100 nm in thickness.

Another application of SAM is elemental mapping. Contamination of surfaces in the semiconductor industry is a serious problem. An example where SAM was able to identify the cause of such a contamination is given in Fig. 23. During fabrication of semiconductor wafers, a dark stain was noted on the aluminum bonding pads used to bond wire leads to the internal circuitry. An elemental fluorine map of the bonding pad area clearly showed the presence of fluorine as a contaminant on the bonding pad surface.

6.2 X-Ray Photoelectron Spectroscopy

X-ray photoelectron spectroscopy (XPS), also named electron spectroscopy for chemical analysis (ESCA), is a technique for probing the surfaces of materials at depths of 2–5 nm (see PHOTOEMISSION AND PHOTOELECTRON SPECTRA). It differs from Auger spectroscopy in that it is possible to determine the oxidation or valence states of atoms as well as detect their presence.

The excitation source in XPS is x-ray photons rather than electrons as in Auger spectroscopy. When such photons impinge on the surface of a material, photoelectrons in turn are emitted from the surface atoms of the material. These photoelectrons originate from discrete electronic energy levels associated

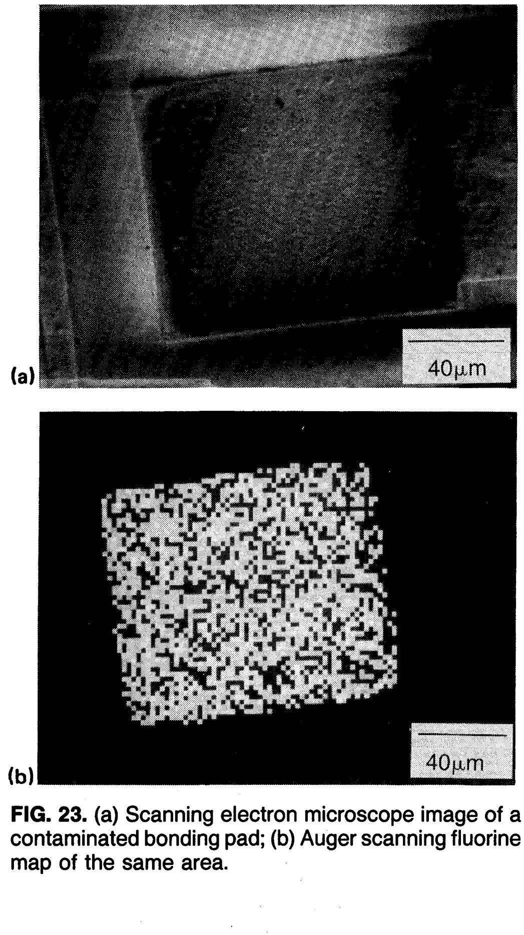

FIG. 23. (a) Scanning electron microscope image of a contaminated bonding pad; (b) Auger scanning fluorine map of the same area.

with these atoms that are unique and characteristic of the atoms. Since these energy levels can be dependent on the oxidation state and/or the electronic state of the atoms, the emitted photoelectrons can in turn give information about the local electronic environment. For example, it is possible to detect the difference between Mo in such compounds as Mo^0, MoS_2, and MoO_3, and the difference in elements in mixed oxidation states such as F_3O_4 (Fe^{2+} and Fe^{3+}) and Pb_3O_4 (Pb^{2+} and Pb^{4+}).

While the high energy of the source electrons in Auger spectroscopy prevents analysis of organic materials, materials such as organic polymers are readily analyzed by XPS. In addition XPS is applicable to metals, alloys, inorganics, and ceramics. In Fig. 24 is given an example of how XPS is used to solve an adhesion problem. The problem involved delamination of a fluoropolymer film from an epoxy-impregnated backing-board composite. The delaminated area reveals the presence of nitrogen and an alteration in the strength of the fluorine signal from that of the bonded area. These data suggested that an amine curing agent migrated from the backing to react with the fluoropolymer at the interface to cause delamination. In Fig. 25 is given an example of how XPS is used to solve a surface wetting problem. The wettability of Pb–In–Ag foils was found to change upon aging. Two major changes were noted upon aging. The lead oxide layer was thicker in the aged material and In, as evidenced by the $3d_{5/2}$ transition line, had migrated to the surface. Both these factors can affect the surface wettability.

6.3 Secondary-Ion Mass Spectrometry

Secondary-ion mass spectrometry (SIMS) can provide surface information on areas ranging from several square millimeters down to the submicron level. Any solid material can be studied with sample size usually limited to slightly less than 1 cm^2 and extending to as small as several micrometers.

In contrast to Auger spectroscopy where excitation is caused by electrons, and XPS where excitation is caused by x-ray photons, SIMS uses energetic ions as the excitation source. Ions such as He^+, Ar^+, and Xe^+ or metal ions can be used which in turn cause ejection of secondary ions from the sample surface. The ejected ions are detected and analyzed by a quadrupole mass spectrometer.

When noble gas ions are used the probe diameters are between about 1 mm and 10

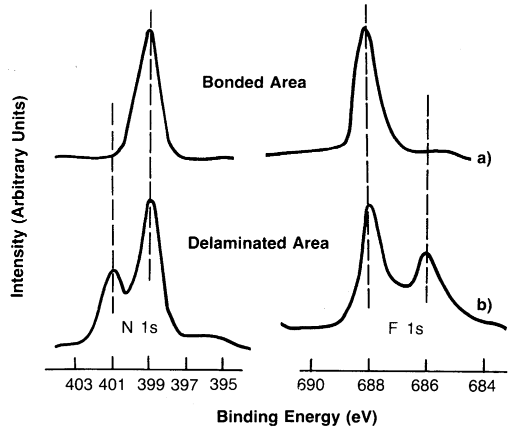

FIG. 24. The N 1*s* and F 1*s* spectra associated with (a) bonded and (b) delaminated areas of a composite board.

μm. However, if a liquid metal ion (LMI) source such as Cs or Ga is used, probe diameters < 50 nm may be achieved.

Both conducting and nonconducting materials can be studied by the SIMS techniques. Metals, ceramics, inorganic catalysts, and polymers can all be studied by SIMS. In Fig. 26 is an example where SIMS is used to detect contaminants on an integrated-circuit chip which could not be detected by Auger spectroscopy. SIMS was able to show that the contaminated surface had a much higher concentration of Na, Li, K, and B atoms, which affected the electrical performance of the chip.

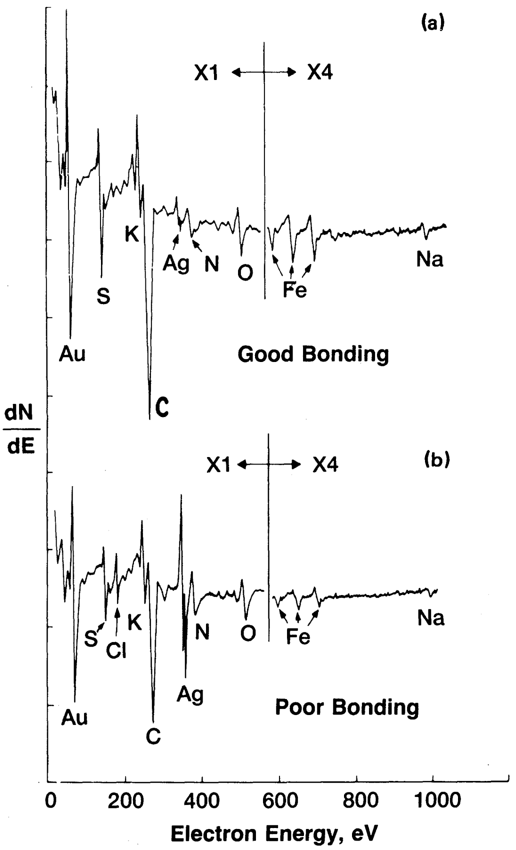

FIG. 26. Secondary-ion mass spectrometry spectra of deposited SiO_2 layers for (a) control sample and (b) contaminated sample. (Reprinted from PHI Application Note, 1979 with permission of the Perkin Elmer Corporation.)

6.4 Rutherford Backscattering

When a beam of energetic ions strikes a solid surface, the change in energy of the backscattered ions is characteristic of the nature of the solid. The intensity of the scattered beam, determined by a suitable detector, is related to the number of atoms doing the scattering and to the depth of penetration, which can be varied by altering the velocity of the exciting ions. Therefore, the method can be quantitative.

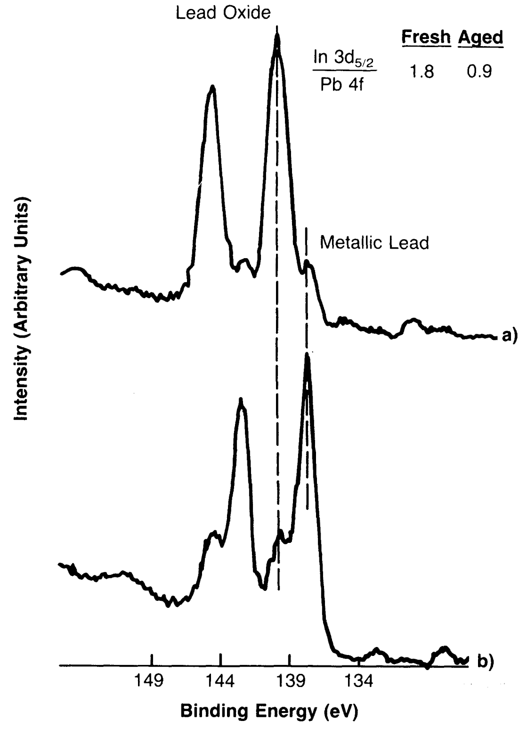

FIG. 25. Typical Pb 4*f* x-ray photoelectron spectra for (a) aged and (b) fresh Pb–In–Ag foil.

He^+ is the most generally used ion although H^+ may be used if deeper penetration into the sample is desired; or C^+, N^+, or O^+ can be used as source ions if greater mass separation is needed. The method can be used to determine the identity of a surface contaminant if the atomic mass of the contaminant is greater than that of the substrate. The technique has been useful in the identification of contaminants of heavy atoms on the surface of solid-state devices, such as might occur after etching, anodizing, or chemical treating.

Rutherford backscattering is also a good technique for determining the thickness of thin films deposited on surfaces, as might occur in chemical vapor deposition or plasma deposition processes. Such measurements have been made for gold, copper, aluminum, and silicon deposited on graphite surfaces. When a surface has been chemically altered, e.g., by oxidation or nitriding, the thickness and composition of the surface layer can be determined.

In general, Rutherford backscattering is applicable to the analysis of impurities which exist in a thin layer either on or within a few hundred nanometers of the surface, when the impurities are of greater atomic mass than the substrate, and when the amount of impurities is not too great.

6.5 Electron Energy-Loss Spectroscopy

In electron energy-loss spectroscopy (EELS), an energetic beam of electrons passes through a thin sample and interacts with it. The loss of energy of the transmitted electrons provides information about the chemical, physical, and electrical nature of the sample. EELS can be accomplished by the addition of an electron energy analyzer after the sample in a conventional STEM or TEM. Sample requirements are similar to those for conventional TEM.

A typical EELS spectrum will consist of three regions. They are a zero-loss region (~ 0 eV), a low-loss region (< 50 eV), and a core-loss region (> 50 eV).The unscattered transmitted beam accounts for most of the zero-loss region, and plasmons and interband and intraband transitions of the outer atomic electrons account for the low-loss region. The core-loss region is the most useful analytical portion of the spectrum and arises from transitions of the core electrons to states above the Fermi level. For lighter elements EELS has an advantage over energy-dispersive x-ray fluorescence spectroscopy. The elemental composition can be quantified by measuring the intensity of the edge signals. In addition the shape of the energy-loss spectral edge will depend upon the chemical and crystallographic environment of the atoms in the sample. For example, different types of carbon, i.e., graphite, diamond, and amorphous carbon, are readily distinguishable by EELS.

6.6 Scanning Tunneling and Atomic Force Microscopy

Scanning tunneling microscopy (STM) (*q.v.*), atomic force microscopy (AFM), and a number of other similar techniques are used to study the morphology and the microstructure of surfaces at the atomic level. The STM technique is based on the use of a tungsten or platinum stylus which is passed over the surface of a relatively flat conductive material. If a potential difference is maintained between the stylus and the specimen and the stylus is scanned very close to the surface, a current will be generated since electrons from the specimen can "tunnel" their way across the gap between the surface of the specimen and the tip of the stylus. As the stylus is traversed over the surface in a constant-current mode, it will experience upward and downward motions corresponding to the surface topography at the atomic level. The motion of the stylus can be sensed by a transducer, the signals from which can be converted into a contour map of the surface. There is also a constant-z mode in which the vertical position of the stylus is maintained constant and the varying current is monitored. In Fig. 27 is shown a contour STM map of the surface of graphite. The resolution is such that a single-atom defect in the surface is clearly shown.

In atomic force microscopy a sharpened stylus, attached to a cantilever, is scanned across a surface. As the stylus is scanned across the sample, the electronic forces between the stylus tip and the surface atoms cause a deflection of the cantilever. These deflections can be monitored in a number of ways, such as by interferometry or by use of a laser beam. A map of the deflections results in a map of the surface topography or morphology at the atomic level. The AFM technique can also be modified to respond to a sample's magnetic field (magnetic force microscopy) or to electric charges on the surface (electrostatic force microscopy).

STM, AFM, and related techniques are used to study the atomic structure on crystal surfaces, cleaved crystal surfaces, and thin films of semiconductors, metals, or biological specimens which have been deposited on suitable substrates.

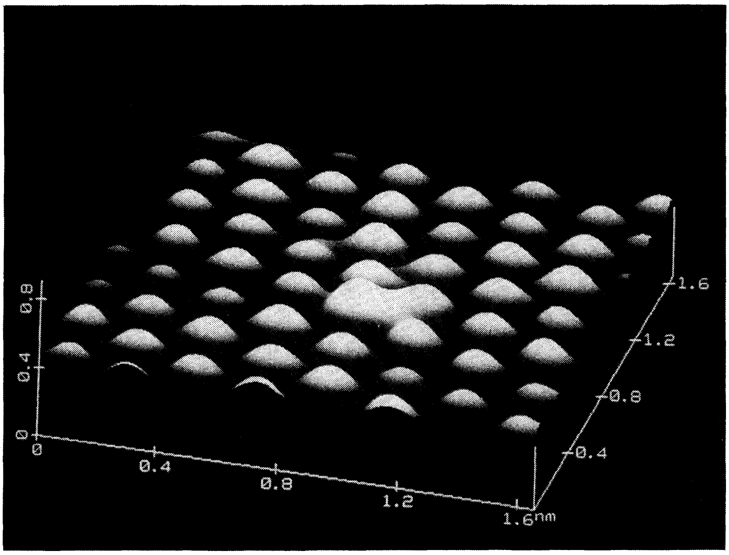

FIG. 27. A single-atom defect in graphite demonstrating the resolution of subtle atomic structures achievable with STM. (Reprinted from Nanoscope II 1990 Bulletin, with permission of Digital Instruments, Inc.)

6.7 Low-Energy Electron Diffraction and Reflection High-Energy Electron Diffraction

Low-energy electron diffraction (LEED) is based on the principle that slow electrons are mainly reflected by the first few atomic layers. Electrons with energies in the range of 10 to 500 eV impinge on a sample at normal incidence and the backscattered electrons which have been diffracted from the first few atomic layers can form a diffraction pattern on a fluorescent screen. In reflection high-energy electron diffraction (RHEED), the high-energy (~ 10 keV) beam impinges on the sample at a glancing angle and the reflected diffracted electrons are collected by a detector such as a photographic plate. The electron diffraction patterns obtained by LEED and RHEED are obtained on solid samples and are essentially the same as those obtained in transmission electron microscopy where electron energies of several hundred keV are used (see ELECTRON DIFFRACTION).

Surfaces must be carefully prepared by polishing, cleaving, or depositing such that appropriate crystal faces and orientations are obtained. Surfaces must also be free of all contaminants. Procedures such as annealing in vacuum, using an oxidizing or reducing atmosphere, or ion beam etching can be used to clean surfaces. Auger spectroscopy is often used in combination with LEED to monitor cleanliness of the surface. LEED provides similar information to RHEED; however, in some cases one technique is more applicable than the other. For example, LEED can determine atomic positions (to 0.01 nm) more readily than RHEED, while three-dimensional surface structures are more readily determined by RHEED.

In general, LEED and RHEED are used to identify surface compositions by measurement of lattice parameters, determine surface crystallography and microstructure, and measure dynamic processes such as surface crystal growth. The techniques have been applied to semiconductors, metals, alloys, catalysts, graphite, mica, and alkali halides. The location and arrangements of atoms on the surface of crystals is very important to the understanding of phenomena such as absorption, vapor deposition, and chemical and catalytic activity.

GLOSSARY

Atomic Spectroscopy: The field of science which involves the qualitative and quantitative elemental analysis of materials on the basis of the frequencies of light that they emit or absorb.

Electron Microscopy: A series of high-resolution microscope techniques based on the principle of the interaction of electrons with materials.

Image Analysis: The analysis of the particle shapes and sizes or morphology of material surfaces accomplished either directly or from a photograph, based on the difference in light contrast in the various features of the sample.

Molecular Spectroscopy: The field of science dealing with the molecular structure of materials as determined from the interaction of the material with electromagnetic radiation.

Morphology: The manner in which molecules are arranged in a material to form larger species such as crystallites, lamellae, grains, etc.

Surface Analysis: The science of examining surface features of materials at probing depths down to 1 nm and at atomic level resolutions.

Thermal Analysis: A series of techniques which can measure the weight loss, heat change, and mechanical property changes which occur in a material when it is heated under controlled conditions.

16.1
Introduction

Chemical analysis is the study and practice of learning about the elemental and molecular compositions of materials. The materials analyzed include all the natural and synthesized materials of the contemporary world as well as perhaps less obvious materials such as the components of flames or the materials at the atomic layer that indicates the interface among liquids, solids, and gases. The practice of chemical analysis involves all of the following: deciding on the various techniques that should be used; proving that the techniques do, indeed, provide the expected information under the conditions present; and demonstrating that the chemical content that is found does, in fact, answer the germane questions. In other words, contemporary chemical analysis invokes the use of the principles of chemistry that describe chemical behavior and structures, the applications of physics to design the instruments used for measurements, and the tools of statistics and logic to weave the technology to societal desires.

16.2
Choosing the Analytical Methods

The great majority of materials are chemically complicated; this means that they generally are composed of a large number (up to millions) of different elements and molecular species. Materials may be solids, liquids, gases, solutions, glasses, flames, and other forms of matter such as rubbers and gels. When one does an analysis to determine the amounts of species and their identities, the work implicitly includes the necessity of proof. Chemical analysis is, then, the study and practice of learning about materials – their elemental and/or molecular composition – and the tools of statistics and logic to determine the level of certainty in the results. Chemical analysis can also involve determining the spatial distribution of chemical species on the surface of or within a material.

A specific element or compound that is being assayed is called an *analyte*. To determine the presence of one or more analytes and the levels at which they are present requires a series of methods of

analysis; this series is called the *methodology* or *protocol of the analysis*.

In Table 16.1, some of the assay techniques that are used for various types of analyses are indicated. This classification is quite rough, and should be understood to be neither exclusive nor complete.

16.2.1
Standards and Validation

Chemical analysis is usually carried out by indirect measurements such as mass, time, volume, and voltage. Such values are converted into measurement of content through calibration. In this sense, to calibrate means to ascertain the relationship between the content of the sample and the response found with the assay method.

As a result, an extremely important requirement is to demonstrate that any analytical procedure measures what the analyst says it measures on a specific type of sample. This is called *validation of the analytical method*. Validation generally means that the methodology must first produce correct results on accepted standards. Chemical standards are pure substances, mixtures, solutions, gases, or materials such as alloys or biological substances that are used to calibrate and determine the validity of each step of a methodology. These steps are sampling, sample preparation for the assay, choice of assay method(s), and statistical treatment of the data to determine the level of certainty in the result. This set of techniques making up the chemical analysis constitute the metrology of chemical analysis, which is covered in greater detail in a separate article in the Encyclopedia of Applied Physics.

16.2.2
Precision, Bias, and Accuracy

We can describe the difference between the precision and the accuracy of results in chemical analysis with the following analogy. Consider a target in which the bull's-eye at the center is analogous to the true result of an analysis. In shooting at the target, we might find that we have a number of hits clustered far off of the bull's-eye. The shooting is, then, precise, but has a bias. The precision of the results from a series of samples of the same material indicates how close they are to each other, that is, the reproducibility. The value of the precision does not describe the bias of the methodology, which is only determined with the aid of standards. Only if the results are closely clustered (labeled as *low imprecision*), and when the bias can be eliminated, does the average of the results lie in or near to the bull's-eye (the ''truth''). The analysis is then said to be *accurate*. Presenting a statistical uncertainty in the measured result is an essential part of the process, for example, 2.53 ± 0.04 ng.

16.2.3
Interferences and Representative Samples

The necessity for proof of a measurement of some analyte in, for example, a semiconductor or the air over a city results from the fact that no method of analysis, whether based on specific chemical reactions or those of applied physics, is free from interferences. Interferences (or interferents) are elements and compounds that are not only being measured but are also present in the material (in this context called the *matrix*) that cause, to some extent, a change in the measurement of the analyte. In other words, the measured quantity of analyte alone (say, in pure water) may not be equal to the same quantity measured in the presence of an interferent (say, in seawater).

The second problem is that the sample that is measured may not truly represent the material that is being analyzed. If one is analyzing for certain organic compounds in, say, a lake, then a decision must be made whether to sample from the mud at the bottom, the sand at the shore, and/or water at different locations and depths. It is highly likely that the organic compounds are not evenly distributed, and some care must be taken on how to report the results.

16.2.4
Destructive and Nondestructive Analyses

Another point to consider in any kind of analysis is whether or not the sample is to be destroyed. For instance, it is doubtful whether we would want to dissolve a priceless Egyptian statuette in acid in order to determine the brass formulation. To keep a sample intact, or cause no unacceptable change in its properties, it is necessary to use nondestructive analytical methods. The material may be modified on the atomic or molecular level to some extent, but otherwise the modification is undetectable. To cause as small a change as possible in the original sample, nondestructive tests are carried out with assay methods that are also used for microanalyses or trace analyses. One method that is useful for both micro- and trace analyses is neutron activation analysis (NAA). Two other microanalytical techniques are the electron microprobe and X-ray photoelectron spectroscopy (XPES, also called *electron spectroscopy for chemical analysis* or *ESCA*). In addition, a number of spectroscopic methods that only require collecting light reflected from the surface can be used to test nondestructively, for example, the composition of paints.

A larger number of techniques require destruction of the sample. Any methodology that requires the digestion with acid or other homogenizing methods must be classified as a destructive analytical methodology. A middle ground in classification arises when a small enough sample is needed for analysis so that sufficient material can be collected, say, from drilling a small pit in an obscure place on a valuable object. The method used for analysis might be destructive, but the sample is so small that the object is essentially intact.

16.2.5
Sample Classification by Size and Analyte Level

The size of a laboratory sample should not be confused with the concentration level of analyte in a sample. A descriptive classification scheme for these two properties is presented in Figure 16.1. The sample masses are divided into macro and micro with a vague boundary. The concentrations range from major through minor to trace

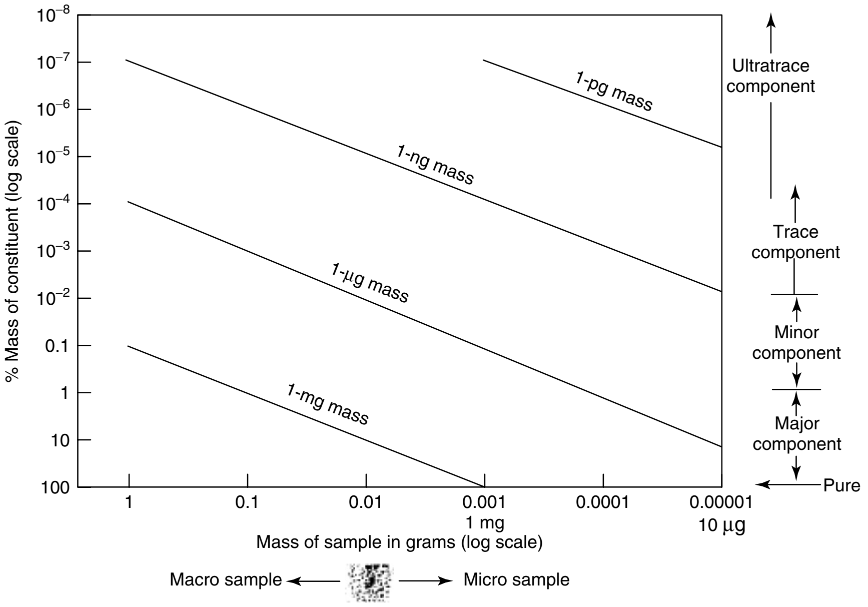

Fig. 16.1 Illustration showing the names given to the ranges of sample size and ranges of analyte content. The horizontal axis has a logarithmic scale of sample size. On the vertical axis is a logarithmic scale of the percentage by weight of a constituent in a sample. The diagonal lines correspond to the mass of the analyzed component. Samples are classified by the relative amount of an element or compound in it. The component can range from major (1–100%), through minor (0.01–1%) and trace (less than 0.01% = 100 ppm), to ultratrace (in the range of parts per 10^9 or less). (Modified from Sandell, 1959.)

and ultratrace. The figure caption contains further details.

When reading the analytical literature of trace and ultratrace analysis, everyone should be aware of a dichotomy in the nomenclature parts per billion (ppb) and parts per trillion (pptr). One group (primarily in the United States) ppb is parts in 10^9, and pptr is parts in 10^{12}, while for another group (primarily Europe) ppb is parts in 10^{12}, and pptr is parts per 10^{18}.

When the content of a component decreases into the parts per million (ppm) range and lower, eliminating interferences from the sample matrix becomes more difficult. As a result, disagreements among laboratories may increase until meaningful exchanges of information on content are not possible. An illustration of the trend is shown in Figure 16.2.

During analyses of trace components, every reagent, such as an acid used to dissolve a solid, must contribute as little interference as possible. Even the containers made of glass or plastic can contaminate solution samples. Such contributions of interfering species is one of the reasons for the trends shown in Figure 16.2. Analyses at the lowest concentration levels require that the laboratory spaces in which samples are handled be clean and filled with filtered air, and that reagents are highly pure and are stored in special containers. At these levels, even the containers that carry the samples to the laboratory must be clean and tested for suitability for the specific sample and for the assay to be run.

16.2.6
Sensitivity and Detection Limit

Two terms that are closely associated with measurements in trace and microanalyses are the sensitivity and the detection limit. The definitions of these terms in a chemical context are similar to our everyday language. If an instrument or other assay methods is more sensitive, it is able to measure smaller changes in content or concentration. *Sensitivity* is defined as the change in response for a given change in concentration or amount; a larger number means the method is more sensitive.

The detection limit is a numerical indication of the level (either concentration or mass) below which we cannot ascertain whether some analyte is present or not. Detection limits of methodologies are extrapolated from experiments done under optimized conditions. (See Table 16.2 for

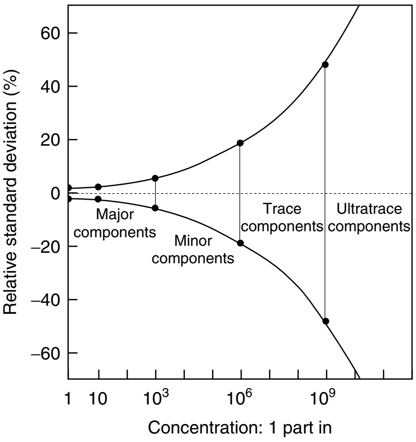

Fig. 16.2 When comparing results among analysts and among different laboratories, a tendency exists to exhibit an increase in the uncertainty of the results with decreasing concentrations of analyte. The horizontal axis is a logarithmic plot of relative concentration (ppb is parts in 10^9, pptr is parts in 10^{12}); the vertical axis is the percent relative standard deviation of the results, a common measure of uncertainty. This plot shows a general trend that has been demonstrated, not a result for a specific analyte or method. (Derived from Horwitz, 1982.)

[a] As a result of historical practices, the detection limits and characteristic concentrations are calculated in a variety of ways depending on the assay method involved. The detection limits and characteristic concentrations apply to ideal samples. This means that the samples have no untoward matrix effects and no interferences. The values reported here are for samples directly assayed by the various methods without any preconcentration, which means without making the analyte more concentrated by, for example, evaporating solvent prior to the measurement. For realistic samples, detection limits are about 100 times higher than those noted here.

Key

A blank value (–) means either not a method for trace (less than ppm) analysis of the element or not reported.

MAS: Molecular absorption spectrometry in conjunction with colorimetric reagents. The values correspond to an absorbance of 0.025 for a 1-cm path length with a sample consumption of 1 ml.

DPP: Differential pulse polarography, assuming a sample consumption of 10 ml.

ASV: Anodic stripping voltammetry, with a sample size of 10 ml and a plating time of 10 minutes. Various media are used for electrodes. Ni and Co are determined by cathodic stripping of their oxides on Pt.

AAS: Atomic absorption spectrophotometry, with flame atomization and pneumatic nebulizer. The values correspond to an absorbance of 0.0025 with a 10-cm path and a 1-ml sample.

ETA–AAS: Electrothermal atomization–atomic absorption spectrometry. The values correspond to an absorbance of 0.025 with a 50-µl sample.

ICP–ES: Inductively coupled plasma–emission spectrophotometry. Values are for a pneumatic nebulizer.

ICP/MS: Inductively coupled plasma/mass spectrometry. This is with 10-seconds integration. All ions determined in the positive-ion mode.

NAA: Neutron activation analysis, with a sample volume of 100µl, thermal neutron flux of 10^{12} n cm^{-2} s^{-1}, and irradiation time of 10 hours followed by immediate counting.

XRF: X-ray fluorescence spectrometry, with a dispersive instrument for a sample of 1 ml over a surface area of 7–9 cm^2.

Sources: Commission on Microchemical Techniques and Trace Analysis (1982) and Morrison (1979). Manufacturer's literature for ICP/MS.

examples of analyses of the elements.) As a result, detection limits for more typical samples and conditions are factors of 10 to hundreds greater than those in the table. However, the values in the table apply more broadly. Reading across the table, the smaller the value of the detection limit generally means that the associated method will be more effective for that element at any concentration. Another term that is similar to detection limit is the characteristic concentration. More details are in the table notes.

16.2.7

Imaging, Hyphenated, and Multidimensional Techniques

In a simple color photograph, the picture can be considered to be a two-dimensional distribution (or map) of colors and their levels of brightness at each point or pixel (short for picture element). A similar map can be made for the response of a chemical measurement on the surface of a material. For example, the different responses of separate zinc and tin crystallites in an alloy could be mapped in two dimensions and a picture of the microscopic structural distributions recorded and analyzed. Another example would be to determine a full color analysis (a spectrum) for each pixel of the image of a material surface. Both these examples are called *spectral imaging*, and the latter, with the full spectra recorded, is also called *hyperspectral imaging*. Additionally, by recording a series of adjacent slices parallel to the surface, a three-dimensional map of the content can be constructed.

Hyphenated methods – also called *integrated* or *combination methods* – provide powerful tools by combining different analytical techniques. Examples are combining a separation of sample components (Section 16.7) by, for example, gas chromatography (GC) followed by identification and quantitation of each separated component using, for example, mass spectrometry (MS) (Section 16.5). The total process is called *gas chromatography–mass spectrometry* and (*GC–MS*) or *GCMS*.

A technique is multidimensional when a similar technique is used two or more times in sequence. In an example of separations, for instance, where different chemical components of a sample are separated in time, ‘‘slices’’ of this output are taken and each further separated with different conditions. Multidimensional methods differ from hyphenated ones in that the second level of analysis is similar in kind to the first. One example of two-dimensional chromatographies has samples that can physically be run on a square plate, first in one dimension and then perpendicular to that. Another example is two-dimensional GC, which is often abbreviated GC–GC or GC×GC, where each time slice of the first separation is relaunched into a second separation. A final example is MS, where molecules from samples are separated by their masses, and each of the masses produced can be chemically broken down by colliding it with inert gas atoms, and the fragments then analyzed by MS. This set of operations is called *two-dimensional MS*, or *two-dimensional* MS^2. In addition, the process can be repeated yet again on the second set of fragments, which results in the analysis of the fragments of the fragments: the overall measurement is labeled MS^3.

Finally, the multidimensional analysis can be part of a hyphenated or of an imaging method. A hyphenated method that has a multidimensional part includes GC–MS^2. Also, an image of organic molecules on a surface might be obtained by scanning the surface with a laser to desorb the molecules and observe the location-dependent material by MS or MS^2.

One common facet of imaging, hyphenated, and multidimensional methods is that they produce huge amounts of data. Fast computers and efficient algorithms are needed to process and make sense of this flood of data.

16.3
Assay Methods Based on Known Specific Chemical Reactions

The three types of assay methods described in this section – gravimetric, titration, and kinetic – are based on various specific chemical reactions that occur between a specific chemical form of the analyte and a chemical reagent that is added. In most cases, the reactions are done in a homogeneous solution, although some kinetic methods may be based on gas-phase processes. On the whole, these techniques are not inherently highly specific. An exception to the relative lack of specificity occurs when assaying for the total acid content of a solution by determining the quantity of hydrogen ion, H^+. This assay is relatively straightforward by titration.

16.3.1
Gravimetric Methods

Gravimetric analysis, as its name suggests, depends on a measurement of weight to determine the quantity of analyte in a sample. Because of the capabilities of weighing technology, the working precision of gravimetric analyses might be in the range of 1 part in 10 000 and, in special cases, 1 part in 100 000. However, the chemical purity and inhomogeneity of weighed materials limit the precisions of gravimetric analyses to 0.1–0.3%.

There are a number of different gravimetric assay methods. One of these is electrodeposition or electrogravimetry. This technique involves the electrochemical conversion of metal ions in solution into the metallic form which plates out onto an electrode. (Electrodes are electrical conductors such as platinum, gold, graphite, or electrically conducting polymers.) The amount of metal present is then found by the difference in weight of the electrode before and after the plating operation. Electrogravimetry is generally used to determine the quantity of a specific, known metal – for example, cadmium or zinc – in a macrosample. It can be highly precise (better than ±0.02%) and accurate. However, for routine determinations, when somewhat lower precision is needed (in the range ±0.2 to ±1%), the method has been supplanted significantly by spectroscopic methods such as atomic absorption (AA) (see Section 16.4.3.4).

A second gravimetric method involves measuring a sample's changes in mass upon heating at a controlled rate in a controlled atmosphere. This is called *thermogravimetry* (*TG*). Uses for TG include determining the water content of numerous types of samples and determining the carbon and ash content of coal. This technique is described further in Section 16.9.

A third technology for gravimetric determinations is to ‘‘weigh'' changes in material deposited on a vibrating surface. A piezoelectric material (one that deforms with the application of a voltage across it) is vibrated at an ultrasonic frequency which is a resonant vibration frequency of the system. (The resonant vibration frequency is the frequency at which the solid would vibrate freely if hit sharply.) Since the resonant frequency changes when mass is added or removed from the surface of the device, the measurement of the frequency change provides a measure of mass. A number of different methods are used to produce the vibrating surface, a surface acoustic wave (SAW). Among the materials used is a quartz crystal that distorts under the influence of a voltage across it, which is used in a quartz crystal microbalance (QCM) that can be used both in air and submerged in a liquid.

16.3.2
Titrations

For a titration assay, a volume of a standardized solution (one of known concentration of the reagent) is added to a solution containing an unknown amount of analyte in order to ascertain the quantity of analyte in the solution. When the standardized reagent solution is added to the analyte solution, the correct term to describe the process is a volumetric titrimetric assay. The chemistry of the reaction between the analyte and the titrant must be relatively specific and well understood.

All titrations require a technique to indicate the equivalence point – the point when the standardized titrant has just finished reacting with all of the analyte that was present. At the equivalence point, the volume of the titrant (the solution added) can be related to the quantity of the analyte. However, to discern the equivalence point some physical change must be observed. The center of that change is the end point of the titration. Ideally, the end point and the equivalence point coincide. The measurement of the end point may be done by any technique that is sensitive to the disappearance of the analyte and the changes in the solution that occur because of that fact.

A number of different types of reactions fulfill the requirements for titrations. These are as follows:

1. reactions of acids with bases;
2. reactions in which one species is oxidized (one or more electrons removed) and one reduced (one or more electrons added) – these are called *oxidation–reduction reactions*;
3. reactions in which a precipitate is formed from two or more soluble species;
4. reactions in which a coordination complex is formed (a coordination complex is a soluble species formed when two separate, soluble ions or molecules bind tightly together in solution); and
5. reactions in which tightly bound stable polymer pairs (the analyte polymer and the reactant polymer) or colloids are formed. Colloids are stable, small agglomerations of molecules that do not settle out of solution.

Titration is not a method used for trace analysis. In general, the lower limit for the use of titration for precise determinations is for solutions containing approximately one-tenth of a milligram of the analyte. The amount and precision of titrant addition are not a problem. Contemporary automatic titrators can add tens of microliters with volumes known to better than a microliter. Overall, imprecision in the range of ±0.1% is possible with moderate care using well-calibrated titrants.

16.3.3
Analyses Based on Chemical Kinetics

Kinetics is the area of chemistry in which the rates of reactions between reagents are studied. Kinetic methods of analysis are those in which analyte content is found by measuring the rate of a chemical reaction. The analyte can have one of the following two different chemical actions:

1. The analyte reacts with the reagent and is transformed in the reaction. This is called the *direct kinetic method*.
2. The analyte acts as a catalyst for a reaction. This is called the *catalytic method*. (A catalyst is a material that speeds the rate of chemical reaction between other reactants but is not itself used up.)

Experimentally, there is little difference between the direct and catalytic methods. The rates of reaction must be determined under a set of standard, reproducible conditions. The rates are determined by monitoring the change in the reagent or product concentrations over time. Often, spectroscopic methods are chosen to follow the reaction, for example the increase or decrease in concentration of a colored material. The time dependence is then related to the initial concentration of the analyte. The great majority of kinetic assays are run in solution. Usually good temperature control is required.

There are four possible reasons for developing kinetic assays.

1. Kinetic assays can be extraordinarily specific. Assays based on enzyme reactions are examples. Often, only a few species that are similar in chemical structure to the analyte will interfere.
2. Kinetic assays also can be quite sensitive and, thus, useful for trace analysis. For example, in a catalytic kinetic assay, the analyte as catalyst can produce many times its concentration in some product.
3. Kinetic assays can be used when the rate of a reaction is so slow that waiting for equilibrium to be reached would be impractical. The rate of reaction itself can be observed relatively quickly.
4. A useful assay reaction might be irreversible: equilibrium cannot be attained. Nevertheless, the rate of reaction can be observed to quantify the analyte.

Since all chemical and biochemical clinical and diagnostic methods that use enzymes as reagents are kinetic methods, the majority of all chemical and instrumental analyses are, in fact, carried out using kinetic methods since millions of clinical analyses are run every day.

16.4
Spectrometric Assay Methods

16.4.1
Fundamentals

The measurement of the absorption and emission of light by materials is called *spectrophotometry*. Spectrophotometry is usually shortened to spectroscopy or spectrometry. The latter term is used here. In spectrometry, the words absorption and emission have the same meaning that they have in everyday use. Absorption means to take up, and emission means to give off. In spectrometry, the word ‘‘light’’ is used as a general term for electromagnetic radiation (simply because it is less cumbersome than ‘‘electromagnetic radiation’’), and we use light as a generic term here.

Spectrometry can be used to assay both the elemental and molecular content of materials. The instruments that are used in spectrometry are referred to as *spectrophotometers* or *spectrometers*, the former associated more with light that is visible to our eyes. The term spectrometer is more common and is used here. The two fundamental variables that are measured in all spectrometric assays are the wavelength or frequency of the radiation and the amount of power at the wavelength. This is called the *spectrum* of the material in some range of wavelength.

Light energy will be absorbed (and/or emitted) by a specific chemical species in a sample only over certain wavelength ranges; at other wavelengths, the species will be transparent (or not emitting). The wavelength at which the energy is absorbed or emitted is a characteristic property of the specific chemical species and not the amount of material. This wavelength property gives spectrometry a measure of chemical specificity. In uncomplicated cases, changes in measured power – or, alternatively, ‘‘brightness’’ or light intensity – are proportional to changes in the amount of the species that interacts with (or produces) the light at the characteristic wavelength(s). As a result, measurement of the power at these characteristic wavelengths allows quantitative analysis of that analyte. This is the basis for all analytical spectrometry.

Because of the different spectra for different species, instead of separating analytes physically, the wavelengths of light associated with each may be measured separately, if the wavelengths do not overlap. Atomic emission spectrometry (AES) utilizes this property. In other cases, the spectra of components in a mixture do overlap. However, the total spectrum can often be separated into contributions from each species present, and the mixture components quantitated without separating them physically.

16.4.1.1 Energy in Spectrometry

An atom or molecule can take up energy from and give off energy to its surroundings in the following three forms: (i) as light; (ii) as heat; and (iii) as kinetic energy (the velocity) of any emitted particles such as electrons.

Different names are given to the spectrometries depending on the form of energy that impinges on the atoms or molecules and the form(s) that leave. These general names are listed in Table 16.3. The first two entries are emission and absorption. In the third, the luminescence can be divided into two types: fluorescence and phosphorescence. On an experimental basis, these can be separated by the differences in time over which emission takes place. When a phosphorescent material is illuminated, the emission may persist for an appreciable time after the illumination is removed. The fluorescence emission ceases virtually immediately. Phosphorescence is usually observed in the ultraviolet–visible range. Fluorescence is used analytically in the infrared, visible, ultraviolet, and X-ray regions. The last but one entry in Table 16.3 relates to electron emission. This is called the *photoelectric effect*, and is the basis for a number of electron spectroscopies, which are most important in the analysis of surfaces.

Tab. 16.3 The transformations of light energy interacting with atoms or molecules.

Energy in as	Energy out as	Spectrometry
Heat	Light	Emission
Light	Heat	Absorption
Light	Light	Phosphorescence, fluorescence
Light	Moving electrons	Photoelectron spectroscopies
Bonding energy	Light	Chemiluminescence

16.4.2
General Types of Spectrometry

Experimental spectrometry can be classified into three general types depending on the components of the spectrometers and their relative geometries. These three classifications are emission spectrometry (ES), absorption spectrometry, and fluorescence spectrometry.

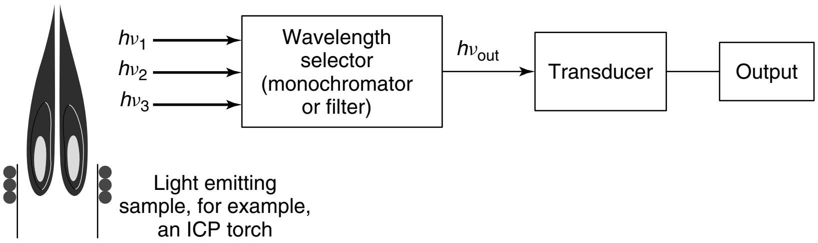
16.4.2.1 Emission Spectrometry

A generalized representation of the equipment used in ES is shown in Figure 16.3. Emission from the sample itself provides the light, and the amount of light emitted at an analyte's characteristic wavelengths is a function of the analyte concentration. The illustration shows the light originating from a luminous flame, but gas discharges, such as are seen in a neon sign, can be used as well. In a few special cases, the energy is introduced from chemical-bond rearrangements; this is chemiluminescence, see the last entry in Table 16.3.

The transducer (a less general term is the detector) converts the light into a signal that we can relate to the concentration of the analyte. A common property of such transducers is that they respond to a range of wavelengths. For example, a transducer for the visible region responds to light of a wide range of colors – much wider than the emissions from specific analytes. Each analyte's emissions are produced at a set of relatively narrow ranges of wavelengths. To measure this set of emissions, each of these narrow ranges of wavelengths must be separated so they can be measured individually. For convenience, each narrow range of wavelength may be referred to as a *single wavelength*,that is, monochromatic, and the device used to isolate these single wavelengths of the spectrum is a monochromator. In ES, the monochromator is placed between the emitting sample and the transducer. Alternatively, after the wavelengths are spread out (dispersed), they can be measured simultaneously (see Figure 16.4).

16.4.2.2 Absorption Spectrometry

The second general spectral method involves measuring the amount of light at various wavelengths that pass through a sample. The geometry of the equipment is illustrated in Figure 16.4, where a separate radiant source generates light. Overall, the instrument measures the amount of light absorbed by the analyte at each wavelength. Both scanning and multichannel types are used.



$h\nu_1$
$h\nu_2$
$h\nu_3$
Wavelength selector (monochromator or filter)
$h\nu_{out}$
Transducer
Output
Light emitting sample, for example, an ICP torch

Fig. 16.3 Generalized pictures of equipment designed to measure light emission. Shown is a scanning spectrometer. The light from the source is collected and passed through a monochromator, which only allows a specific wavelength to pass through. The transducer converts the light energy at that wavelength to an electrical signal, which is amplified and displayed as the instrument output. The wavelengths are scanned and associated intensities collected over time.

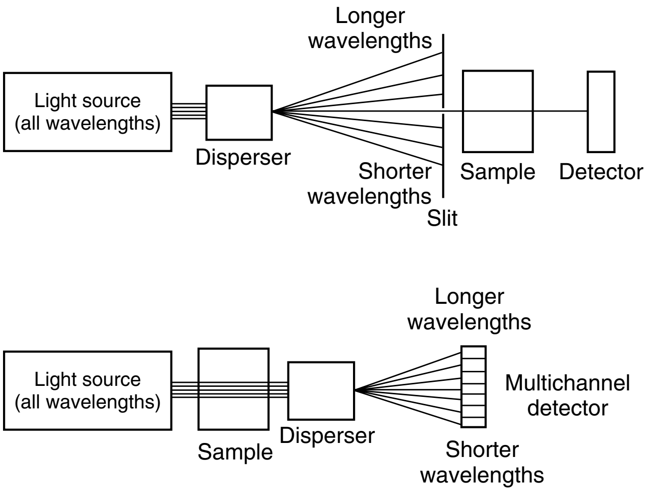


Fig. 16.4 Generalized picture of scanning instrument designed to measure sample absorption or transmittance. (a) A scanning spectrometer where the source light passes into a monochromator, which allows only a specific wavelength to pass through. The light passes through a sample that absorbs a part of the energy, and that which remains is converted to an electrical signal in the transducer. The monochromator is not needed if the light source is generated at a single wavelength such as a specific radiofrequency or a laser light emission. (b) A polychromator (multichannel) system where all the wavelengths are collected at once by a multichannel detector.

Most sources produce light with unwanted wavelengths in addition to the ones that are desired. (The exceptions to this general characteristic are radiofrequency sources and lasers.) Passing the light through either a monochromator or a filter selects the wavelength that is desired for the assay. The picture shows the monochromator between the source and the sample. However, in some instruments, the monochromator is placed between the sample and the transducer.

Absorbance and Concentration The amount of light absorbed by a sample can be reported as the absorbance of a sample. Experimentally, it can be shown to be directly proportional to, a constant that is a property of the material itself as well as the wavelength at which the measurement is being made; *b*, the length of the path through which the light travels in the sample; and *c*, the concentration of the material that absorbs the light. Algebraically, the relation is written as

$$A = \epsilon bc \tag{16.1a}$$

This equation describes Beer's law. When the concentration c is in (moles per liter), then ϵ will have the units (liters per mole centimeter), and is called the *molar extinction coefficient* or *molar absorptivity*. The value of b, the path length, must be expressed in units consistent with the units of ϵ. Labeling the units in Equation 16.1a, we get

$$A(\text{unitless}) = \epsilon(l(\text{mol}^{-1}\text{cm}^{-1}))b(\text{cm})c(\text{mol})^{-1} \tag{16.1b}$$

where l stands for liter, and a mole equals 6.022×10^{23} particles. A rough measure of the values of in the visible range with light passing through the sample's 1-cm

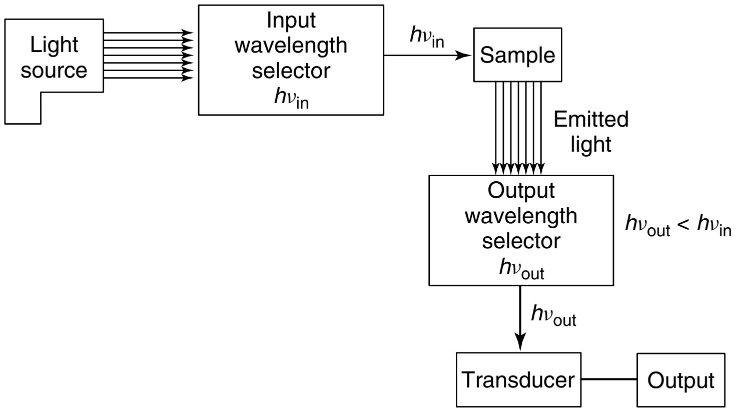

Fig. 16.5 Generalized picture of the equipment designed to measure sample luminescence in the wavelength regions from infrared through X-ray. The source light is collected and passed through a monochromator where a specific wavelength passes and impinges on the sample. The light emitted from the sample is collected and passed through a second monochromator set at a different wavelength. The light energy at that wavelength is converted to an electrical signal in the transducer. This is amplified and displayed as the instrument output. Various types of filters may be used in place of the monochromators.

path length are weakly colored, 10–100; moderately colored 100–10 000; intensely colored 10 000–200 000 in units (liters per mole centimeter).

16.4.2.3 **Fluorescence/Phosphorescence Spectrometry**

When light impinges on a sample and is absorbed, the energy can be reemitted in all directions as light of longer wavelengths. This emission of radiation is called *luminescence*. Measurement of the luminescence from analytes is done with the general instrument geometry shown in Figure 16.5. A light source for the appropriate energy region is required. The incident light is monochromatic after passing through the first monochromator. The light that comes from the sample is measured at an angle which is not in line with the source–sample axis. This angle is often 90°, but that is not the only angle possible. Figure 16.6 shows an example of both the spectrum of absorption and the spectrum of an analyte's reemission.

For chemical analysis, the division of luminescence into its two types – fluorescence and phosphorescence – is not too important. If the luminescence is present and is proportional to the analyte content, it can be used to quantify the substance. However, if a time-dependent spectrometric method is used, the light due to phosphorescence and that due to fluorescence may be separated. On this practical basis, phosphorescent reemission generally can last a much longer time after the light source no longer provides radiation to the phosphorescing sample. For both, measuring the quantity of analyte involves measuring the intensity of the emitted light at one or more wavelengths.

The organizing principle of the remainder of this section is simply the decreasing wavelength of the region of the spectrum that is used: γ-ray, X-ray, ultraviolet, visible, infrared, microwave, and radiofrequencies.

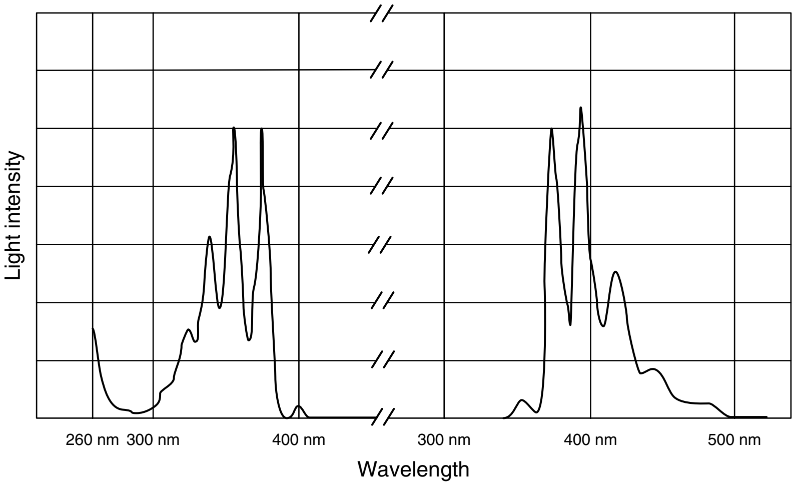

Fig. 16.6 Illustration of the absorption and reemission of radiation by molecules. The energy is absorbed with a wavelength dependence illustrated at the left. Absorbed energy is reemitted with a characteristic spectrum as shown on the right. The emission spectrum is at lower energy than the absorption spectrum; some energy is lost as heat. Sometimes light may be reemitted without changes in the spectrum, but merely with a decrease in intensity.

16.4.3
Specific Spectrometric Methods

16.4.3.1 Gamma Spectrometry: Neutron Activation Analysis

Unstable atomic nuclei that undergo spontaneous nuclear transformations with a concomitant emission of energy are called *radioactive*. Owing to the high energies of the electromagnetic radiation and the high kinetic energies (energy of motion) of the particles emitted upon nuclear decay, individual decay events are measured and counted. The emitted radiation, both electrons (e^-) and photons (the quantum of light), is dangerous physiologically and relatively difficult to block. As a result, analytical methods using the measurement of the radioactive decay have, for the most part, been developed for trace- or microanalyses.

Most radioactive isotopes used in chemical analyses are synthesized. This means that by an appropriate nuclear transformation, a nucleus is converted from a stable form to an unstable, radioactive form. Such transformations can be accomplished for a wide variety of elements by means of a reaction between a neutron and some other elementary particle with a stable atomic nucleus.

Sample irradiation with neutrons followed by measurement of the radioactivity characteristic of the atomic species present is called *neutron activation analysis* (*NAA*). The neutron source is a nuclear reactor in which the sample is placed. The radioactivity produced is characteristic in energy for each type of radioactive nucleus. A typical spectrum can be seen in Figure 16.7. The number of counts of each wavelength is used to quantitate the elemental contents of the material.

Virtually all NAAs are carried out by comparing the radioactivity induced in a sample with that of a standard. To make precise comparisons, the samples must have the same geometry. When these conditions are satisfied, the relative intensities

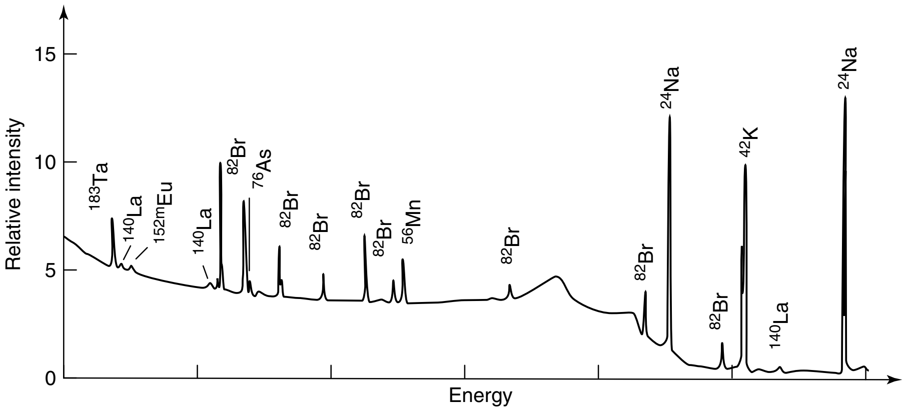

Fig. 16.7 Illustration of the γ-ray spectrum of a neutron-activated sample of tobacco leaf. A large number of different elements can be determined simultaneously in this manner. In this spectrum the lowest peak is 312.7 keV and the highest is 1732.9 keV. (Data from Ahmad *et al.*, 1979.)

of the characteristic radiation of the sample and standard are simply proportional to the total masses of the elements in each. In that way, an analysis utilizing γ-emissions is similar to any other ES.

An optimally sensitive and accurate NAA requires that isotopes be formed which have half-lives in a middle range of a few minutes to a few years. (The half-life is the time for half of the nuclei present to decay. For example, after two half-lives, a quarter of the original is left.) A list of the detection limits of NAA of some representative elements is presented in Table 16.2.

16.4.3.2 **Gamma Spectrometry: Mössbauer Spectrometry**

Mössbauer spectrometry is a γ-radiation spectrometry in which different, narrow ranges of wavelengths are characteristic of specific nuclear isotopes. The absorption and emission of radiation arise from spectroscopic levels of atomic nuclei and lie in the "hard X-ray/soft γ-ray" region of the spectrum. The precise wavelength depends on the chemical form of the atom.

A majority of elements of the periodic table have at least one isotope which is expected to be measurable by Mössbauer spectrometry. However, relatively few elements have been systematically studied and are, thus, useful in analysis. The isotopes that are used are listed in Table 16.4. One of the most commonly investigated elements is iron. A Mössbauer spectrum is illustrated in Figure 16.8.

Tab. 16.4 Most commonly studied Mossbauer isotopes and γ-emission energies).

Isotope	***E* (keV)**
^{57}Fe	14.39
^{99}Ru	90
^{119}Sn	23.88
^{121}Sb	37.15
^{125}Te	35.48
^{129}I	27.75
^{129}Xe	39.58
^{193}Ir	73.08
^{197}Au	77

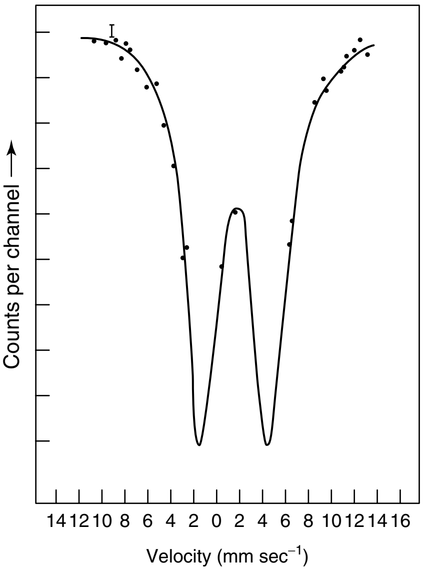

Fig. 16.8 An ^{57}Fe Mössbauer spectrum showing the two lines typical for iron. (This doublet – that is, two lines – results from a single line split by the charge distribution on the nucleus of the atom.)

Mössbauer spectra may be obtained in either absorption or emission, but usually are run in absorption. Emission spectra are usually used to investigate surfaces. The samples must be solids. The spectral energy levels are highly sensitive to the oxidation state of the atom and the chemical environment around the Mössbauer nucleus.

The absorption, which results from the Mössbauer effect, is quite small. Under normal experimental conditions, usually, only a few percent of the energy irradiating a concentrated solid sample is absorbed in the narrow-wavelength range. As a result, spectra are collected and averaged over times from minutes to days in order to see the absorption bands clearly among the noise.

Mössbauer spectrometry is used primarily for qualitative analysis of materials containing a known element in an unknown chemical form. Quantitation can be done, but its precision is subject to a number of assumptions. Only one isotope/element can be investigated at a time.

16.4.3.3 **X-ray Spectrometry: X-ray Fluorescence, X-ray Photoelectron Spectrometry, and Particle-Induced X-ray Emission**

Radiation in the X-ray region of the electromagnetic spectrum arises from transitions within the quantized energy levels of the most strongly held electrons of atoms. After an excitation, each element emits at characteristic wavelengths that can be used to identify the elements present in a sample (see Figure 16.9). The wavelengths of X-ray emission lines follow a regular pattern with the nuclear charge. The higher the nuclear charge is, the higher are the energies of the respective transitions.

After correcting for substantial background radiation, the intensities of the X-ray fluorescence are used to quantitate the amounts of the analytes that are present. In common with other luminescence methods, a number of elements may be determined during one experiment. X-ray fluorescence is used to determine the elemental composition of materials

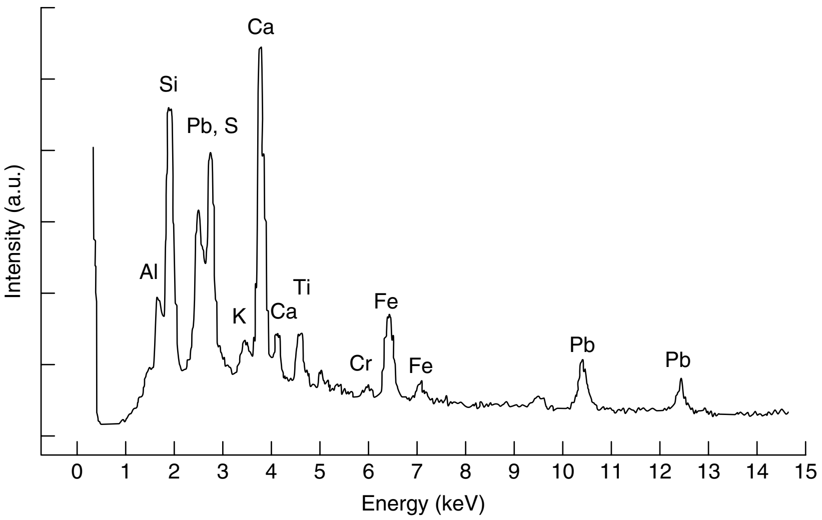

Fig. 16.9 Energy-dispersive X-ray spectrum of air particulates excited by X-rays generated by bombarding aluminum with electrons. Each point is the output summed over time (in counts of X-ray photons) in each of a number of channels of a computer memory. The peaks characteristic of the elements present and are labeled. The concentration of each element can be calibrated. (Redrawn from Wawros, Talik, and Pastuszka, 2003.)

since the X-ray spectra change little with changing chemical forms of elements. One of the method's main strengths is that it can be used for analysis of solids without sample dissolution.

The chemical elements which may be quantified by X-ray fluorescence are those heavier than neon, that is, sodium upward. Also, since almost all elements produce X-rays under the experimental conditions, the "contrast" is not especially high. As a result, X-ray fluorescence generally is limited to higher concentration levels – greater than about 0.1%, as can be seen from the detection limits listed in Table 16.2.

X-rays are relatively strongly absorbed by materials; on average, about 90% of the energy is absorbed within about 0.2 mm (see Table 16.7 in Section 16.8 below). Because of this strong absorption (and also because of possible surface contamination), samples must be prepared with reproducible physical properties.

This complicated spectral interference is one of the principal reasons that carefully prepared standards are important for high-precision (±1%) quantitative spectrometry. However, mathematical methods have been worked out to enable matrix corrections to be determined with fewer standards or to use some of the nonfluorescent, scattered radiation to calibrate the absorption coefficient. Contemporary instruments have both the hardware and software built in to do the corrections automatically after measuring the intensities of the peaks of all the elements present.

Another possible process that can occur when a material is irradiated with X-rays is the ejection of electrons from the atoms with energies characteristic for each element. These are called *photoelectrons,* and the ejection is called the *photoelectric effect.*

The depth from which these electrons can escape is only a few atomic diameters. As a result, these electrons can be used for surface analysis. The analytical technique is called *XPS* or *XPES*) and is described further in Section 16.8 on surface-sensitive techniques.

In contrast to this shallow probe, high-energy particles – with kinetic energies in the million electron volt range – penetrate into the bulk of a sample and cause the emission of both particles and X-ray fluorescence. The X-rays, since they can escape from the bulk, can be used to analyze the atomic species in the first half-millimeter or so of the material. This is particle-induced X-ray emission (PIXE). If the accelerated particles are protons, the technique is proton-induced X-ray emission, also called *PIXE*.

16.4.3.4 **Ultraviolet, Visible, and Near-Infrared Spectrometry**

Analytical methods using luminescence and absorption spectra in the ultraviolet through near-infrared regions (100–2000-nm wavelength), including the visible-light region, are among the most popular and broadly used in chemical analysis. Among the reasons for this popularity is that a large number of analyses of this type were developed before instrumental techniques were available, and the instruments allowed greater sensitivity, lower detection limits, and better precision. Experimentally atomic and molecular assays are often quite different. Atomic spectrometry is used for elemental analysis of analytes. An important condition of such an analysis is to break down the sample into its atomic components. On the other hand, an important condition of analytical molecular spectrometry is to leave the molecules intact.

Measurements are made of the relative amount of light absorbed (absorption) or emitted (emission) or the amount of light reemitted (fluorescence) by components of a sample. Essentially all elements can be assayed by AES or atomic absorption spectrometry (AAS). Also, essentially all molecules can be assayed by molecular absorption and/or fluorescence in the UV–visible or near-infrared spectral region. In this spectral range, atomic analysis is most commonly done on the atoms in the gas phase (usually in a flame or plasma) while molecular analytes tend to be dissolved in a liquid solvent.

Atomic Analysis Atomic spectra are strongly influenced by the atomic environment, and reproducibility in the spectra can best be obtained by producing isolated atoms (atomizing) in the gas phase. AA and atomic emission can be used for all levels of analyte from major to ultratrace by using a variety of methods to prepare and atomize the samples. Table 16.5 lists some sources such as flames, furnaces, plasma torches, and electric arcs that are used to heat and atomize nonvolatile samples.

AE or AES is inherently a multielement technique. The emission source must possess an extremely stable temperature to obtain the best precision. Also, hotter sources generally produce more complete atomization. As a result, in ES, a plasma source is now preferred to a flame source since plasma sources are both hotter than flames and more homogeneous in relative temperature. The major drawback to ES is difficulties with interferences. Nevertheless, quantitation of ±1% is possible with good control.

Unlike AES, AAS is inherently a method to assay a single element at a time since a light source producing a wavelength specific for one element is used. However,

Tab. 16.5 Sources of free atoms.

Method used to produce isolated atoms	Used in
Direct-current arc between two carbon rods in an inert atmosphere such as in argon	Emission
Radiofrequency-induced plasma in argon or helium (inductively coupled plasma)	Emission, fluorescence
Sample heated rapidly inside a hollow graphite tube (graphite furnace)	Absorption
Acetylene/air flame	Absorption, emission
Acetylene/oxygen flame	Emission

the offsetting benefit is that there are nearly no problems with interferences from other elements, which is a common problem in emission. Precision in AA assays better than ±1% is possible.

Molecular Analysis It is difficult to make generalizations about molecular analysis in this wavelength region because the spectroscopic properties of molecules vary so greatly. The basis for the analyses is Beer's law stated in Equation 16.1a. The value of A, the absorbance, can be measured below the 0.001 range with some contemporary instruments. Then, the lowest concentrations detectable depend on the molar absorptivity ε and the length of the light path (limited to about 10 cm for routine liquid analysis). With mirrors, the light's path for gases can be many meters by using multiple reflections through a relatively short cell. Precision in such absorption analyses depends more on the methodology than on the instruments. For instance, measurable variations in the amount of light passed can be seen with slight changes in angular position (order of a few degrees) of a sample. However, with rigid geometries or reproducible placement of samples, variations in results can be as good as ±0.1% for each sample.

Few generalizations can be made about molecular analyses with fluorescence except that the analytes must fluoresce. The practical limit of detection for highly fluorescent molecular species is in the picogram (10^{-12} g) range. That lower limit is practically routine since fluorescence from individual molecules can be measured, although such measurements are generally not done in the context of quantitating the fluorescent molecules.

For both absorption and fluorescence analyses, more than one molecular species can be analyzed in a mixture if standards for the analytes are available. In this case, spectral measurements are taken at a number of different wavelengths, and the concentrations of each of the analytes can be calculated from those data and the spectral properties of the standards. Fluorescence and absorption are two extremely popular methods for monitoring chromatographic separations (see Section 16.7) and quantifying the analytes separated chromatographically, and a majority of such detectors are multichannel systems that measure the entire spectrum continuously. Fluorescence is also used to monitor capillary electrophoresis (Section 16.7.4) as a part of DNA sequencing. Four different colors are used for the four different nucleotide bases.

16.4.3.5 **Vibrational Spectrometry: Infrared Spectrometry and Raman Spectrometry**

Infrared (IR) spectrometry and Raman spectrometry are used to probe the characteristic vibrations of molecular species in solids, liquids, and gases, as well as the vibrations of atoms and ions in crystals, glasses, and other condensed phases. The frequencies of vibrations of molecules correspond to the frequencies of infrared radiation. However, Raman spectrometry shows these vibrational frequencies as a set of lines separated from the illuminating laser line by those individual vibrational frequencies. (Experimentally, Raman spectrometry might more correctly be classified with visible spectrometries.) Infrared spectrometry for analysis is usually run as an absorption spectrometry (as Figure 16.4) while Raman is experimentally a fluorescence method (as Figure 16.5).

Vibrational spectra appear with numerous characteristic bands over the infrared wavelength range from 2.5 to 100 μm. (In chemistry, more commonly, the line energies are given in wave numbers, abbreviated as cm^{-1}, the inverse of the wavelength in centimeters. The infrared is from ~ 100 to $4000\,\mathrm{cm}^{-1}$.) Individual vibrational absorption bands can often be associated with specific chemical groups such as carbonyls, C=O, organic chlorides, –C–Cl, or ethers, –C–O–C–. As for all quantitative spectrometries, the wavelengths of the bands depend on properties of the molecules while the intensities can be used to determine concentrations. Quantitation to ±1% can be achieved.

Vibrational spectra are often complicated. Seldom can every band be assigned as originating from vibrations of specific groups in the molecule. However, an incomplete understanding of the spectra does not detract from their usefulness in both qualitative and quantitative analysis.

Since no two molecular species have the same vibrational spectrum – with every band matching in peak position (wave number), intensity, and widths of the absorption bands – infrared spectra can be used to identify molecular components of samples by matching the spectrum of an unknown with a library spectrum. (A library spectrum is one obtained from a pure species of known identity – from a standard.) An example of such spectrum matching is shown in Figure 16.10. The matching can be done by lining up spectra as shown in the figure or with computerized pattern-matching techniques.

Infrared spectrometry together with MS (and gas chromatography with mass spectrometry (GC/MS)) and nuclear magnetic resonance (NMR) form the basis for contemporary organic chemical qualitative analysis: identifying the molecular structure of unknown compounds and the compositions of mixtures.

Infrared spectra can be obtained on samples as small as a few micrograms although it is far easier to work with milligram samples. In this manner, infrared spectra are used in qualitative analysis of solids, liquids, and gases. In general, quantitation can be done relatively easily when individual bands are completely separated. With the best contemporary instruments, infrared spectra with precisions as good as for UV–visible spectra are obtained: easily ±1% and below. Raman spectral quantitation depends strongly on the properties of the sample and the stabilities of the laser

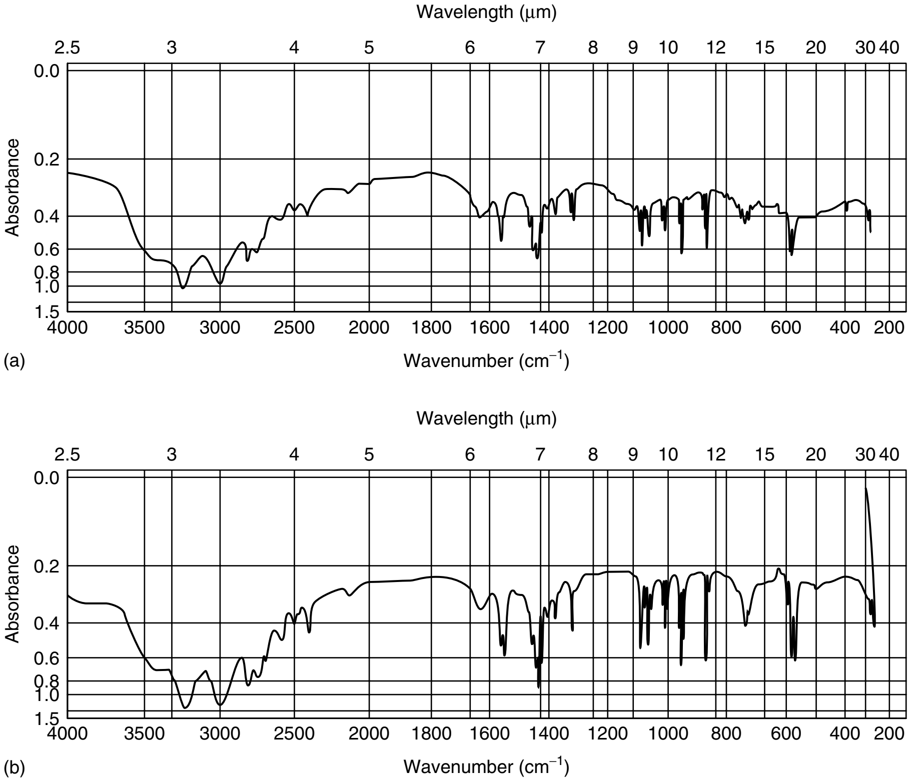

Fig. 16.10 Infrared spectra can be used to identify materials. The (a) is of some unidentified solids collected from a boiler. The (b) is of the tars formed on heating HCl salts of a corrosion inhibitor. There is one-to-one correspondence of all the features in the spectra. Since IR spectra are highly sensitive to structure, the identity of the two samples is quite certain.

light sources. As a result, precision can also be in the ±1% range.

Raman spectrometry tends, in general, to be limited to solids and relatively concentrated solutions. However, the intensity of the spectrum can be enhanced for the gas phase using a far more complicated experimental setup. This is the technique called *coherent anti-Stokes Raman spectrometry* (*CARS*), which is used to investigate, for example, the compositions of flames. Also, Raman spectral intensities can be enhanced by adsorbing to certain specially prepared metal surfaces, a method called *surface-enhanced Raman spectrometry* (*SERS*). Neither of these methods is as commonly used as simple Raman scattering.

16.4.3.6 Microwave Methods: Microwave Spectrometry, Electron Paramagnetic Resonance

Microwave Spectrometry In the microwave region of the spectrum, gas-phase molecules absorb and emit radiation due to changes in the energies of molecular rotations. The frequencies of the narrow spectral absorption lines are able to be measured with high accuracy, and can be used to identify the presence of numerous small molecules and the individual isotopic species such as $^{12}C{=}^{16}O$ and $^{13}C{=}^{16}O$. Rotational spectrometry is not a widespread analytical technique, but it has been used to identify a number of chemical species in astronomy.

Electron Paramagnetic Resonance (EPR) Spectrometry Electron paramagnetic resonance (EPR) spectrometry (or electron spin resonance (ESR) spectrometry) is an absorption spectrometry in the microwave region – 2–200 GHz – for which the sample is placed in a magnetic field. Experimentally, the frequency is fixed and the magnetic field is scanned. The magnetic field required is directly proportional to the microwave frequency. It is in the range around 0.3 T (3000 G) when the frequency is 10 GHz and 1 T when the frequency is 30 GHz. In EPR spectrometry, magnetic field positions are listed as "*g* values." The *g* values of a large number of compounds are near 2.0.

The primary requirement for a chemical entity to be measurable by EPR is that it contains a net electron spin. Such compounds include organic radicals (also called *free radicals*) such as $CH_3^{\bullet}$ and metal ions in specific oxidation states. As an example of the metals, cobalt as Co^{3+} has no EPR spectrum, but as Co^{2+} it does. As a result, EPR may be used to determine some oxidation states and quantities of a number of metal ions. However, not all paramagnetic metal ions exhibit EPR spectra. Some do so only in special chemical environments and the spectra of others may only appear at cryogenic temperatures. For analytical purposes, EPR spectra are run on solids and on liquid and frozen solutions.

A number of atomic constituents can be identified from the number of lines that appear in a characteristic spectrum. These lines are due to the interaction of the electron spin with the spin of nuclei in the molecule. Figure 16.11 illustrates the EPR spectrum of vanadium in its + 4 oxidation state.

As a result of the techniques used to increase instrument sensitivity, EPR spectra are presented as derivative spectra such as in Figure 16.11. The spectra are plots of the derivative of the energy absorbed

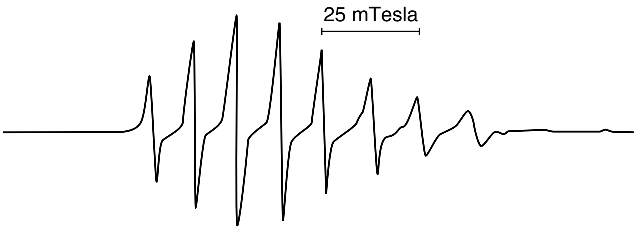

Fig. 16.11 Electron paramagnetic resonance spectrum of vanadium in its + 4 oxidation state in water solution. The eight individual lines result from the interaction of the electron with the nuclear spin. This is called *nuclear hyperfine interaction*. The spectrum is a mathematical derivative (the slope) of the absorption spectrum, and the different heights of the lines are due to the tumbling of the molecule.

versus a linear scale of magnetic field. The peaks (both positive and negative) of EPR spectra are at the points where a regular absorption spectrum has a maximum slope (either positive or negative, respectively). Precision in quantitation by EPR tends to be in the range ±5%. The detection limits are reached around 10^{12} spins for organic radicals (around 10^{-12} moles) and a factor of 10–100 higher for metal ions.

16.4.3.7 Radiofrequency Spectrometries: Dielectric Absorption, Nuclear Magnetic Resonance

Dielectric Absorption Absorption of radiofrequency electromagnetic energy by materials can occur through the interaction with the electric field or the magnetic field of the electromagnetic radiation. The former is the basis for dielectric absorption, and the latter is a property of NMR. The frequencies and magnitudes of dielectric absorption are used to characterize polymers and are the basis for some instrumental methods of moisture determination. However, in general, the absorption bands are not specific enough to be used alone to identify and quantify different molecular species.

Nuclear Magnetic Resonance (NMR) NMR spectrometry is one of the most powerful methods for identifying the chemical structures of organic – including biological and polymer – compounds. The reasons for this utility are primarily threefold. First, NMR spectra for nuclei – such as carbon (^{13}C) and proton (^{1}H) – are sensitive to an atom's chemical type, for example, $-CH_3$, $-CH_2-$, $=CH_2$, $-COH$ differ significantly for both the carbons and hydrogens. Second, the frequencies at which each of the chemically different nuclei appear in the spectra are characteristic for each. For example, hydrogens in methyl groups, $-CH_3$, appear consistently in one range of the spectra. And third, the chemical structures and magnetic resonance properties of atoms immediately adjacent to the resonant groups also influence the spectra. For example, the spectrum of a methyl group attached to a $-CH_2-$ group, that is, CH_3-CH_2-, differs in an obvious way from a methyl group attached to a $-CHCl-$ group although they both show up in the same ''methyl region.'' As a result, it is possible to ascertain molecular structures from NMR spectra alone. The spectrum of a compound does change its appearance somewhat with different magnitudes of the magnetic field. However, these changes are well understood, and usually present no problems in interpretation.

NMR spectra are most easily obtained on species in solution, but more advanced techniques allow useful spectra of solids to be measured.

Because of the sensitivity to small chemical differences, the spectra can be complex, with large numbers of lines overlapping. An example is shown in Figure 16.12. Simple NMR spectra can be used in quantitation, and internal standards are recommended. Multidimensional NMR is still qualitative in the chemical sense; it is used more for identification. The atoms most commonly investigated in chemical systems by NMR are hydrogen, carbon, phosphorus, and fluorine. The NMR phenomenon is limited to specific isotopes of the heavier elements: ^{13}C, ^{31}P, and ^{19}F.

Obtaining NMR spectra involves measuring the interaction of radiofrequency radiation with a sample material that resides in a strong magnetic field (see, *inter alia*, Nuclear Magnetic Resonance in the Encyclopedia of Applied Physics). The radiation used is in the 100-MHz to 1

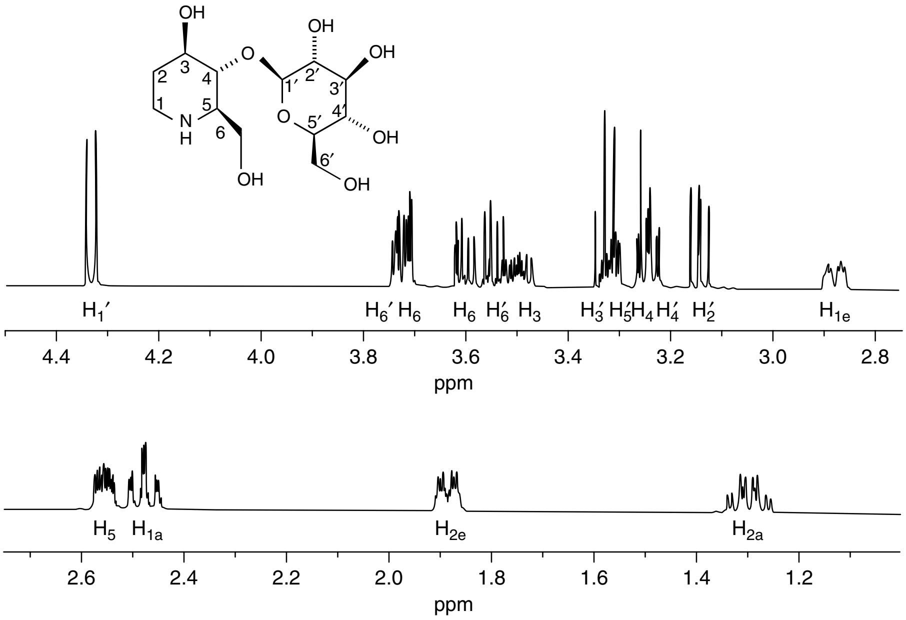

Fig. 16.12 A ^1H nuclear magnetic resonance spectrum of the molecule pictured. The assignments of the features in the spectrum to the various protons are noted below the spectra. The numbers refer to the carbon atoms to which the protons are bound. The numbers of the ring on the right are primed. By convention, the protons are not drawn but are understood to be attached. The bonds drawn as broadening lines indicate the bonds directed out of the plane of the paper. The dotted lines indicated bonds directed below the plane of the paper. The horizontal axis is numbered in ppm, which refers to parts per million of the radiofrequency used. (From Derome, 1987. Reproduced by permission.)

GHz range: the lower range is the frequency of FM radio in the United States and the higher end is near a common frequency for cell phones. The magnetic fields are large; the most sophisticated instruments use some of the largest constant, homogeneous magnetic fields that can be generated. Essentially all contemporary instruments collect the data as the sample's response to a train of high-power radiofrequency pulses that are a few microseconds long. The data obtained are mathematically transformed (a Fourier transform) to produce a spectrum such as shown in Figure 16.12. This method of data collection has the effect that all lines of the NMR spectrum are measured simultaneously. This manner of operation – so-called Fourier transform nuclear magnetic resonance (FT-NMR) – increases the sensitivity and improves the detection limit of the experiment. However, even with the best contemporary instruments, NMR is not really a trace method. To obtain proton spectra at least 10 μ g is required, and for carbon more than 1 mg of a species is needed. These limits can be lowered somewhat by using miniature coils surrounding a cell on the order of 1 μl in volume. The analyte must be relatively concentrated.

NMR of Solids To obtain optimum NMR spectra, the analyte molecules should be

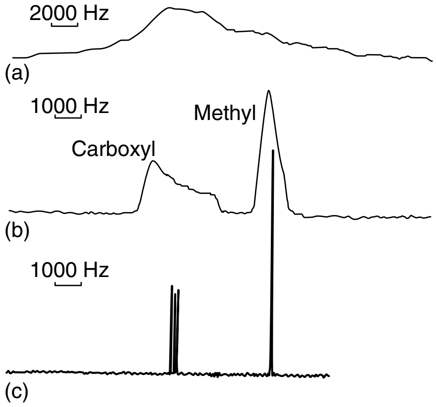

Fig. 16.13 Solid-state spectra of calcium acetate hemihydrate, $Ca(CH_3CO_2)_2 \cdot \frac{1}{2}H_2O$. (a) The solid-state spectrum; (b) the result when the various nuclear spin-nuclear spin interactions are removed by specific radiofrequency irradiation; and (c) when the sample is spun at the magic angle as well. (From Harris, 1983. Reproduced by permission.)

tumbling rapidly relative to the magnet. Part of the reason for this is to average out the interactions with neighboring molecules. In solids, neither the tumbling nor environmental averaging occurs within a sample, and the spectra tend to be broad and nearly featureless, with little chemical information (see Figure 16.13). However, moderate spectra can be obtained through two fundamental tricks. One is to spin the sample at a specific angle – 54°44′, called the *magic angle* – at a rate in excess of 200 KHz. This is called *magic-angle spinning* (*MAS*). The second is to average the magnetic interactions of the surroundings using strong radiofrequency fields at specific frequencies related to the resonance frequencies of the H nuclei present in the sample. This is the technique of proton decoupling. A spectrum is shown in Figure 16.13. A relatively large sample is needed. More commonly used instruments require tens of milligrams, while instruments with microcoils need a thousandfold less.

Two-Dimensional NMR A simple, one-dimensional NMR spectrum (such as shown in Figure 16.12) shows the magnitude of resonance (vertical) as it changes with a scale related to frequency (horizontal). The horizontal measure, ppm, is parts per million of the radiofrequency: 1 ppm equals 500 Hz for the 500-MHz instrument used to obtain the spectrum. A 2D-NMR spectrum, such as that shown in Figure 16.14, shows the resonance changes related to two frequency scales. In this case, both the horizontal scale (labeled on the bottom in ppm) and the vertical scale (labeled v_1) are identical to the ppm scale of the spectrum in Figure 16.12. The 2D spectrum shown is drawn as a contour plot. The usual 1D spectrum runs along the diagonal from lower left to upper right. The peaks that occur off the diagonal (which appear at the intersections of the vertical and horizontal positions of peaks on the diagonal) are called *cross peaks*. Where cross peaks occur, they show which of the peaks of the 1D spectrum are magnetically connected: their nuclei interact magnetically and are, thus, spatially close together. Two-dimensional NMR allows dissection of complex spectra into their component contributions, and because of the localized nature of the magnetic interactions, provides structural information. The results are qualitative in a chemical analysis sense.

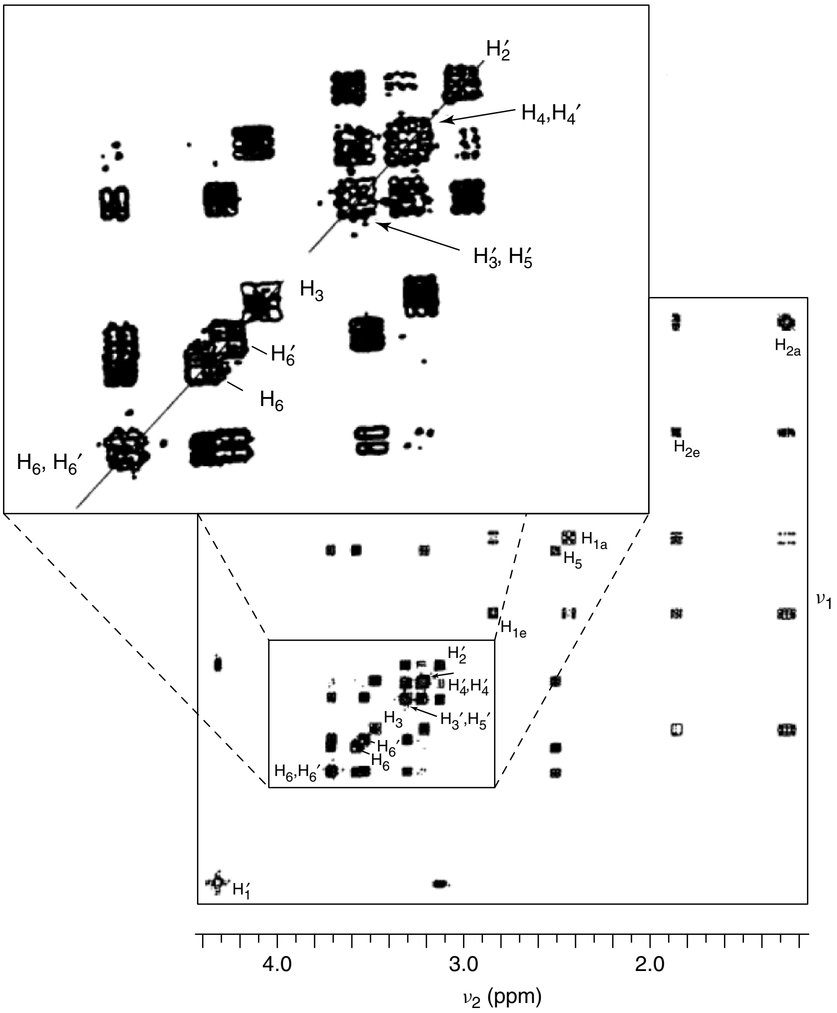

Fig. 16.14 The output from one type of 2D NMR as a contour plot. This is a spectrum of the same chemical as used for the 1D NMR in Figure 16.12. The 1D-NMR spectrum lies on the diagonal from lower left to upper right. The off-diagonal peaks lie on the vertical and horizontal locations of the two peaks that are magnetically connected. (From Derome, 1987. Reproduced by permission.)

Multidimensional NMR Other advanced methods – called *collectively multidimensional NMR* – involve three- and four-dimensional NMR spectroscopy. As for two-dimensional NMR, each added dimension involves a different range of frequencies and indicates how peaks of different nuclei are connected in space. Three- and four-dimensional NMR can be used to unravel far more complicated spectra to provide information that can be used to determine reliably the chemical structures of proteins up to molecular masses of about 30 000 Da. The methods require that the protein be partly enriched in ^{13}C and ^{15}N and require days of data collection on the most sophisticated instruments and extensive, intricate data analysis.

16.5
Mass Spectrometry

MS is the name for a collection of different techniques that are used to measure the relative numbers and the masses of ions that are in the gas phase. The methods of MS are among the most versatile and powerful tools of chemical analysis. This broad usefulness is due in part to having a wide choice of capabilities to transform atoms and molecules for analysis into gas-phase ions, and the sensitivity of ion detectors. Ions from hydrogen to as large as proteins can now be brought into the gas phase with varying amounts of excess energies, that is, energies beyond that needed to vaporize them. This energy causes the molecules to break up and/or ionize. Small amounts of excess energy – soft ionization – leaves the molecules relatively intact. Larger amounts cause fragmentation in amounts proportional to the excess. There are benefits to both having the molecules intact and causing fragmentation.

Once the ions are formed in the gas phase, their separation is determined by the ratio of the mass of the ion to its electric charge; this is written as m/z, the mass-to-charge ratio. A mass spectrum of the fragments of a small molecule is shown in Figure 16.15.

Analysis of organics for both qualitative (identification) and quantitative (the amount present), the method of choice is now the combination of GC (see Section 16.7) with a mass spectrometer as detector of separated species (GC/MS). The chromatography section of this instrument is used to separate the individual species of a sample, and the mass spectrometer allows identification from the pattern of the mass spectrum. Computerized methods of pattern identification are used. Similar mass spectral techniques are employed with liquid chromatography (LC) when separating, identifying, and quantifying less-volatile compounds. MS can be used to quantitate nanogram amounts of

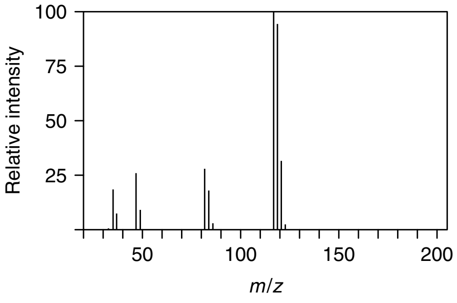

Fig. 16.15 A mass spectrum of carbon tetrachloride, CCl_4. The four peaks at the highest m/z are all the isotopic forms of CCl_3^+ :^{12} $C^{35}Cl_3$,^{12} $C^{37}Cl_3$,^{12} $C^{37}Cl_3$,^{12} $C^{37}Cl^{35}Cl_2$, $^{12}C^{37}Cl_2^{35}Cl$,^{12} $C^{37}Cl^{35}Cl_2$, with a small fraction contributed by the ^{13}C set as well.

molecules and atoms. With internal standards, precisions of ±0.5% are achievable.

16.5.1
Mass Spectrometers

Mass spectrometers, regardless of the design of the various parts, are constructed to separate ions of gas-phase molecules and atoms according to their masses. All mass spectrometers are constructed to carry out four operations as the following:

1. introduction of the sample as a gas;
2. ionization of the molecules in the gas;
3. separation by mass; and
4. detection of the separated species.

All the operations are done under high vacuum – generally around 10^{-9} Pa (1 Pa = 0.0075 torr = 0.0075 mm Hg.) The first two steps occur in the ion source (see Figure 16.16). (Some techniques of sample introduction inherently produce ionized molecules, which combines steps 1 and 2.) The third step is done by mass analyzers. The fourth step involves a transducer, usually an electron multiplier.

Bringing the atoms and molecules into the gas phase can be done in numerous ways; heating is the simplest. Others involve impact on the material with other particles, such as argon atoms, which dislodges molecules from the surrounding matrix of a sample; this is fast atom bombardment (FAB). If ions are used to dislodge the analyte, the ions expelled are called *secondary ions*, and the technique is called *secondary-ion mass spectrometry* (*SIMS*) (see Section 16.8.2). Ions of an analyte may also be formed by using a fast pulse of an ultraviolet laser to ablate a light-absorbing, low molecular mass matrix holding the analyte molecules. The gas-phase ions then pass into mass spectrometer. This is matrix desorption/ionization mass spectrometry (MALDI), which can bring polymers and proteins into the gas phase for analysis.

The methods for vaporization/ionization noted above require that the sample be placed into a high-vacuum chamber. A number of sources start with the samples at atmospheric pressure where they are brought into the gas phase and then pass

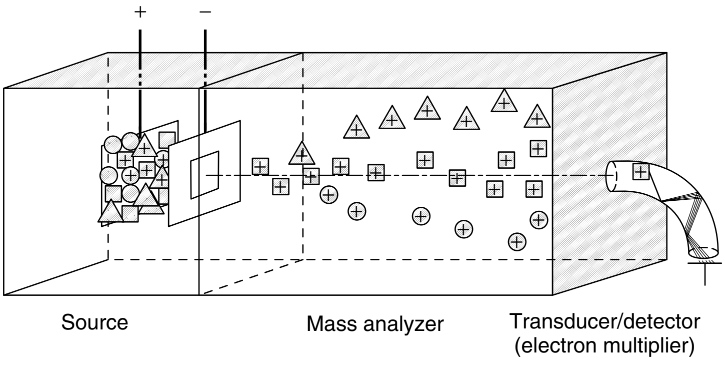

Fig. 16.16 Diagram of the major features of a mass spectrometer. The sample molecules travel from the left, where they are introduced, to the right. Shown in the source are three types of ions with different masses indicated by circles, triangles, and squares. They are separated in the mass analyzer, which may be a magnetic sector, a quadrupole mass filter, time-of-flight delay path, one of many forms of ion traps, or a small, highly precise cyclotron (FT-MS). The arrival of the ions is detected after the separation; here the detector is shown at the right.

into the vacuum for separation through a series of orifices with progressively lower pressures. The general method is called *atmospheric pressure ionization* (*API*). The most commonly used member of these atmospheric sources has a solution containing the sample pass through a hot (temperatures up to 10 000 K) plasma torch where the sample is atomized (broken into atoms) and the atoms ionized. Coupling the inductively coupled plasma with mass spectrometry (ICP/MS) is an extremely powerful method used for trace and ultratrace elemental analyses where nanograms per milliliter of most elements are easily quantitated (see Table 16.2)

In another external sample ionizer, a solution containing analytes can be ejected as an aerosol through a small, highly charged needle into warm air. The electric charges on the droplets cause the aerosol to break up into smaller and smaller droplets eventually yielding gas-phase ions such as proteins, which are drawn into the spectrometer. This source is called an *electrospray* and the general method is called *electrospray ionization* (*ESI*). The electrospray itself can be used as a solvent source to sample surfaces from which the solvent together with the analytes it picks up from the surface are drawn into the mass spectrometer. In that form it is called *desorption electrospray ionization* (*DESI*). A "dry" method of atmospheric ionization for small, relatively stable organics causes the molecules to be vaporized and ionized directly from a surface by placing the sample into a beam of excited helium atoms in front of the pickup orifice. An example of such an analysis is cocaine from paper money. The method is called *direct analysis in real time* (*DART*). These methods are only semiquantitative.

If ions are not produced by the above processes themselves, the molecules can be ionized in a number of different ways. One of the two most common methods is hitting the gas-phase molecules with accelerated electrons: this is electron-impact (EI) ionization. In the second method, chemical ionization (CI), a reagent gas such as methane (CH_4) is ionized by the accelerated electrons and, through subsequent reactions, forms a molecule ion, CH_5^+. The CH_5^+ then donates a proton, H^+, to the analyte to form a molecular ion with a mass one unit higher than before the protonation. (The extra mass mass unit is the mass of the added proton.) A molecule tends to break down into molecular fragments less with CI than with EI.

16.5.2
Multidimensional Mass Spectrometry: MS^n

It is somewhat like a picture puzzle to ascertain the identity of a molecule from the mass spectrum alone, especially if some material is not well purified. For instance, the fragments CO and C_2H_4 both have nominal mass of 28. However, if these fragments are further broken down, their identities become more certain; CO breaks into C and O while C_2H_4 produces CH_3 and CH fragments, among others. This analytical process can be carried out with a tandem mass spectrometer, such as is illustrated diagrammatically in Figure 16.17. In effect, a second mass spectrum is run on the breakdown products of a single peak of the first mass spectrum. MS/MS is an immensely powerful technique for identifying molecular species.

Such processes can be continued: measurement/breakup/measurement/breakup and so forth. This repetitive process is abbreviated MS^n as in MS–MS–MS, and so on, and can be observed with mass spectrometers based on various ion trap

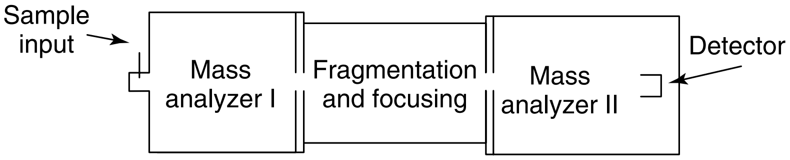

Fig. 16.17 A block diagram of one type of tandem mass spectrometer. The ions travel from the source through the first mass analyzer. Those that pass through this first mass spectrometer enter a region filled with a gas and surrounded by ion-focusing structures. The fast moving ions collide with the gas molecules and fragment. The ion fragments pass into the second mass analyzer, where they are separated by mass and detected.

designs. The ions are held in a vacuum in a small space inside the ion trap where by radiofrequency fields of specific geometries and frequencies, they are both held and manipulated to break up and then ejected to a detector.

16.6
Electrochemical Methods

In this section, some of the analytical instrumental methods used to measure electrical currents, charge, and/or electric potentials that originate from chemical reactions are presented. The analytes determined with electrochemical techniques must be contained in solutions containing unreacting ions called *spectator ions.* Many atomic and molecular species can be assayed from major to ultratrace levels. The subsections below deal with electrochemical methods in the following order: potentiometry, conductimetry, coulometry, amperometry, and voltammetry.

Briefly, electric potential differences (voltages, potentials) can arise in chemical systems due to differences in concentrations of ions and due to differences in the abilities of different species to give off or take up electrons (oxidation and reduction, respectively). The techniques based on measurements of these potentials when minimal current is allowed to flow are those of potentiometry.

When the content is quantified by measuring the changes in the electrical resistance of solutions of ions (electrolyte solutions), the techniques are those of conductimetry.

A potential can be applied to an electrode in a solution causing electrons to be exchanged with electroactive analytes (able to be oxidized or reduced) in the solution. When the analyte loses an electron it is said to be oxidized; when the analyte gains an electron, it is said to be reduced. We can relate the magnitude of the current and the time it flows to the amount of analyte present. The product current × time is the total charge transferred. The amount of the charge transferred for oxidation or reduction is the basis of a number of different techniques called *coulometric methods.*

One group of techniques combines the simultaneous measurement of a potential and current as they change with time. These are called the *voltammetric methods.* They are, perhaps, experimentally the most elegant and yet simple methods for trace and ultratrace analyses.

A straightforward electrochemical technique that does not fit well into the section's organization is electrogravimetry. It was discussed with other gravimetric methods in Section 16.3.1.

16.6.1
Potentiometry

The concentrations of analytes that are ions or change ion concentrations can be measured in solution with potentiometric methods, that is, those where the electric potentials of chemical reactions (their voltages) are obtained. The concentrations are related to the voltage logarithmically; for example, the voltage change for a 100-fold increase in concentration is twice the voltage change for a 10-fold increase in concentration.

Such a measurement requires a potential to which the measured one can be referred – a reference potential. Common references are the saturated calomel electrode (SCE) and the silver–silver chloride electrode. It is difficult to measure a cell potential to better than about $\pm 1\,\text{mV} = \pm 0.001$ V, which represents an uncertainty in concentration greater than 4%. This is the limit of precision for potentiometry. If more precision is needed, potentiometry can be used to detect end points of titrations (Section 16.3.2). The electrodes used for such measurements are designed to respond to one or a few ions specifically. The generic name for these devices is ion-selective electrodes. A well-known example is the pH electrode, which responds to the amount of H^+ in the solution. The operation of this electrode depends on the response of a surface that binds specifically to the analyte ion; this is an ion-selective surface. The oxidation state of the H^+ remains unchanged by the measurement. For potentiometric measurements, the current flow is kept as small as possible. For example, a common pH meter will measure the potential when the current flowing is on the order of 100 pA.

To find the analyte concentration, the voltage in the presence of the analyte must be calibrated with a solution containing a standard, known concentration of the same analyte. There are two ways to do this. First, the concentration is found by comparing the voltages from the standard and the analyte and recognizing the logarithmic relationship to find the analyte concentration. Second, we can extrapolate from a set of voltages measured after adding a series of known amounts of the analyte into the original solution after its potential has been measured. This latter technique is known as *standard addition* or, alternatively, *spiking*. Both these techniques can also be used for all electrochemical and spectroscopic analyses.

16.6.2
Conductimetry

Experimental values of conductivities (the amount of current an ionic solution can carry when a voltage is applied) almost always are found using rigidly fixed electrodes placed in the analyte solution. One type of conductivity cell is illustrated in Figure 16.18. Quantitation using conductance measurements can be done simply by calibrating the instrument with known concentrations of the ion-forming analyte and then measuring the conductivities of the solutions to be analyzed. The use of conductimetry is limited to analytes that are ions in solution. Conductimetry is used both to measure multiple species together, such as for monitoring contamination in streams and rivers, and for a single species such as continuous monitoring of an acid concentration.

Quantitative conductivities can be determined to about $\pm 1-2\%$ if the resistance between the electrodes is in the range of 1000Ω and the temperature is thermostated to within $\pm 0.1^\circ$. With proper standards and temperature control, special

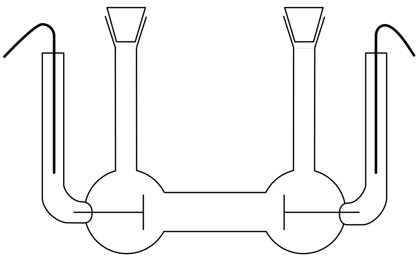

Fig. 16.18 Illustration of a conductivity cell. Usually the electrodes are platinum foil covered with a finely divided platinum on the surface. From its color, it is called *platinum black*, and it provides a large surface area – much larger than the dimension of the electrode. Samples fill the cells so that the geometry is the same for all runs.

high-precision conductimetry can be done with errors in the range of 0.1%. However, such precision is not routine.

16.6.3
Methods that Use Oxidation and Reduction

The remainder of the electrochemical methods discussed here depends on oxidation and/or reduction of the analytes with measurement of the amount of electric current that flows during the process. Either the current that flows or the total charge required for the oxidation/reduction process is measured. They are directly proportional to the analyte content. The types of materials that can be assayed include both elements and molecular species. When molecules contain organic groups that can be reduced electrochemically, they can be assayed by these methods. A number of electroactive groups are listed in Table 16.6.

16.6.3.1 **Coulometry**

A coulometric assay relies on measuring the total charge that is needed to complete an electrochemical oxidation or reduction. This total charge is relatable directly to the total amount of material electrolyzed. It is relatively easy to measure a total charge of millicoulombs over periods of minutes. A general calculation shows this to be representing about 1μ g of analyte.

The apparatus that is used is designed to keep a constant potential at the electrode where the analytical reaction (oxidation or reduction) occurs. The apparatus is a general piece of electrochemical equipment called a *potentiostat*, and it can also be used for electrogravimetry, coulometry, and the various forms of amperometry.

Coulometric assays are carried out in stirred solutions; at one time or another, all the analyte must come in contact with the electrode, and stirring hastens the process. An alternative to stirring is to use only a

Tab. 16.6 Bond types that can be reduced for electrochemical measurements.

thin layer of solution so that the inherent diffusion of analyte is sufficient to result in a uniform concentration throughout the solution volume within a few minutes without stirring.

16.6.3.2 **Amperometry and Voltammetry**

Amperometric analyses are achieved by measuring the electrical current that passes into a solution and causes oxidation or reduction of the analytes at a fixed potential. The assay depends on quantitative measurements of the limiting current, i_L, which is proportional to the concentration of the species being oxidized or reduced at the electrode (see Figure 16.19). A relatively powerful but specialized use for fixed-potential amperometry is in LC. An electrode is set at a potential that will cause oxidation or reduction of the analytes, and the electrode is placed so that the analytes pass over it after they are separated on an LC column. The resulting increase and decrease in current as a band of material passes by can be used to quantify the amounts of each separated analyte. This is called *liquid chromatography with electrochemical detection* (*LC/EC*). Nanogram amounts of electroactive compounds can be determined inexpensively compared to other methods with comparable limits of detection.

A second, general set of amperometric methods involves measuring the changes in the current (as amperes or amps) as the voltage is changed; hence the name *voltammetry*. These voltammetric methods include polarography (a voltammetric method using mercury as its electrode), differential pulse voltammetry, and anodic stripping voltammetry (ASV). Figure 16.19 shows representative data of the current for an electroactive species as the applied potential varies from zero to more negative potentials. At first, little current flows since the analyte does not react in this voltage range. Then, the current increases relatively rapidly with voltage, and finally a plateau is reached where there is little further increase in current over the projected baseline as the potential is changed further. This is the limiting current, i_L. The curve shown in Figure 16.19 results from

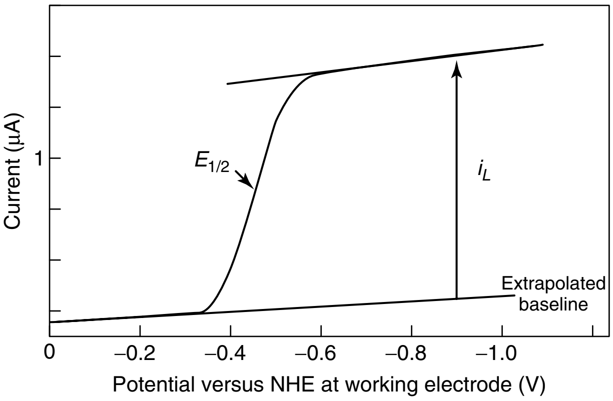

Fig. 16.19 Illustration of the output of one type of voltammetric experiment. The current flow is plotted versus electrode potential. At the left, only a background current is seen. Then, the electroactive species begins to react, finally reaching the limiting current. The midpoint voltage is characteristic of the analyte. The limiting current after the subtraction of the projected background is proportional to its concentration.

the simplest case of voltammetry, where the potential at the electrode changes with a constant increase or decrease with time. This is a voltage scan.

An increase in the flow of current can be measured more precisely by a careful combination of pulsing the potential together with selective data acquisition. The background current and the current produced when electrons are transferred after a voltage jumps are collected at specific times before and after the voltage jumps, superimposed on a more slowly changing voltage. One method that works this way is differential pulse voltammetry. (With a small mercury drop as the electrode, it is called *differential pulse polarography* (*DPP*)). Results of such determinations appear as seen in Figure 16.20. By comparing the area under the curve or just its height with the results from standards, one obtains the analyte content. DPP is a method suitable for trace analysis of both atomic and molecular species. The detection limits for various elements appear in Table 16.2.

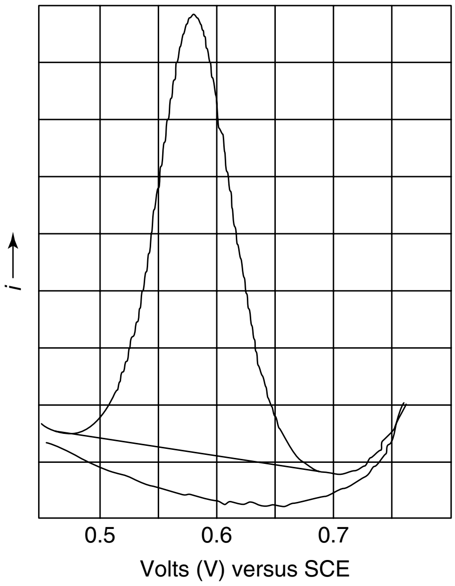

Fig. 16.20 Illustration of a differential pulse voltammogram and, underneath, the background current. The scale is about 5 nA per division. The shape of the curve is the slope of a curve such as seen in Figure 16.19. (From Rubinson and Rubinson, 2000.)

16.6.3.3 Anodic (and Cathodic) Stripping Voltammetry

ASV is a technique that can be used to assay a number of metals and nonmetals at the trace and ultratrace levels. The technique contains a step that first concentrates the analyte, which allows far lower detection limits for many metals than without such a step (compare DPP and ASV in Table 16.2). For example, for metals, the ions are first reduced to their metallic forms, which dissolve in the small mercury drop electrode (the mercury/metal solution is called an *amalgam*). The concentrated, dissolved metals are subsequently reoxidized, and the resulting current provides a measure of their concentrations. Differential pulse techniques give the best detection limits. An example of the type of data obtained is shown in Figure 16.21. When the analyte is first oxidized to concentrate it and then subsequently reduced for the assay, the technique is called *cathodic stripping*; both are used primarily for elemental analysis.

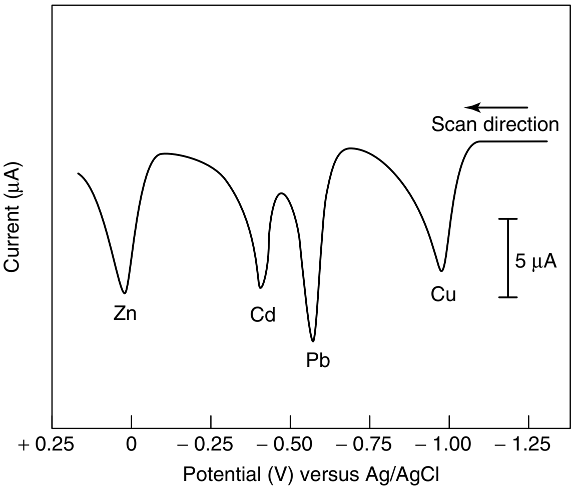

Fig. 16.21 An anodic stripping voltammogram of a solution 2.5 ppm in copper and zinc and 5 ppm in lead and cadmium. The sample was reduced and concentrated as an amalgam and then scanned as shown. The peak areas are proportional to the concentrations. (From Rubinson and Rubinson, 2000.)

16.7
Separations and Chromatography

To isolate quantities of pure substances involves the science and art of separations. Separation methods are based on the differing chemical properties of the components of a sample. In contemporary chemical analysis, separation is synonymous with chromatography. Figure 16.22 diagrammatically shows one type of chromatographic instrument in which the separation occurs within a hollow tube – the chromatographic column – containing the adsorbent or stationary phase that has a flowing fluid in contact with it. The stationary phase in column chromatography consists of either the column surface itself or particles of a solid material to which the analyte molecules bind. The analyte is placed at the beginning of the column and washed through with the liquid eluent. The individual components elute at the other end at earlier or later times depending on their differences in binding to the stationary phase. The analytes that spend more time on the stationary phase elute later.

The reasons for the wide applicability of chromatographic methods involve the variety of conditions that can be used to separate components of materials. For instance, we can use different mobile phases: gases, liquids, and supercritical fluids for LC, GC, and supercritical phase chromatography, respectively. Further flexibility arises from having many types of stationary phases (minerals and numerous kinds of polymers alone or with surfaces modified with molecules having varying properties). In addition, the geometries of the stationary phases can differ (inside columns of various sizes, on plates) or the scale of the separation can vary (large for preparative, smaller for analytical).

In contemporary analysis, the components that have been separated are detected as they elute from the stationary phase by measuring changes in any of a number of different chemical or physical properties. Virtually every instrumental and wet analytical chemical method has been used to detect and identify the components separated chromatographically. Four examples among these are electrical conduction, light absorption, ion production in flames, and atomic or molecular mass. The response of the detector with time as an eluted band passes – that is, a rise and fall (or

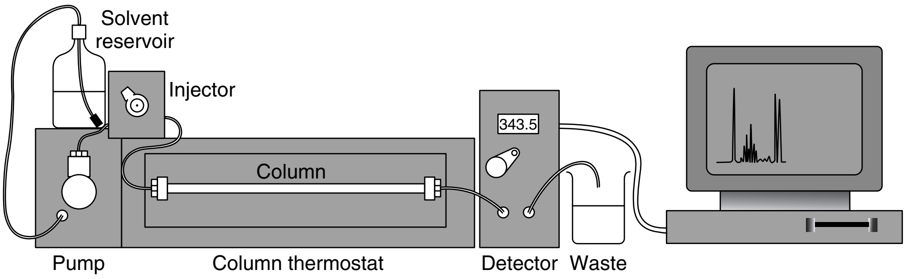

Fig. 16.22 Diagram of the components of a column liquid chromatograph. The sample of known volume is injected onto the column where the components are separated as they flow at a rate fixed by a pump. They elute and are detected, where a plot versus time is the chromatogram, as seen on the screen. Another chromatogram is shown in Figure 16.23.

fall and rise) in the property from the baseline level – produces a series of peaks as shown in Figure 16.23. This chart of detector response versus time is called a *chromatogram*.

16.7.1
Liquid Chromatography

16.7.1.1 Column Chromatography

Within that broad definition of LC are a myriad of techniques, and many of them are associated with more than one name. The names focus on many different aspects of LC methods. For instance, one of the primary classification schemes of LC is by the physical shape of the solid support such as column chromatography, thin-layer chromatography (TLC) (with the solid support forming a layer on a plate), capillary LC (with the inner surface of the capillary as the solid support), and flat-bed chromatography. Classification is also based on the efficiency of the separations such as high-performance liquid chromatography (HPLC) or high-performance thin-layer chromatography (HPTLC). Sometimes names of LC methods identify solutes which are separated and detected such as ion chromatography (done with column methods). One of the reasons that LC has become ubiquitous in analytical laboratories is the development of HPLC. The solid phase is composed of carefully packed particles that are between 10 and 2 μm in diameter. The size of the particles makes it necessary to pump the mobile phase through the column at pressures up to thousands of pounds per square inch (the commonly used, nonmetric pressure measurement, $1\,\text{lbf in.}^{-2} \approx 6895\,\text{Pa}$). HPLC pumps keep a highly precise eluent flow rate regardless of the conditions in the column. As a result, after calibration with standards, the positions of the peaks in time can be used for identification, and the peak heights and peak areas can be used to quantify analyte species without needing frequent recalibration.

Usually one of four basic types of chromatographic supports is used in LC. The general type of chemical interaction that occurs between the solid support and the solutes gives each separation a different name. The classifications are denoted as follows:

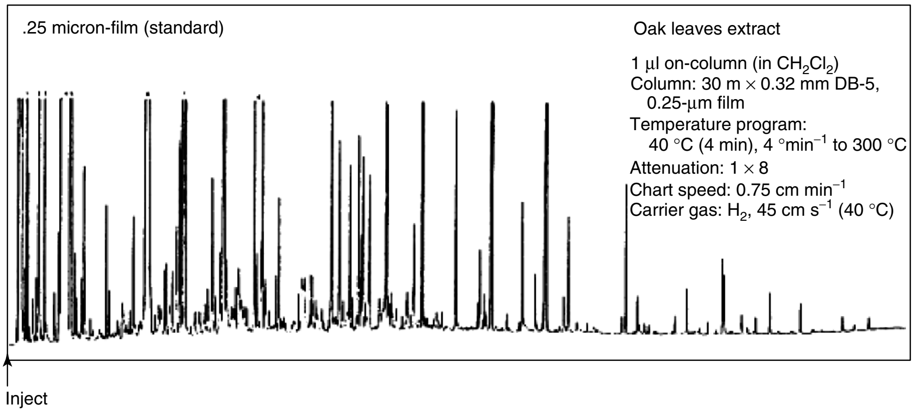

Fig. 16.23 Gas chromatogram of the volatile components of oak leaves. This was done on a capillary column. As complex as this appears, statistical arguments suggest that more than one component is under many if not most of the peaks. (Courtesy of J&W Scientific, Inc., Rancho Cordova, California.)

1. Normal phase or adsorption. The stationary phase is highly polar (i.e., large electric dipoles at the surface) and the eluent is somewhat less polar.
2. Reversed phase. The stationary phase is less polar than the eluent.
3. Ion exchange. The stationary phase has ionic charges on it and the separation is based on differences in charge.
4. Gel filtration, also called *gel permeation* or *exclusion*. The stationary phase has pores into which the analytes can migrate. Separation is by size.

Less commonly used are some solid supports that are designed to interact with specific chemical functional groups, such as thiols (–SH) or diols (–COH–COH–), that are on the solutes being separated. With a similar strategy of specific interactions, solid phases can be made with molecules that bind to one specific protein and can pull it out of a mixture. Chromatography with such protein-specific groups on the stationary phase is called *affinity chromatography*.

Running a chromatographic separation can take up to hours. In many cases, the process can be speeded up at least 10-fold if the analyte can withstand the conditions needed, which involve higher pressure to provide faster flow, higher temperatures, and shorter columns. However, the speed also requires detection methods that respond faster and possibly to smaller amounts of material. Nevertheless, this is an important trend.

Quantitation in column LC with automatic sample injection and with the use of internal standards can approach ±0.1%. Precision of ±1% is relatively straightforward with current instruments.

16.7.1.2 **Separations of Chiral Molecules**

There exist numerous molecules, particularly most biological ones, which, while having exactly the same compositions and same atoms attached to each other, nevertheless have different structures. Their differences are similar to the differences between right and left hands. As is true for hands, the molecular structures are mirror images of each other. These are chiral molecules. Significant progress has been made in recent years in both GC and HPLC separations of chiral molecules, that is, separating the right-handed isomers from the left-handed isomers.

The approaches are threefold. In one, a reaction is carried out binding a chiral reagent to the analytes, and the now-different reaction products separated with an ordinary chromatographic method. In the second, the analytes are chromatographed on a chiral stationary phase, and, since the two different structures are retained differently, they are separated. The third approach is a variation on the second; the stationary phase is not chiral, but the mobile phase has a chiral species added to it. This chiral species interacts reversibly with the chiral analytes, which allows a separation of the various products to occur on a nonchiral column. All three methods have been developed for HPLC. However, only the first two are used for GC chiral separations.

16.7.1.3 **Thin-Layer Chromatography**

In TLC, the adsorbent particles comprising the stationary phase are laid down as a layer a fraction of a millimeter thick attached to a solid backing plate of aluminum, glass, or polymer. Separations carried out on these stationary phases are called *TLC*.(Unfortunately, sometimes thick-layer chromatography, with layers 0.5–2 mm thick and primarily used for preparations, is also abbreviated TLC.) The primary advantage of TLC is that a number of samples and standards can be analyzed simultaneously side by side on the same plate. Using column chromatography, individual samples and standards must be analyzed sequentially. One other advantage of TLC is that samples that are difficult to resolve may be developed in two different solvents run in perpendicular directions: a two-dimensional separation. In this way, two or more species that run together in one solvent system may be separated from each other in the perpendicular direction in a second solvent system. One disadvantage of TLC is that quantitation tends to be less precise than in column chromatography. The greatest precision on intact plates is obtained with calibrated imagers.

16.7.1.4 **Field-Flow Fractionation**

When liquids flow without turbulence through a tube, the liquid at the walls is immobile, and that in the center flows the fastest. Since any suspended particles flow along with the fluid, the particles that reside in the center flow along the fastest and those nearer the wall more slowly. This is the basis for field-flow fractionation (FFF), which is carried out with the fluid flowing through a closed thin rectangular flow channel. FFF is the name of a set of techniques that use different kinds of forcing fields applied perpendicular to the flow direction across the thin direction to separate solutes of high molecular weight. The small separation set up by the field is, in effect, amplified by the flow of the fluid. The forcing fields can be set up by centrifuging (sedimentation), or by applying a voltage (electrical), or by applying a temperature difference (thermal). They find applications in the separation of macromolecules such as proteins, synthetic polymers, biological cells, and microscopic beads of various materials. Detection of the fractions is done with the same methods as for other LC methods: spectroscopic, electrochemical, and chemical.

16.7.2
Gas Chromatography

GC is an analytical method which has been studied and used intensively for more than 60 years in solving a wide variety of problems. Most classes of compounds that can be carried in the gas phase have been studied, and good separation conditions found for them.

GC equipment is quite different from that for HPLC. GC requires precise control of the flow of gases instead of liquids. The column, almost always, is significantly longer and/or narrower. Packing materials and stationary phases differ. The detectors differ both in construction and operation.

GC may be arbitrarily divided and named in terms related to the types of columns and column packings used. If the internal diameter of the column is in the range of 0.2–0.5 mm, this is called *capillary-column gas chromatography*, or *capillary GC*. With only a few exceptions, GC now means capillary GC when used in the context of analyses.

The analytes dissolve into and evaporate from the stationary phase multiple times while passing through the column. For analysis of organics on capillary columns, the material of the stationary phase generally is one of a number of different high-boiling-point liquids or stable solids that is coated on the inside surface of the capillary. With both these types of packings, the technique is called *gas chromatography* (*GC*). However, the latter is often called *gas–liquid chromatography* (*GLC*).

GC is routinely used for analyses of gases and for organic compounds with boiling points below about 450 °C. With boiling points in that range, the compounds have vapor pressures that are high enough so they will be carried in the gaseous mobile phase while the temperature is still low enough not to decompose either the analytes or the column materials. As a result, high-boiling materials are, perhaps, better separated by HPLC.

On the other hand, the GC column may be cooled during a separation of low-boiling materials such as methane or hydrogen. For such materials, GC can be run conveniently under conditions down to dry ice temperature, −80 °C.

The most broadly applicable detector for GC is a mass spectrometer (Section 16.5). With GC/MS, it is possible to identify most peaks that are of adequate size with good probability through the use of pattern-recognition methods. GC/MS is the method of choice for general organic chemical analysis, that is, when the identities of many different species are desired.

Other detectors, such as the electron-capture detector (ECD), are more sensitive and more specific than MS, and the specificity is often a benefit rather than a drawback. The ECD, which is relatively specific for halogens (F, Cl, Br, and I), is one of the most sensitive known; its detection limit is approximately 10^{-13} g s^{-1} of material passing into it. Even with capillary GC, in which the total sample may be in the microgram level, it is possible to obtain ppm determinations.

Numerous other types of detectors exist. Their use depends on the types of materials being analyzed and the sizes of the samples that are available. Two of the most common are the thermal conductivity detector, where the eluting gas flows over a hot wire and the temperature changes when eluents pass through, and the flame ionization detector. The latter works by burning the output material and causes gaseous ions of the separated components to form as they arrive, and the ions' quantities are measured. However, GC/MS is so powerful and flexible that MS has become the general detector of choice.

16.7.3
Supercritical Fluid Chromatography

In the chemistry of molecules that can be liquids at some temperature, there exists a temperature above which the substance will not condense to form a liquid-gas boundary at any pressure. This temperature is called the *critical temperature*. Above this temperature, the material is neither a liquid nor a gas; it is conveniently called a *supercritical fluid*. The mobile phase of supercritical fluid chromatography (SFC) is of this type. The most commonly used fluids are carbon dioxide and various lower molecular weight fluorocarbons. The equipment used for SFC is similar to GC, but the pressure throughout the column and the detector must be kept high enough to keep the conditions supercritical.

SFC is useful for certain classes of less-volatile analytes. Among these are molecules with hydrocarbon chains 12–50 carbons long such as the simple hydrocarbons themselves and detergents and fatty acids with such longer chains. Methods of separations and detection are well developed for these classes of compounds.

16.7.4
Electromigration

Electromigration is the movement of particles suspended in solution (most often water) in an electric field. The main electromigration technique that appears in chemical analysis is electrophoresis. Separations of charged particles from the size of individual ions of atoms to particles tens of micrometers in diameter are carried out by electrophoresis.

Electrophoresis separates various analytes based on their differences in rates of migration across the applied voltage. More highly charged particles migrate faster than less charged ones of the same size, and smaller particles migrate faster than larger ones with the same charge. The various analytes that are separated appear as zones as in other separation methods, and the name zone electrophoresis is used synonymously with electrophoresis alone. Electrophoresis is carried out either in a tube filled with solvent, or on a porous support – such as a plate with a gelled solution on it. The gel is, in fact, porous to the molecules which separate as they migrate through it. Gel electrophoresis is one of the primary techniques of biomacromolecule analysis. A popular technology involves carrying out electrophoretic separations in capillary tubes tens of micrometers in diameter – the diameter of hair. This produces high-resolution separations of small ionic species in micro samples. Perhaps the best known use of electrophoresis is the separation of sets of short DNA strands, which provides the experimental basis of most of contemporary genetic analysis.

16.8
Surface-Sensitive Methods

The difference between ‘‘regular’’ spectrometry and surface spectrometry is due not to the thinness of the sample, but to the thinness of the layer from which the analytical information is obtained. For example, in order to measure properties of a surface layer only, we can excite the spectral emission with particles, such as high-velocity electrons and ions. These can only penetrate through short distances (less than a few nanometers) of a solid. The name for the effective distance varies; two of these names are the penetration depth and the mean free path (see Table 16.7). The same limitation to penetration holds for the particles – such as electrons – expelled from the atoms residing in the interior.

With this idea in mind and from the information in Table 16.7, the following general statement can be made. To limit the spectrometric measurements to surface layers requires only that either energy is added using a bombarding charged particle or atom or a charged particle or atom is given off from the sample. Surface analyses are usually carried out under high vacuum, 10^{-10} Pa and less. ($1\ \text{Pa} = 9.87 \times 10^{-6}\ \text{atm} = 7.50 \times 10^{-3}$ torr.)

Other surface investigatory methods have been discussed in earlier sections although the surface analytical capabilities were not specifically emphasized. These methods are SIMS, and ultraviolet, visible, infrared and Raman, and X-ray spectrometry, done either at low angles of incidence or with total internal reflection methods. These methods can all be quantitative with precisions about ±20%.

Surface analyses heave two significant points of difficulty. Both result from the thinness of the sampled region – the "surface" of the assayed material. First, the quantity of sample is always small, and, as a result, the methods all involve microanalytical techniques. Second, the sample preparation methods are crucial to obtain a meaningful analysis. For instance, if a thin layer of oil about 5–10 *atoms* thick covers a metal sample, surface analysis may show only organic components in the sample.

16.8.1
Electron Spectrometry

16.8.1.1 Photoelectron Spectrometry

Electrons can be caused to be emitted from atoms and molecules upon irradiation with light. This is photoemission, and the electrons emitted are called *photoelectrons*. Each electron emitted has a kinetic energy (E_k) which is related to the wavelength of the exciting light and to the bonding energy of the electron that is emitted. Weakly held electrons have higher kinetic energies when emitted; strongly held ones have lower kinetic energies. An increase in irradiation intensity only increases the number of emitted electrons and not the individual kinetic energies.

When ultraviolet radiation is used, the spectrometry is called *ultraviolet photoelectron spectrometry* (*UPS* or *UV-PES*). If X-ray radiation is the source of ionizing energy, then the spectrometry is called *XPES* or *XPS*. Another name for XPS is ESCA. The two originally were separate classifications but are now joined together because a bright enough source of light tunable through both regions is available as synchrotron radiation.

Tab. 16.7 Approximate sampling depths of radiation (photons) and particles.

Name	Energy (eV)	Penetration depth (nm)
Infrared	0.5	100
Visible–UV	2–3	20
X-ray	1000	1000
Electron	2	0.5
Electron	1000	2
Ion	1000	2
Ion (proton)	10^7	10 000

For analysis of chemical content, however, it is XPS that is more often used, and its sensitivity tends to increase with atomic number of the elements. The strongly held electrons that are excited by the radiation are only slightly affected by chemical bonding. As a result, the values of the electron energies can be used to characterize the composition of the sample surface layer, but only major differences in chemical type can be seen. For example, sulfur in the form of sulfide and sulfate can be discriminated, but differences in the chemical environment of, for example, a sulfide, do not register.

In contrast, UPS causes electrons to be ejected from energy levels that change significantly with changes in molecular bonding. As a result, UPS is used more to investigate the types of chemical bonding present than for analyzing chemical makeup.

16.8.1.2 **Auger Spectrometry**

Strictly defined, the Auger electrons are also photoelectrons. However, it is convenient to separate them into their own category for a number of reasons. Irradiation with X-rays is comparatively inefficient in producing Auger electrons. Irradiation with accelerated electrons (a few hundred electron volts or so) is far more effective, and, thus, greater analytical sensitivity for the Auger method is obtained with electron excitation.

Auger spectrometry is primarily used to measure the elemental composition of a surface. Auger lines can be obtained for all elements except H and He. Its sensitivity is such that in the most favorable cases, less than 0.01 monolayer can be detected. Also, Auger spectra are characterized by a relatively high intensity, since the emitted electrons are able to be detected with excellent sensitivity. Further, the probability of Auger electron emission is high for elements lighter than zinc, making Auger spectrometry a complementary method to XPS. Auger spectrometry has become the method of choice for surface composition studies while XPS (ESCA) is used more for characterizing the chemical form of surface species.

If the electron beam which excites the Auger emission is focused onto a small (fraction of a micrometer) spot, the Auger electrons will be emitted only from the position of the spot on the surface. An Auger electron energy analysis can be used to quantify the elements at the one small part of the surface. The name given to this type of assay is electron microprobe analysis.

If the exciting electrons are focused to a small point and are scanned in a raster pattern over the sample (as done by the electron beam of a non-digital television screen to produce a picture), then a spatial distribution of the emissions can be made. For instance, either the characteristic X-rays or Auger electrons of a specific element can be monitored to obtain a picture of the spatial distribution of an element. An enlarged picture of the surface is generated on a television screen by simultaneously scanning the larger screen and a small area of the sample in synchrony. If the intensities of the Auger emissions for a specific element are recorded as a range of light intensity to produce a picture with good contrast, it will show the locations of the analyte. The Auger electrons without energy discrimination provide the basis for imaging in scanning electron microscopy (SEM).

16.8.2
Secondary-Ion Mass Spectrometry

If an accelerated charged particle impinges on a surface, it is stopped within a few atomic layers. One effect of this impact is to cause particles to be ejected from the surface. This is the process of sputtering. The emitted particles can be atoms, molecules, and molecule fragments. These may be analyzed with a mass spectrometer to determine information about the composition of the surface. The technique is called *secondary-ion mass spectrometry–SIMS*.

Of the sputtered material, only those that are ionized by the sputtering process can be accelerated directly into the mass spectrometer. As a result, complete analysis is problematic. However, quantitation and characterization can be more complete if all species are ionized. The neutral sputtered species can be ionized with UV light after their escape from the surface; this is photoionization. SIMS with photoionization has the potential to be far more reliable for quantitation.

Layer analysis can be carried out by obtaining a SIMS spectrum followed by ablation of the surface and another SIMS measurement. Alternate measurement and ablation can be reconstructed to view the chemical analysis of adjacent layers. Calibration of the ablation can provide an absolute depth scale.

16.8.3
Rutherford Backscattering

Rutherford backscattering involves, in effect, bouncing high-energy particles (usually helium ions with a few million electron volts of kinetic energy) off the nuclei of the surface atoms. Some of the energy of the incoming particles is transferred to the stationary atoms, and the amount of the energy transferred depends on the masses of the target atoms. As a result, the surface elemental composition can be probed by measuring the kinetic energy remaining with the probe particles after the collision. The technique is independent of the chemical bonding of the surface atoms, which results in this being a quantitative assay method. Absolute values of the coverage can be obtained without calibration of each sample since the scattering properties of each type of nucleus remain constant over the different samples. Less than a monolayer at the surface can be quantified if the surface layer is composed of heavier atoms on a solid composed of much lower weight atoms.

The mass resolution is not linear with the atomic mass of the analyte, and depends on the quality of the instrument. For instance, with 2-MeV ^{4}He probe particles, unit atomic masses can be resolved for atoms lighter than about chlorine, and, at the high end of atomic mass – near 200 amu – only masses differing by about 20 amu can be resolved.

16.9
Thermal Methods of Analysis

Energy added in the form of heat can cause changes in the structure or chemical content of materials. Examples of these changes are boiling (vaporization), melting (fusion), changes in crystalline form, transformation to and from a glass (glass transition), loss of water (dehydration), and chemical decomposition. These changes of structure occur at or above a characteristic temperature or range of temperature. Quantitation of the temperatures at which these changes occur and the amount of heat needed to cause these changes can be used to characterize or identify numerous materials. Among these are cements, ceramics, polymers, and plastics.

A large number of different techniques of thermal analysis have been devised including measurements of changes of electrical and magnetic characteristics, changes of elastic force, as well as changes in mass while a sample is heated. However, for chemical analysis, only a few are commonly used, and these are described briefly below.

16.9.1
Thermogravimetric and Evolved-Gas Analyses

Thermogravimetric analysis (TGA), or TG, involves measuring the change in mass of a substance as it is heated. TGAs involve recording the mass of a sample as its temperature is increased; mass is lost as decomposition occurs and volatile products escape, each process beginning at a characteristic temperature. Usually the temperature is raised at a steady rate, and the sample is kept in an atmosphere of flowing inert gas. Changes that occur in the sample that do not involve changes in mass, such as melting, cannot be studied by TG.

Characterizing the gaseous products of the decomposition as a function of sample temperature, a method called *evolved-gas analysis* is complementary to TG. The losses in mass from the sample may be due to loss of solvent or to breakdown of molecules in the material. Relatively detailed analyses can be done on sub-milligram samples. The analysis generally involves GC and/or MS of the volatiles.

16.9.2
Differential Scanning Calorimetry; Differential Thermal Analysis

The basis for calorimetric analyses is the measurement of the rise in temperature of a material for a given amount of heat added. The ratio of the temperature change to the heat added (T/Q) per unit weight is called the *heat capacity*. The heat capacity depends on the identity of the material and on the temperature at which the heat is added. Differential scanning calorimetry (DSC) works on the principle of keeping a constant rate of temperature change in a sample by regulating the amount of heat that is added. The rate of heat added is

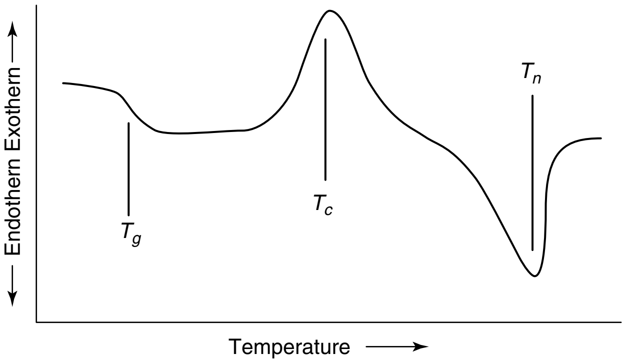

Fig. 16.24 Schematic differential scanning calorimetry thermogram of a polymeric material. The horizontal axis is a linear temperature scale, and vertical axis indicates the derivative of the amount of heat needed to obtain that temperature increase. The line would be flat if a material used the same amount of heat per degree to raise the temperature over the whole temperature range. The three deviations from the baseline (a flat line) are, from left to right, the glass transition, an exothermic (produces heat) chemical reaction, and endothermic (requires heat be added) melting.

plotted versus temperature as shown in Figure 16.24. This is called a *thermogram*.

An older method is differential thermal analysis (DTA) for which the heat is added at a constant rate, and the rate of temperature change is measured. The difference in temperature between a sample and standard is plotted versus temperature. The information obtained in DTA is similar to DSC, but they differ in experimental technique.

Acronyms of Analytical Techniques and Instruments

AA: Atomic absorption (spectrometry).
AAS: Atomic absorption spectrometry.
AE: Atomic emission (spectrometry).
AED: Atomic emission detector.
AES: Atomic emission spectrometry.
AES: Auger electron spectrometry.
AF: Atomic fluorescence.
ASV: Anodic stripping voltammetry.
ATR: Attenuated total reflection.
CARS: Coherent anti-Stokes Raman scattering (spectrometry).
CD: Circular dichroism spectrometry.
CI: Chemical ionization.
CI/MS: Chemical ionization mass spectrometry.
CP/MAS-NMR: Cross polarization magic-angle spinning nuclear magnetic resonance.
CW-NMR: Continuous-wave nuclear magnetic resonance.
DCP: Direct-current plasma.
DME: Dropping-mercury electrode.
DPP: Differential pulse polarography.
DSC: Differential scanning calorimetry.
DTA: Differential thermal analysis.
DTG: Differential thermogravimetry.
EAA: Electrothermal atomic absorption.
ECD: Electron-capture detector.
EDX: Energy-dispersive X-ray (spectrometers).
EDXF: Energy-dispersive X-ray fluorescence.
EGA: Evolved-gas analysis.
EI: Electron impact, electron ionization.
ELCD: Electrolytic conductivity detector.
EMP: Electron microprobe analysis.
ENDOR: Electron nuclear double resonance spectrometry.
EPR: Electron paramagnetic resonance (spectrometry).
ES: Emission spectrometry.
ESR: Electron spin resonance (spectrometry) (EPR).
ESCA: Electron spectrometry for chemical analysis.
ETA: Electrothermal atomization (electric furnace).
EXAFS: X-ray absorption fine structure.
FAA: Flame atomic absorption.
FAB: Fast atom bombardment.
FAE: Flame atomic emission.
FD: Field desorption.
FFF: Field-flow fractionation.
FFT: Fast Fourier transform.
FIA: Flow injection analysis.
FID: Flame ionization detector.
FT-IR: Fourier transform infrared (spectrometry).
FT-MS: Fourier transform mass spectrometry.
FT-NMR: Fourier transform nuclear magnetic resonance.
GC: Gas chromatography.
GC-IR: Gas chromatography with infrared detection.
GC-MS: Gas chromatography with mass spectrometry.
GDMS: Glow-discharge mass spectrometry.
GFAA: Graphite-furnace atomic absorption.
GPC: Gel permeation chromatography.

HPLC: High-performance liquid chromatography.

HPTLC: High-performance thin-layer chromatography.

IC: Ion chromatography.

ICAP: Inductively coupled argon plasma.

ICP: Inductively coupled plasma.

ICP/MS: Inductively coupled plasma/ mass spectrometry.

IC: Ion chromatography.

INAA: Instrumental neutron activation analysis.

IR: Infrared (spectrometry).

ISE: Ion-selective electrode.

LAMMS: Laser microprobe mass spectrometry.

LC: Liquid chromatography.

LC/EC: Liquid chromatography/electrochemical detection.

LC/MS: Liquid chromatography/mass spectrometry.

LEED: Low-energy electron diffraction.

MAS-NMR: Magic-angle spinning nuclear magnetic resonance.

MCD: Magnetic circular dichroism (spectrometry).

MIP: Microwave induced plasma.

MS: Mass spectrometry.

NAA: Neutron activation analysis.

NHE: Normal hydrogen electrode.

NIR: Near infrared.

NMR: Nuclear magnetic resonance.

NPD: Nitrogen phosphorus detector.

NQR: Nuclear quadrupole resonance (spectrometry).

ORD: Optical rotatory dispersion (spectrometry).

PAS: Photoacoustic spectrometry.

PD: Plasma desorption (in mass spectrometry).

PID: Photoionization detector.

PIXE: Particle-induced X-ray emission.

PMT: Photomultiplier tube.

QCM: Quartz crystal microbalanceRBS: Rutherford backscattering (spectrometry).

RI: Refractive index.

RIS: Resonance ionization spectrometry.

RP: Reversed phase (in liquid chromatography).

SAM: Scanning Auger microscopy (spectrometry).

SAW: Surface acoustic wave (sensor)SCE: Saturated calomel electrode.

SEM: Scanning electron microscopy.

SERS: Surface-enhanced Raman scattering.

SFC: Supercritical fluid chromatography.

SHE: Standard hydrogen electrode.

SIMS: Secondary-ion mass spectrometry.

SNMS: Sputtered neutral mass spectrometry.

STM: Scanning tunneling microscopy.

TCD: Thermal conductivity detector.

TG: Thermogravimetry (see TGA).

TGA: Thermogravimetric analysis.

TLC: Thin-layer chromatography.

TLC: Thick-layer chromatography.

TMS: Tetramethylsilane.

TOF/MS: Time-of-flight mass spectrometry.

TS: Thermospray.

UV: Ultraviolet (light) spectrometry.

vis: Visible (light) spectrometry.

WDX: Wavelength dispersive X-ray (spectrometer).

XRF: X-ray fluorescence.

XPS: X-ray photoelectron spectrometry (see ESCA).

XPES: X-ray photoelectron spectrometry (see ESCA).

XANES: X-ray absorption near-edge spectrometry.

Glossary

Accuracy: A qualitative measure of the closeness with which an analytical result corresponds to the true content of a material.

Analyte: The species for which one is analyzing.

Assay: As a noun, a chemical analysis to determine the level of a specific analyte. As a verb, to carry out such an analysis.

Bias: The quantitative amount that a result with high precision varies from the ''true content'' as a result of the analysis shortcomings.

Calibrate: To determine the bias and precision of the methodology used for an analysis or to determine an instrument's response to some known quantity of analyte.

Contaminant: Any material that is picked up during an analytical procedure that may cause the sample not to be characteristic of the original material from which the sample was taken.

Destructive Method: An analytical method that requires some obvious portion of a material to be removed and destroyed in the process of analysis. The opposite of a nondestructive method.

Detection Limit (Limit of Detection): The limit below which a particular instrument or analytical method cannot be used to observe the presence or absence of some analyte in a sample.

Electromagnetic Radiation: Depending on the frequency of oscillation, also called radio waves, infrared, visible, and ultraviolet light (or, simply, light), X-rays, and γ *rays*. Electromagnetic radiation is also described as oscillating orthogonal electric and magnetic fields that travel through space.

Interferent(s): A component or components (not the analyte) in a sample that cause a measure of the analyte content to be greater or less than it would be in the absence of the interfering components.

Matrix: The part of the material to be analyzed that is not of interest in an analysis.

Micro Analysis: An analysis of a sample that weighs less than approximately 10 mg.

Nondestructive Method: An analytical method that, after analysis, leaves the material being analyzed with no apparent changes.

Potential: Electric potential difference. Voltage. The difference in electric potential energy per unit charge.

Parts per Million: A relative measure of content. One ppm is one part in 10^6 of the sample such as grams per gram.

Parts per Billion: A relative measure of content. In the United States, one ppb is one part in 10^9 of the sample such as nanograms per gram. In Europe, one ppb is one part in 10^{12} such as nanograms per kilogram.

Parts per Trillion: A relative measure of content. In the United States, one pptr is one part in 10^{12} of the sample. In Europe, one pptr is one part in 10^{18}.

Precision, Imprecision: A measure of the scatter of experimentally determined values of content. The highest precision corresponds to the least scatter. Not the same as accuracy.

Sample, Laboratory Sample: The part of the original material that is used to produce an analytical result. It should accurately represent the contents of the original material.

Spectrum: A graph of the changes in the amount (more precisely, power) of electromagnetic radiation that is absorbed or emitted by a sample versus the wavelength, frequency, or energy of the radiation. Also, instrument response versus mass in mass spectrometry.

Sensitivity: The ability of an analytical method to measure changes in content or concentration. Greater sensitivity means that smaller changes give a measurable difference in response.

Standard: Substances that are used to ascertain the accuracies and precisions of analytical methods.

Standard Addition: A method of running standards in which a measurement is made on a sample and then repeated after known quantities of the analyte are added to the sample. Used for complicated mixtures.

Trace Analysis: Analyses for components that are less than 0.01% (100 ppm) of a material but more than ~1 part in 10^9.

Ultra-microanalysis: An analysis of samples of total mass in the range below about 10μg.

Ultratrace Analysis: Analyses for components of a sample that are at levels below ~1 part in 10^9.

Verification: Demonstration that an analytical procedure measures what it is claimed to measure.

Voltage: See Potential. Electric potential difference.

INTRODUCTION

Chemical kinetics is the description of rates of chemical transformations, the rates at which chemical species interact with one another to produce new chemical species. Along with the study of rates, chemical kinetics investigations usually seek to understand how chemical transformations occur. At the molecular level, a description of how the atomic motions facilitate the conversion of one species into another is the fundamental question that ultimately leads to a detailed understanding of chemical reactions.

Chemical reactions (*q.v.*) are ubiquitous in nature. They are essential for life, and they also occur in nonliving environments. Reactions are found in the gas phase, in liquids, and in solids. For example, gas-phase reactions occur in planetary atmospheres, including that of the Earth, and in flames and combustion. The well-known topics of urban air pollution (*q.v.*) and stratospheric ozone depletion have at their heart a very large number of gas-phase chemical reactions involving man-made pollutants that account for the production of harmful substances and, in the case of the stratosphere, the removal of ozone. Liquid-phase reactions span the range from biological reactions, such as enzyme catalysis and cellular processes, to industrial applications, such as the manufacture of polymers and organic and inorganic chemicals. Examples of solid-state reactions may be found in cooking food and in explosives. Many more examples could be cited. Chemical reactions are also of enormous practical importance. The chemical industry depends upon chemical reactions to convert raw materials or other

feedstocks into higher value substances. The modern standard of living would be quite different without sufficient knowledge of chemical reactions for success of the chemical industry.

The rates of reactions span an enormous range of time scales, from geologic to 10^{-15} s, the former for natural processes in the Earth's crust, and the latter for the fastest motions of atomic nuclei. Laboratory investigations span a somewhat shorter range, from a few days or so, depending on the patience of the experimenter, to a few femtoseconds. The latter has only recently become possible through the development of ultrashort pulsed laser sources that make time-resolved spectroscopic investigations on such a short time scale possible.

There is a trinity of levels for approaching problems in chemical kinetics. The first of these is empirical measurements of overall rates of change. This approach goes back to the beginnings of kinetics in the last century, and is still practiced today. A more detailed level consists of examining rates of change of individual molecular events. Such changes are referred to as elementary reactions. The most detailed level, called molecular dynamics (*q.v.*), seeks to understand how individual quantum states evolve during a reaction.

This article will cover the three approaches to kinetics. However, chemical kinetics is such an obviously broad field that complete coverage would be impossible in the limited space available. To narrow the scope, only gas-phase reaction kinetics will be covered, although the section on empirical kinetics is not restricted, the principles there being applicable to liquids and solids as well. The choice of gas-phase reactions is appropriate since it is only in the gas phase that the enormous wealth of detail that comes from being able to examine the chemical consequences of individual collisions, and of molecules in isolation, is accessible.

1. ELEMENTARY CONCEPTS

1.1 Empirical Kinetics

Overall chemical reactions, or stoichiometric reactions, describe the stoichiometric relationships between the reactants, those chemical species that are brought into contact initially, and products, those that are formed as a result of the contacting. They contain no information on reactive intermediates, such as free radicals, ions, or other species that may be present during the transformation but that are not found among the stable products. The stoichiometric relationship is conventionally expressed as

$$aA+bB+\cdots=mM+nN+\cdots, \tag{1}$$

where the lowercase letters are the stoichiometric coefficients and the uppercase letters are the chemical species. The stoichiometric coefficients prescribe the relative number of moles of each reactant producing the observed molar abundance of the products. This can be viewed as an algebraic equation and rearranged to $-aA-\cdots+mM+\cdots=0$, which can then be written in the compact notation

$$\sum \nu_i A_i=0, \tag{2}$$

where the ν_i are the stoichiometric coefficients, and the A_i are the chemical species. The stoichiometric coefficients are usually taken as being negative for reactants and positive for products. The summation runs over all chemical species.

The rates of consumption of reactants and formation of products, in moles n per unit time, in a closed system are related by the stoichiometry:

$$\begin{aligned} R&=(-1/a)(dn_a/dt)\\ &=(-1/b)(dn_b/dt)\cdots\\ &=(1/m)(dn_m/dt)\cdots,\\ R&=(1/\nu_i)(dn_i/dt). \end{aligned} \tag{3}$$

Consequently, for a self-consistent set of rates, the differentials dn/dt should always be divided by the appropriate stoichiometric coefficients. The above definition of rate makes it an extensive property. To make the rates independent of system size, the concentration, $[A_i]=n_i/V$, where V is the system volume, should be used. In nonconstant volume systems, the intensive rate has two terms,

$$\begin{aligned} r=R/V&=(\nu_i V)^{-1}(d/dt)(V[A_i])\\ &=(1/\nu_i)(\partial[A_i]/\partial t+[A_i]\partial\ln V/\partial t). \end{aligned} \tag{4}$$

At constant volume this reduces to

$$r=\nu_i^{-1}(d[A_i]/dt). \tag{5}$$

In open systems, the definition of rate must include terms for convection and diffusion. Most kinetics experimentation is designed to exclude transport effects since these may obscure the principal objectives of the work. Hence the description of open systems will not be elaborated upon here.

The functional dependence of the rate upon system parameters is called the rate expression. Important parameters are the concentrations of the reactants and (sometimes) the products, and the temperature. Other quantities may also play a role. In gas-phase reactions the total pressure is often important, while in liquid solutions ionic strength and dielectric constant are frequently found to influence the rate. Rate expressions are empirically determined, and in principle may take any form that fits the data:

$$r=f(T,A_1,A_2,\ldots,A_i\ldots,\text{other quantities}). \quad (6)$$

A common form is

$$r=k(T)[A_i]^{\alpha_1}[A_2]^{\alpha_2}\cdots[A_i]^{\alpha_i}\cdots=k(T)\Pi[A_i]^{\alpha_i}, \quad (7)$$

where $k(T)$ is called the rate constant or rate coefficient; the latter is preferable since $k(T)$ is not a constant, but in a properly determined rate expression is a function of temperature only. In such an expression the α_i's are the order of the reaction with respect to each chemical species. They are numbers that may take any value given by the results of the experiments, including negative numbers. Since they are empirically determined, they are not necessarily integers, although they often are found to have whole-number values. The overall order of the reaction is given by the sum of the individual orders,

$$\text{overall order}=\sum \alpha_i. \quad (8)$$

Frequently, the order is not defined. For example, the rate expression for the reaction between hydrogen and bromine, $H_2+Br_2=2HBr$, is

$$\tfrac{1}{2}d[HBr]/dt=(a[H_2][Br_2]^{1/2})/(b+[HBr]/[Br_2]), \quad (9)$$

where a and b are coefficients that are functions of temperature. Initially, before much HBr has accumulated, so that $[HBr]/[Br_2]\ll b$, the reaction appears to be first order in H_2 and one-half order in Br_2, while by the time enough HBr has accumulated that $[HBr]/[Br_2]\gg b$, the reaction appears to be first order in H_2, three-halves order in Br_2, and of order minus one with respect to HBr. Thus the order is observed to change during the course of the reaction. This behavior is by no means limited to this particular reaction, but is possible for any empirically determined rate expression. It should be kept in mind that the goodness of rate expressions is limited to the range of experimental conditions used, and should not be trusted outside this range.

The experimental determination of kinetic rate expressions is a subject that has been treated at length in the literature (Freiss *et al.*, 1961, 1968; Espenson, 1981). A survey of methods would be too lengthy for this article.

1.2 Elementary Reactions

The overall reactions described above are composed of a list of elementary reactions called the mechanism. An elementary reaction is a molecular event that normally involves chemical transformation of the reactant(s) into new chemical species, and frequently also involves collisional transfer of energy without chemical change. The reactants may be atoms, molecules, free radicals, or ions. The molecularity of an elementary reaction is defined as the number of molecules involved in the event. In unimolecular reactions a single reactant undergoes a spontaneous transformation

$$A\rightarrow\text{product(s)}$$

while bimolecular and termolecular reactions involve interactions of two and three species, respectively,

$$A+B\rightarrow\text{product(s)},$$

$$A+B+C\rightarrow\text{product(s)}.$$

Reactions of higher molecularity are not observed because the probability of obtaining simultaneous or nearly simultaneous interaction between four or more species is very small. The kinetic order of an elementary reaction is equal to its molecularity, and is thus limited to the positive integral values 1, 2, and 3, in contrast to the order of an overall reaction. Furthermore, the rate expression for an elementary reaction can be written by inspection. For example, the rate of the reaction between Cl atoms and methane, $Cl + CH_4 \rightarrow HCl + CH_3$, is expressed as

$$-d[Cl]/dt = k(T)[Cl][CH_4], \tag{10}$$

which is kinetically second order overall and first order each with respect to Cl atoms and methane. Elementary reactions are fundamental descriptions of chemical change, in contrast with the empirical nature of overall reactions. The rate coefficient can be described by rate theories, and since it is unique to the reaction between two specific species, such as Cl and CH_4, it can be used with confidence in any overall reaction in which that reaction occurs. Accordingly, much effort has been devoted to obtaining rate coefficients of elementary reactions, not only for use in describing overall reactions, but for the insight they provide in understanding how chemical transformations occur.

1.3 Kinetic Data

The kinetics of a reaction are determined by measuring concentrations of the reactants as functions of time. It is desirable to make similar measurements of products and, if possible, of reactive intermediates. Elementary reactions are studied by arranging experimental conditions so that the reaction being observed is the only kinetically important process, other reactions having negligible effect on the rate of the one being measured. Considerable effort is usually spent on experimental design to ensure isolation of the elementary reaction, and accuracy of the rate constants. Physical methods for *in situ* determination of concentrations without perturbing system composition are most desirable. Optical spectroscopies and mass spectrometry are common methods, but other physical measurement techniques may be used. Chemical analysis (*q.v.*) and chromatographic methods are usually only suitable for analysis of the final reaction mixture because they are slow and require removal of material. Reaction times that can be dealt with range from the very long, days or more, to as short as femtoseconds with the use of femtosecond pulsed lasers. Modern optical and electronic technology make investigations of highly reactive species, such as atoms and free radicals, on microsecond to nanosecond time scales possible. Fast reactions that require mixing of reagents are limited to milliseconds or perhaps slightly shorter times by mixing rate limitations. Experimental methods are treated in detail in several texts (Freiss *et al.*, 1961, 1963; Melville and Gowenlock, 1964; and Bamford and Tipper, 1969).

1.4. Mechanism

The list of elementary reactions that comprise the mechanism of a given overall reaction must yield the correct stoichiometric relationship for the overall reaction, with cancellation of reactive intermediates, when the reactions are regarded as algebraic relationships. Important energy-transfer steps must be included. Also, the net rate given by the mechanism must agree with the empirical rate expression. Writing the rate equation for each elementary reaction in the mechanism gives a set of coupled differential equations. When an analytical solution to this set of equations can be obtained, it must correspond with the empirical rate expression. Otherwise, if the rate coefficients of the elementary reactions are known, numerical simulation must yield the experimentally observed concentration-time relationships for the reactants. More than one mechanism can usually be found to satisfy these criteria. To distinguish between mechanistic possibilities normally requires careful experimental diagnostics. The nature of the experimentation is to attempt to disprove certain steps, or to obtain evidence in support of them. This gives rise to the frequently quoted caveat that a mechanism can never be proved, only disproved. Nevertheless, with modern experimental methods for direct, time-resolved detection of short-lived intermediates, it is possible to compile a compelling case in favor of a mechanism.

The analysis of complex overall reactions is a problem in the solution of simultaneous differential equations. The equations are usually coupled through the chemical species, which may occur in more than one rate equation. In homogeneous systems with uniform composition, it is a set of ordinary differential equations. If spatial variations of concentration exist, then a set of partial differential equations must be solved. In some cases, analytical solutions exist. There is extensive documentation of these in the literature (Szabo, 1961). However, in the vast majority of cases, analytical solutions cannot be obtained, and approximate methods must be sought.

An important method that has been much used in the past is the steady-state approximation. This can be understood by considering the sequence of irreversible reactions

$$A \rightarrow B \rightarrow C$$

for which the rate expressions are $-d[A]/dt = k_1[A]$, $d[B]/dt = k_1[A] - k_2[B]$, and $d[C]/dt = k_2[B]$, and for which analytical solutions $[A](t)$, $[B](t)$, and $[C](t)$ exist. It can be shown that in the limit as $k_1/k_2 \rightarrow 0$ the solution reduces to that for the set of equations $-d[A]/dt = k_1[A]$, $d[C]/dt = k_2[B]$, and $k_1[A] - k_2[B] = 0$. The three differential equations become two differential equations and an algebraic equation that can be obtained by setting $d[B]/dt = 0$ in the original set of differential equations. Since $[B]$ is now time invariant it is in a steady state. In practice k_1/k_2 does not approach zero, although the value of the ratio may be quite small when B is a reactive intermediate, such as a free radical. In such cases $d[B]/dt \cong 0$, and setting $d[B]/dt = 0$ is called the steady-state approximation. In the mechanism of a complex reaction it is common practice to set the time derivatives of all reactive intermediates equal to zero, converting, in each case, the differential equation to an algebraic equation. In this way a mixed set of differential and algebraic equations that has an analytical solution may be obtained.

When the mechanism consists of a set of linear differential equations the Laplace transform method can be applied (Jenson and Jeffreys, 1963; see also FOURIER AND OTHER MATHEMATICAL TRANSFORMS). This is of somewhat limited use since most mechanisms have reaction rate terms that are nonlinear. In these cases it is possible to linearize the equations, but the linearization, which is usually done by Taylor-series expansion, is only accurate near the origin of the expansion. Systems of first-order kinetic equations can also be solved by matrix methods (Jenson and Jeffreys, 1963). With the increasing use of digital computers, numerical methods (*q.v.*) have become more prevalent. Small sets of equations can be efficiently solved by Euler methods, or Runge-Kutta methods. The fourth-order Runge-Kutta method is particularly useful and accurate. A problem frequently encountered is called stiffness. This occurs when widely varying time constants are present. To calculate rapidly changing species concentrations accurately, small time steps are required, but these mean that computation of slowly changing compositions consumes large amounts of computer time. Fortunately, efficient algorithms employing variable time steps have been developed. These permit numerical integration of large, stiff mechanisms on modern, fast main-frame computers in very short times. Mechanisms describing atmospheric chemistry, and combustion reactions, including flames, have been developed that consist of upwards of 100 reactions. Clearly, with such large sets of coupled differential equations, numerical simulation is required.

1.5 Microscopic Kinetics

Microscopic kinetics seeks to understand the role of individual quantum states (see QUANTUM MECHANICS). The goal here is to observe the effect of molecular internal energy levels and of translational energy on the state and course of a reaction, and to see what energy levels of the products are populated. Studies aiming at this kind of a description are frequently called state-to-state kinetics. At this level of detail it is possible to gain insights into chemical reactivity that cannot be realized from research on the kinetics of overall reactions and conventional studies of elementary reactions. The use of crossed molecular beams, where each reactant is formed into a molecular beam intersecting the other in a well-defined region, and spectroscopy, particularly with tunable lasers, has permitted great progress to be made in this area. Experiments designed to select the initial states of the reactants are normally performed. In such work one is dealing with non–thermal-equilibrium energy distributions.

A bimolecular reaction between state-selected reactants leading to one pair of product states would be represented as

$$A(n_a,v_a,J_a,\mathbf{u}_a) + B(n_b,v_b,J_b,\mathbf{u}_b) = C(n_c,v_c,J_c,\mathbf{u}_c) + D(n_d,v_d,J_d,\mathbf{u}_d). \quad (11)$$

The quantities n_i, v_i, and J_i represent the electronic, vibrational, and rotational energy of each species, and $\mathbf{u}_i$ is the velocity. Although there has not yet been a report of a completely state-selected reaction, many examples of partially state-selected reactions can be found in the literature. Common cases are those where reactant(s) are observed in a single internal energy state, but have a Maxwell–Boltzmann distribution of translational energies, or have been velocity selected in a molecular-beam experiment, but have a distribution of internal energy states.

The connection between reaction rate at the microscopic level and the elementary reaction level can be made if the rate of the state-to-state process is written conventionally. For convenience, define A_i to be chemical species A in quantum state i, and B_j the same for species B. Then the state-to-state reaction rate is

$$r_{ij}=k_{ij}[A_i][B_j]. \tag{12}$$

In a situation where many states are populated, the total rate will be given by the sum of the individual rates,

$$r=\sum\sum r_{ij}. \tag{13}$$

If the population distributions are written as $[A_i]/[A]=f_i(\epsilon)$ and $[B_j]/[B]=f_j(\epsilon)$, then the rate becomes

$$r=[A][B]\sum\sum k_{ij}\,f_i(\epsilon)f_j(\epsilon), \tag{14}$$

and in systems where thermal equilibrium is maintained a Boltzmann distribution, $f(\epsilon)=g\exp(-\epsilon/kT)$, can be used:

$$r=[A][B]\sum\sum k_{ij}g_ig_j \times\exp[-(\epsilon_i+\epsilon_j)/kT]. \tag{15}$$

In systems where the rate of reaction is slow compared with the rate of collisional redistribution of energy, the Boltzmann distribution will be an excellent approximation. However, when the reaction rate is faster than redistribution the Boltzmann distribution may become significantly perturbed as reaction depletes states that have large microscopic rates.

Since the rate of a bimolecular reaction is written as

$$r=k(T)[A][B], \tag{16}$$

it can be seen that the thermal rate coefficients $k(T)$ can be associated with the microcanonical rate coefficients by the equations

$$k(T)=\sum\sum k_{ij}\,f_i(\epsilon)f_j(\epsilon),$$

$$k(T)=\sum\sum k_{ij}g_ig_j\exp[-(\epsilon_i+\epsilon_j)/kT]. \tag{17}$$

1.6 The Effect of Temperature

The rate coefficient $k(T)$ depends only upon temperature. The most common form of the temperature dependence is the Arrhenius equation,

$$k(T)=A\exp(-E_a/RT), \tag{18}$$

an empirical equation in which the preexponential factor A and the activation energy E_a are temperature-independent parameters, and R is the gas constant. The historical development of this important equation in the late 19th century has recently been summarized (Laidler, 1987). The Arrhenius equation predicts that a plot of $\ln k(T)$ vs $1/T$ (an Arrhenius plot) will be linear. The slope of the plot defines the activation energy according to the relationship

$$E_a=-R[d\ln k(T)/d(1/T)]. \tag{19}$$

In the vast majority of kinetics investigations over the past century the linearity of such plots has been repeatedly verified. More recently, it has been recognized that when data are available over a wide temperature range, Arrhenius plots are curved. Moreover, for some kinds of reactions, most notably elementary association reactions of the type $A+B=C$, the temperature dependence is definitely non-Arrhenius. The reasons for this will be discussed in Sec. 6.

A sketch of $k(T)$ vs T for the Arrhenius equation is given in Fig. 1, which clearly shows that the preexponential factor can be associated with the value of the rate coefficient as $T\to\infty$. The inflection point is easily shown to be $T_i=E_a/2R$. Activation energies typically have values that range from the vicinity of zero or a few kJ/mol to 400 kJ/mol, or in a few cases somewhat higher. For $E_a=200$ kJ/mol, $T_i=12\,000$ K, while for $E_a=20$ kJ/mol, $T_i=1200$ K. Thus, unless relatively low activation energy reactions are carried out at high temperatures, rate constants will normally be measured on the rapidly rising portion of Fig. 1.

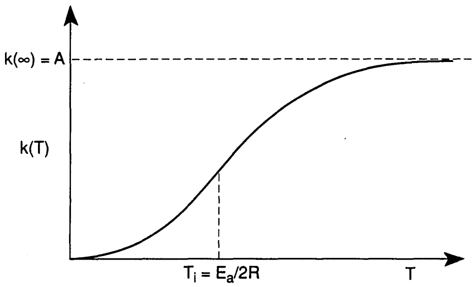

FIG. 1. Temperature dependence of the rate coefficient, $k(T)$, according to the Arrhenius equation, $k(T) = A \exp(-E_a/RT)$. T_i is the inflection point, and $k(\infty)$ is the rate coefficient as $T \rightarrow \infty$.

Theories of chemical kinetics usually predict temperature-dependent preexponential factors of the form $A = BT^n$, where n is normally a small number, which may be either positive or negative. Arrhenius plots are frequently found to be linear because the temperature dependence of the exponent is so much stronger than the temperature dependence of the preexponential factor. When experimental error is taken into account, curvature due to the preexponential is only detectable when data are available over an extended temperature range. An example of this is given in Fig. 2 for the elementary reaction of the OH radical with methane, an important combustion reaction. The activation energy is only 1060 J/mol, making the temperature dependence of the exponent less important, and the rate data extend from about 250 K to about 2000 K. It can easily be seen that over a temperature range of only 50–100 K, which is not uncommon in experimental studies of reactions, curvature would go undetected.

The activation energy is also temperature dependent, although the dependence is very weak. There is a statistical mechanical argument, due to Tolman (Fowler and Guggenheim, 1939), showing that the activation energy is given by the equation

$$E_a = \langle E^* \rangle - \langle E \rangle, \tag{20}$$

where $\langle E^* \rangle$ is the average energy of those molecules that can react, and $\langle E \rangle$ is the average energy of all of the molecules. The criterion for a molecule to be able to react is that it must have energy greater than the critical energy, a threshold energy below which molecules cannot react. Since $\langle E^* \rangle$ and $\langle E \rangle$ have similar temperature dependences, E_a is only weakly temperature dependent. It is worth emphasizing that Tolman's equation provides an interpretation of the activation energy.

1.7 Microscopic Reversibility and Detailed Balance

The principle of microscopic reversibility derives from the fact that the equations of motion for atoms and molecules are invariant under time reversal. Thus if in the final state after a molecular collision (reaction) all the momenta are reversed, including those of internal energy states, then the system will exactly retrace its path in the reverse direction to form a state similar to the original initial state, but with reversed momenta. This will be true of all of the energy states of a reacting molecule or pair of molecules. Application of microscopic reversibility to a macroscopic system consisting of a statistically large assembly of molecules leads to the conclusion that all chemical reactions are reversible. Furthermore, at chemical equilibrium, where all species concentrations are stationary in time, the rates of reaction in the forward and

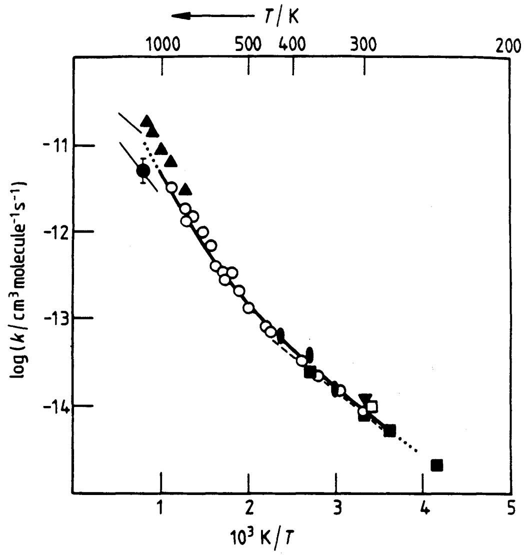

FIG. 2. Arrhenius plot of the rate coefficients for the reaction $OH + CH_4 \rightarrow H_2O + CH_3$. Symbols are data points, the thick solid line is a fit using the equation $\log(k/\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}) = -20.24 + 3.08 \log(T/K) - 1.01 \times 10^3 K/2.303T$, and the other solid and dotted or dashed lines are fits to subsets of data. [Reproduced from Smith (1980) with permission of the author.]

reverse directions are equal. This leads to the principal of detailed balance. Consider the elementary reaction

$$A+B \underset{k_r}{\overset{k_f}{\rightleftarrows}} C+D,$$

where the reverse arrows indicate the reversibility of the reaction, and k_f and k_r are the rate coefficients for the forward and reverse reaction, respectively. It is readily shown that at chemical equilibrium,

$$k_f/k_r=K(T), \tag{21}$$

where $K(T)$ is the chemical equilibrium constant, defined in Eq. (22). Since the rate coefficients are independent of composition, this relationship is also true when the reaction is not at equilibrium, and holds over the entire course of the reaction. In a complex reaction, detailed balance applies to each elementary reaction in the mechanism. It rules out some types of mechanisms, such as the cyclic process

$$\begin{tikzcd} & A \arrow[dr] & \\ C \arrow[ur] & & B \arrow[ll] \end{tikzcd}$$

which cannot occur as written, although it is possible to envision starting, for example, with pure A and reacting until a cyclic equilibrium is obtained. Instead, for these three reactions each step must be reversible.

1.8 Thermodynamic Restrictions on Kinetics

The conclusions about reversibility of chemical reactions reached from considerations of microscopic reversibility are also available from thermodynamic considerations. The well-known relationship between the equilibrium constant, $K(T)$, and the standard Gibbs free-energy change,

$$K(T)=\exp[-\Delta G^0/RT], \tag{22}$$

combined with the ideal solution relationship between chemical equilibrium composition and the equilibrium constant,

$$K(T)=\Pi[A_i]^{\nu_i}, \tag{23}$$

where $[A_i]$ is the concentration of the ith chemical species and ν_i is the stoichiometric coefficient, shows that a reaction would only be irreversible if $\Delta G^0 \rightarrow -\infty$. In general, then, all reactions are reversible, although in cases where the Gibbs free-energy change is large and negative the reaction may appear to go to completion in the sense that only very small quantities of reactant remain at chemical equilibrium.

In the case of overall reactions the relationship between forward and reverse rate constants and the equilibrium constant given above for elementary reactions must be replaced by the equation

$$k_f/k_r=K(T)^n, \tag{24}$$

where n is a number that may have any positive value (Denbigh, 1964). This relationship holds for overall reactions that have rate expressions of the form $r=k_f(T)\Pi[A_i]^{\alpha_i}-k_r(T)\Pi[A_k]^{\alpha_k}$ where subscript i is for reactants and subscript k is for products. For empirical rate expressions having other forms this expression should not be used.

2. POTENTIAL ENERGY

At the most fundamental level, one can attempt to understand the factors that control chemical reactivity and energy transfer in terms of the forces between atoms and molecules. Since the force **F** as a function of interparticle separation **r** is given by

$$\mathbf{F}(r)=-dV(\mathbf{r})/d\mathbf{r}, \tag{25}$$

the problem becomes that of determining the potential energy $V(r)$. The rate coefficients of elementary reactions and the microscopic rate coefficients of state-to-state processes depend upon the potential-energy function. For reactions involving ions it is normally found that long-range forces dominate. Interactions between ions can be described by the Coulomb potential

$$V(r)=z_1z_2e^2/r, \tag{26}$$

while for ion-molecule reactions there are two cases, ion-induced dipole interactions, where the potential for the interaction with a neutral molecule for atom) having polarizability α is

$$V(r)=-\alpha(ze)^2/2r^4, \tag{27}$$

and ion-dipole interactions where the potential depends upon both the interparticle distance and the angle θ between the direction of the dipole, μ, and r,

$$V(r,\theta) = -ze\mu \cos\theta / r^2. \tag{28}$$

For interactions between neutrals, both long- and short-range forces have to be taken into account. To describe binary interactions empirical potentials have been extensively used to avoid the difficult problem of determining potentials from first principles. In the case of nonreactive collisions, the Lennard-Jones potential

$$V(r) = 4\epsilon[(\sigma/r)^{12} - (\sigma/r)^6] \tag{29}$$

provides a reasonably realistic representation. The r^{-6} term represents attraction due to dispersion forces, while the r^{-12} term gives a steeply rising short-range repulsion. The parameters ϵ and σ are defined in Fig. 3. The potential energy of diatomic molecules is frequently represented by the Morse function

$$V(r) = D_e[\exp(-2\beta r) - 2\exp(-\beta r)] \tag{30}$$

sketched in Fig. 4. The features of this function are a long-range attraction to describe the forces driving the formation of the chemical bond, and a short-range repulsion required by the Pauli exclusion principle. D_e is a dissociation energy (see Fig. 4), $r = R - R_e$ is the displacement from the potential minimum, and $\beta = \nu(\mu/2D_e)^{1/2}$, where ν is the frequency of the fundamental vibration, and μ is the reduced mass, $\mu = m_1 m_2/(m_1 + m_2)$.

For polyatomic molecules, the electronic potential is a function of more than one internuclear distance. It cannot be graphically represented in the plane of $V(r)$ and r, as for diatomics, but requires a space of higher dimensionality. For an N-atom polyatomic, $3N$ Cartesian coordinates are required to specify the position of each atom. The potential, however, depends upon the relative positions of the atoms, which for the arbitrary pair x and y are given by the vector $\mathbf{R}_{xy}$. Thus, only $N-1$ vector distances and $3N-3$ Cartesian coordinates are required, three for each vector, the remaining three coordinates fixing the position of the molecule in space, which is of no interest with respect to the potential.

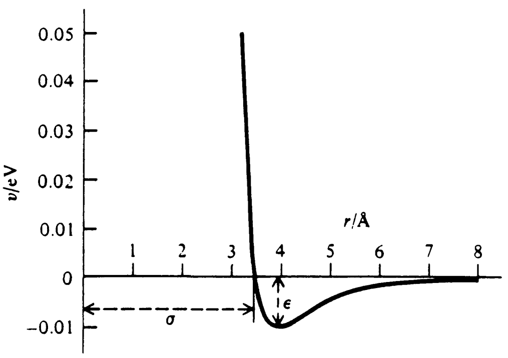

FIG. 3. The Lennard-Jones potential for argon. [Reprinted from Levine (1983), with permission of McGraw-Hill, Inc.]

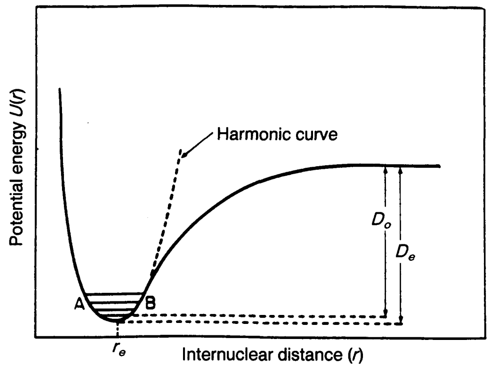

FIG. 4. The potential-energy curve for a diatomic molecule. [Reproduced from Robinson and Holbrook (1972), p. 8, with permission of the copyright holder.]

As an illustrative example we will consider a triatomic molecule, ABC. Choosing $\mathbf{R}_{AB}$ and $\mathbf{R}_{BC}$ specifies $\mathbf{R}_{AC}$ since $\mathbf{R}_{AC} = \mathbf{R}_{AB} - \mathbf{R}_{BC}$, and six coordinates are required. An alternative description would be to specify three scalar distances, either R_{AB}, R_{BC}, and R_{AC}, or R_{AB}, R_{BC}, and the bond angle Θ, as shown in Fig. 5, and three coordinates for the orientation of the plane containing atoms A, B, and C. Since the potential is independent of orientation, a graphical representation requires only four dimensions. Most mortals have difficulty visualizing four dimensions, so the representation is simplified by keeping one variable, usually the bond angle, constant. Then the potential can be presented as a surface which is a

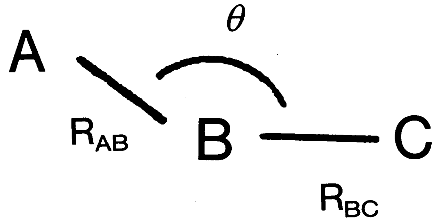

FIG. 5. Triatomic molecule A-B-C, with bond lengths R_{AB}, R_{BC}, and bond angle Θ.

function of R_{AB} and R_{BC} at a specified bond angle. Figure 6 shows a projection of such a surface onto the R_{AB}–R_{BC} plane, with contour lines of constant electronic potential. The minimum in the lower left-hand corner is the stable configuration for the bond angle, and the plateau in the upper right-hand corner gives the energy of the separated atoms. Starting at the minimum and moving parallel to either R_{AB} or R_{BC} describes dissociation of the triatomic molecule into an atom and a diatomic molecule. The trace of the surface on a cut perpendicular to the R_{AB} axis at large R_{AB} gives the potential curve for diatomic molecule *B–C*. A cut perpendicular to R_{BC} gives the *A–B* potential.

In a chemical reaction between an atom and a diatomic molecule,

$$A+BC=AB+C,$$

the triatomic molecule *ABC* formed by the close interaction resulting in reaction is unstable. This can be understood by examining the potential-energy surface, which can be described by using the same coordinates as for the stable triatomic molecule, but which has a different shape. Figure 7 shows a typical surface for this type of reaction. It can be seen that the minimum of Fig. 6 is replaced by a feature that resembles a mountain pass. A trace starting in the valley floor at either large R_{AB} or R_{BC} and proceeding along the minimum potential passes through a maximum which clearly shows the instability of *ABC*, which may dissociate into an atom and a diatomic molecule in either direction. The trace is a reaction path along the minimum potential energy. The potential-energy barrier is related to the activation energy, and plays an important role in determining the magnitude of the rate coefficient. Motion on the surface that is orthogonal to the reaction path corresponds to a bound system, as the potential energy increases in either direction. It can be seen that motion orthogonal to the reaction path corresponds to the symmetric stretch vibration, while motion along the reaction path would correspond to the antisymmetric stretch in a bound system. The bending vibration is not represented, since the bond angle is fixed.

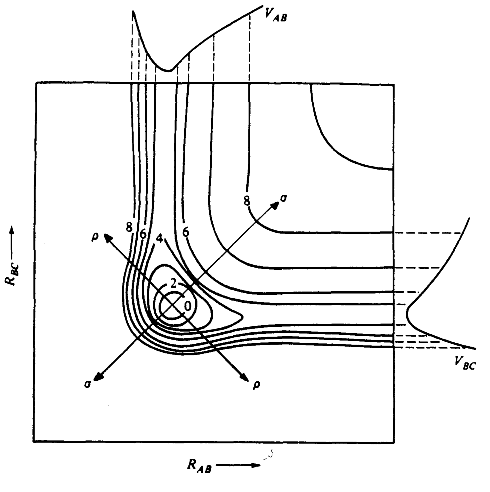

FIG. 6. The potential-energy surface for a stable, linear, triatomic molecule. Motion along directions ρ and σ represents asymmetric and symmetric stretch vibrations, respectively. (Weston and Schwarz, 1972, p. 34. Reprinted by permission of Prentice-Hall, Englewood Cliffs, NJ.)

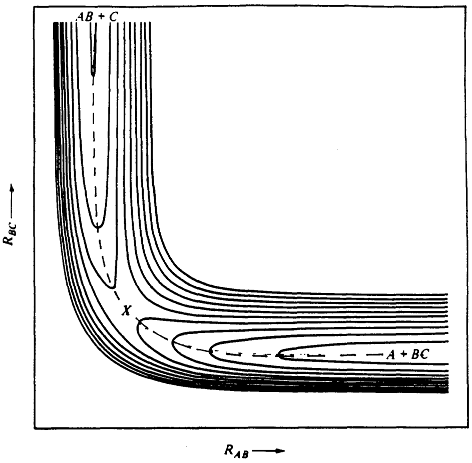

FIG. 7. Potential-energy surface for the reaction $AB+C \rightarrow A+BC$. The reaction path is indicated by the dashed line. The maximum along the reaction path is indicated by the *X* at the saddle point. (Weston and Schwarz, 1972, p. 36. Reprinted by permission of Prentice-Hall, Englewood Cliffs, NJ.)

A useful construction is the reaction-path profile, shown in Fig. 8. This is essentially an energy-vs-distance projection of the trace of the minimum-energy path for the *ABC* reaction, although the distance cannot be interpreted in terms of specific bond lengths, but should be seen as a somewhat vaguely defined reaction coordinate. The reaction-path profile is a convenient illustration of how potential energy changes as reaction proceeds. It is also frequently used to represent more complex polyatomic reactions, although in these cases

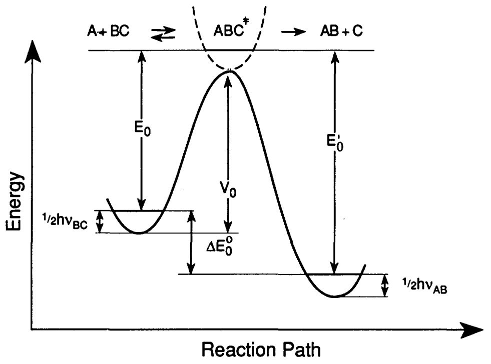

FIG. 8. Reaction-path profile corresponding to a surface of the type shown in Fig. 6.

the interpretation is strictly qualitative since the reaction-path profile exists on a hypersurface.

Electronic potentials for polyatomic molecules which have not been constrained for presentation in three dimensions require higher dimensionality, and are termed potential-energy hypersurfaces. There will be many hypersurfaces, each corresponding to an electronic state of the molecule, or an electronic state of the reacting system. Reactions may occur on a single hypersurface, in which case they are said to be electronically adiabatic, or they may occur with transitions between hypersurfaces (nonadiabatic). Chemical reactions most commonly occur on the ground-state hypersurface, although in excited-state kinetics, photochemistry, and nonadiabatic reactions, electronically excited hypersurfaces must be considered.

The electronic potential hypersurface plays a critical role in determining the rate and mechanism of a bimolecular reaction, as is apparent from the triatomic example above. It is enormously useful to know the surface both for understanding how the reaction proceeds, and for *a priori* calculation of rate parameters. While information about the potential for stable molecules may be experimentally obtained from spectroscopy, this has not been feasible in the past for reactions since the number of species in the midst of reacting at any instant is usually extremely small, and undetectable by suitable spectroscopies. This situation is currently changing, however, due to the application of sensitive laser-based spectroscopies. For example, a simple procedure for the inversion of femtosecond temporal spectra to yield the potential has recently been described (Bernstein and Zewail, 1990).

The determination of potential-energy hypersurfaces is most commonly approached by quantum-mechanical calculation. The *ab initio* approach requires solution of Schrödinger's equation

$$\mathscr{H}\psi=E\psi, \tag{31}$$

where the electronic potential is in the Hamiltonian operator,

$$\mathscr{H}=\sum -\hbar^2/2m_i\nabla_i^2+V(\mathbf{R}_{12},\ldots), \tag{32}$$

and it is convenient to employ the Born-Oppenheimer principle to separate electronic and nuclear motion,

$$\psi=\psi_e(\mathbf{r},\mathbf{R})\psi_n(\mathbf{R}). \tag{33}$$

Since exact solutions are not possible for the polyatomic systems of interest, variational methods, employing trial wave functions, have been developed extensively (Hirst, 1985). The experience of years of work on this problem has resulted in computational methods that usually give accurate structural information, but the situation with respect to energetics is less satisfactory. The self-consistent-field method is known to give unreliable energetics, while multiconfiguration and configuration-interaction approaches can give activation energies of simple reactions that are in error by only a few kJ/mol. There are presently surfaces of high accuracy for the reaction $H+H_2=H_2+H$ (Liu, 1973; Siegbahn and Liu, 1978; Truhlar and Horowitz, 1978), which is the simplest bimolecular reaction between neutral species in the sense that it involves only three protons and three electrons. Potential-energy surfaces have been calculated for many other reactions. A recent summary of progress over the last 40 years (Karplus, 1990) noted advances in the power of computers and in calculational methodology, so that "...It is now possible to do *ab initio* calculations that are of sufficient accuracy to answer chemically important questions for reasonably complex molecules and for potential surfaces describing their reactions."

The difficulty of *ab initio* calculations led to the development of semiempirical and empirical methods. Principal among these are the London-Eyring-Polanyi-Sato (LEPS) (Sato, 1955) and bond-energy–bond-order (BEBO) (Johnston, 1966) methods. The former is based upon the London equation for H_3, which in turn is based upon the Heitler-London theory for H_2. The latter is based upon conservation of bond order during a concerted bimolecular atom transfer reaction. Bond order n is defined by the relationship $r=r_s-0.26 \ln n$, where r is bond length, and r_s is the length of a single bond. The empiricism used in this approach does not come from kinetics, but from spectroscopy. Furthermore, BEBO does not give the complete surface, only the trace along the minimum potential-energy reaction path.

3. BIMOLECULAR COLLISION DYNAMICS

3.1 Simple Collision Theory

Since bimolecular reactions require an encounter between the two reactants, the upper limit of the reaction rate in the gas phase is the collision rate. For reaction between species A and species B, each considered to be structureless, spherical masses interacting according to the "hard-sphere" potential [$V(r)=0$, $r>d_{AB}$; $V(r)=\infty$, $r=d_{AB}$], the collision rate is

$$Z_{AB}=\pi d_{AB}^2(8kT/\pi\mu)^{1/2}n_A n_B, \tag{34}$$

and for reaction between two A species it is

$$Z_{AA}=\pi d_{AA}^2(4kT/\pi m)^{1/2}n_A^2. \tag{35}$$

The collision diameters are $d_{AB}=(d_A+d_B)/2$ and $d_{AA}=d_A$, where d_A and d_B are the respective diameters of species A and B, μ is the reduced mass of the collision pair, n_A and n_B are number densities, k is Boltzmann's constant, and T is the absolute temperature. The diameters d_A and d_B are normally taken from determinations via gas viscosity measurements, or other transport properties. The appropriateness of using this kind of data for reactive collisions is questionable, since the interactions leading to reaction might reasonably be expected to be "closer" than the physical interactions governing transport properties. The derivation of these equations can be found in any textbook of physical chemistry, and most chemical kinetics texts.

The collision rates can be expressed in conventional kinetics notation,

$$-dn_A/dt=k_{\text{coll}}n_A n_B \tag{36}$$

and the association $k_{\text{coll}}=\pi d_{AB}^2(8kT/\pi\mu)^{1/2}$ made. If $d_{AB}=4\times10^{-8}$ cm, and $\langle v\rangle=(8kT/\pi\mu)^{1/2}=4\times10^5$ cm s^{-1}, then $k_{\text{coll}}=2.5\times10^{-10}$ cm^3 molecule^{-1} s^{-1}. If this is taken as the bimolecular reaction rate constant, then at a pressure of one atmosphere, the one-half time (time taken for one-half of the reactants to be converted into products) is only 3×10^{-10} s! It is worth noting that πd_{AB}^2 and πd_{AA}^2 are collision cross sections, σ, so that $k_{\text{coll}}=\sigma\langle v\rangle$.

Of course, k_{coll} is the upper limit of the reaction rate constant because any potential barrier that must be surmounted will cause the reaction to be slower, and because there may be orientational restrictions. For example, a real molecule is not a sphere, but has chemical bonds that are directional. Some orientations of A and B as they collide may be favorable for the breaking and forming of bonds (reaction), while others may be unfavorable, and result in no reaction. The energetic requirement is usually treated by assuming that the probability of reaction upon collision is zero if the relative energy of the reactants along the line of centers is less than a critical energy, E_c, while the reaction probability is unity for all energies greater than E_c. Since the probability of having $E>E_c$ is given by $\exp(-E_c/RT)$, and a simple correction for orientation can be made by incorporating a temperature independent factor $p<1$, the simple collision theory (SCT) bimolecular rate constant is

$$k_{\text{SCT}}=k_{\text{coll}}p\exp(-E_c/RT). \tag{37}$$

Since $E_a=Rd\ln k(T)/d(1/T)$, according to SCT $E_a=E_c+\frac{1}{2}RT$ and the Arrhenius preexponential factor is $A=p(8\pi kT/\mu)^{1/2}d^2_{AB}\,e^{1/2}$. To predict k_{SCT} a value of E_c is needed. It is reasonable to obtain E_c from V_0 plus zero-point energy, but we have seen that calculation of potentials is difficult and frequently inaccurate. The common procedure has been to make comparisons of A_{SCT} with A_{expt} when an experimental value of E_a is available. Taking $p=1$, and typical collision diameter, A_{SCT} is of order 10^{-10} cm^3 molecule^{-1} s^{-1}, with very little variability with size or structure of the reactants. Values of A_{expt}, on the other hand, while in reasonable agreement with A_{SCT} for some cases, are most frequently smaller, sometimes by orders of magnitude. While some of this may be accounted for if the collision diameters from transport properties are too large to describe reactions, the correct diameters to use are generally not available. A modified SCT, in which orientation and collision energetics are taken into account, has been presented (Smith, 1980). This predicts probability factors p between 0.1 and 0.01, but fails to account for the smaller p's, 0.001 or less, that are frequently required to reconcile SCT with experiment.

The simple collision theory is an early treatment that contains a number of assumptions and approximations. Among these are the oversimplified interaction potential, no provision for nonadiabatic reactions, and the position that only energy of relative translation along the line of centers is important. In view of these, its inadequacy is perhaps not surprising. In the 1930s transition-state theory, a statistical theory of reaction rates, was developed and became highly successful. Collision dynamics was largely ignored in chemical kinetics, in spite of the physically satisfying picture of reactions it makes possible, until the 1950s when experiments on reactive scattering in crossed molecular beams were initiated.

3.2 Collision Dynamics

Most of the underlying concepts in modern approaches to collision dynamics can be understood from the classical treatment of collisions between structureless particles with spherically symmetric interaction potentials. Although this situation can only describe elastic scattering, and is only applicable to two-body collisions of atoms, it yields analytical solutions that provide a basis for understanding inelastic and reactive scattering of more complex species. For a specified potential, $V(r)$, the outcome of an elastic collision depends only upon the initial relative velocity g and the impact parameter b. The collision can be represented as the motion of a particle of mass μ, the reduced mass of the collision pair, with respect to a fixed scattering center. The impact parameter is the closest approach of μ to the scattering center that would occur in the absence of the potential. Figure 9 sketches this situation for a potential that is attractive at long range and repulsive at short range, for example, the Lennard-Jones potential. The deflection of the trajectory, χ, is given by

$$\begin{aligned}\chi &= \pi - 2\theta_m \\ &= \pi - 2b \int_{r_m}^{\infty} r^{-2}\left(1-\frac{b^2}{r^2}+\frac{V(r)}{E_0}\right)^{-1/2} dr, \end{aligned} \tag{38}$$

where $E_0 = (1/2)\mu g^2$. By considering the flux of particles scattered into solid angle $d\Omega$ as a function of b, a differential scattering cross section $\sigma(E,\chi)$ can be derived,

$$\sigma(E,x) = \frac{b}{\sin\chi}\left|\frac{db}{d\chi}\right| . \tag{39}$$

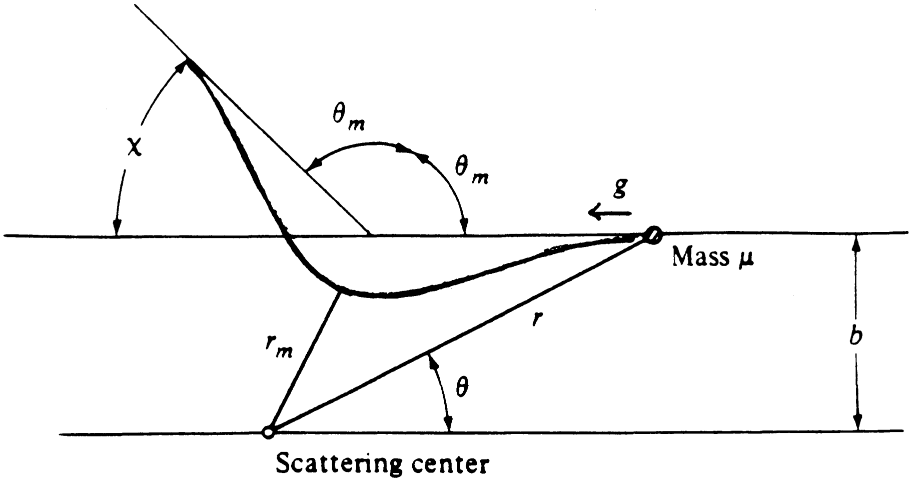

FIG. 9. Representation of a binary collision as the center-of-mass motion of a hypothetical particle of mass μ with respect to a fixed scattering center. (Weston and Schwarz, 1972, p. 47. Reprinted by permission of Prentice-Hall, Englewood Cliffs, NJ.)

By integrating over the deflection χ, the total scattering cross section can be obtained,

$$\sigma(E)=2\pi\int_0^\pi \sigma(E,\chi)\sin\chi\, d\chi. \tag{40}$$

Since the long-range part of the potential goes asymptotically to zero as $b\rightarrow\infty$, $\chi(b)\rightarrow 0$, and $\sin\chi\rightarrow 0$, so $\sigma(E,\chi)$ [and also $\sigma(E)$]$\rightarrow\infty$. This shortcoming of the classical treatment is removed by quantum mechanics, which predicts finite cross sections due to interference effects when the motion of the scattering particles is treated by wave equations. There are other unsatisfactory aspects of the classical picture of scattering which are also taken care of by quantum mechanics (Levine and Bernstein, 1987). In practice, there will be some minimum experimentally measurable deflection that is determined by the apparatus. The classical treatment can be adapted by setting this as a cutoff value of χ in the cross-section equations. Both $\sigma(E,\chi)$ and $\sigma(E)$ then become finite. The total cross section can then be expressed in terms of the impact parameter,

$$\sigma(E)=2\pi\int_0^{b_{\max}} b\, db, \tag{41}$$

where $b_{\max}$ is the largest value of b that produces a detectable deflection.

Another aspect of the elastic scattering picture that turns out to be useful in describing association reactions without a potential barrier comes out of considerations of angular momentum conservation. The centrifugal energy associated with a pair of particles can prevent them from having a close collision for large impact parameters. The centrifugal energy acts as a low repulsive barrier that is placed at relatively long range. The effective potential seen by the pair is then the sum of the electronic potential and the centrifugal contribution,

$$V_{\text{eff}}=V(r)+\tfrac{1}{2}\mu b^2g^2/r^2. \tag{42}$$

The effective potential is sketched in Fig. 10 for a specific b and g. A family of V_{eff} curves exists, depending on b and g. The long-range maximum has been used in some models to locate the position of the transition state in association reactions occurring without an electronic barrier. Note that the position of V_{eff} is energy dependent.

It is worthwhile to examine further the connection between cross sections and rate constants at this point. The hard-sphere collision-rate coefficient, shown above to be equal to the product of the cross section πd^2 and the average speed, can be readily generalized to any collision cross section. Since collision cross sections are found to be functions of the relative speed g, a microscopic rate coefficient may be expressed for collisions with specified relative speed,

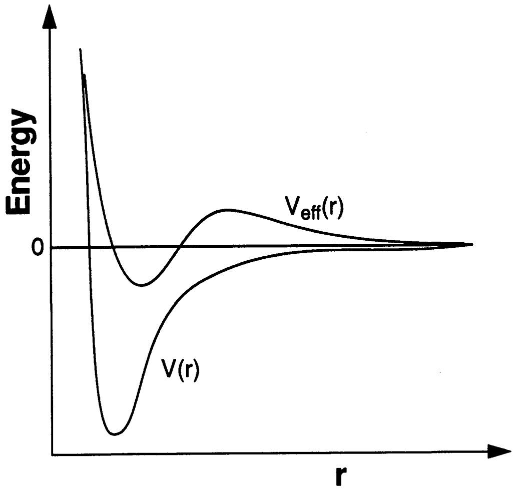

FIG. 10. The effective potential compared with the electronic potential for a binary collision.

$$k_{\text{coll}}(g)=\sigma(g)g, \tag{43}$$

and the thermal collision rate coefficient is obtained by thermally averaging over all relative speeds, $P(g)$ being the Maxwell-Boltzmann distribution:

$$k_{\text{coll}}=\int_0^\infty \sigma(g)gP(g)dg. \tag{44}$$

We are interested in reactive collisions, not just the total collision rate, which lumps together elastic, inelastic, and reactive collisions. The thermal rate constant can be obtained if $\sigma(g)$ is replaced with a reactive cross section, $\sigma_r(g)$:

$$k(T)=\int_0^\infty \sigma_r(g)gP(g)dg. \tag{45}$$

Although σ_r is taken here to be a function only of g it may also depend upon vibrational, rotational, or electronic energy. The reactive cross section is of central importance in any collision theory treatment of bimolecular reactions. Although at first glance it appears that cross sections could be determined by deconvolution of the integral in Eq. (45) if measurements of $k(T)$ were available, Fig. 11 illustrates that only limited information on cross sections can be obtained from thermal kinetics data. The product $gP(g)$ is plotted vs g in the figure, along with an assumed, but realistic, cross section that is a monotonically increasing function of energy, and has a threshold, ϵ_c, below which the cross section is zero. It can be seen that the integrand, $\sigma_r(g)gP(g)$, is only able to sample the cross section in the vicinity of the threshold because of the rapidity with which $P(g)$ dies out. Reactive cross sections are obtained from special experiments, particularly from scattering in crossed molecular beams, which is discussed in Sec. 7.

3.3. Classical Trajectory Calculations

Further development of collision theories aimed at deducing analytical expressions for cross sections and rate coefficients has been usurped by the advent of classical trajectory calculations. This method uses the classical equations of motion, Hamilton's equations, to calculate classical collision trajectories. Implementation of this approach was facilitated by the increasing availability of high-speed digital computers, particularly because many trajectories must be obtained to calculate cross sections and rate coefficients, which are statistically averaged quantities. The validity of this approach depends upon whether classical mechanics provides an adequate representation of what, strictly speaking, is a quantum phenomenon. There is a body of evidence supporting the position that classical trajectories give satisfactory results for many reactions. The limitations are being explored by quantum-mechanical scattering calculations.

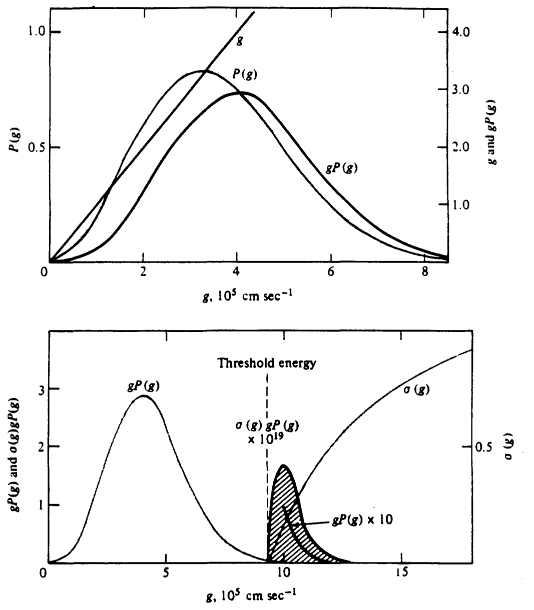

FIG. 11. Factors contributing to the rate coefficient given by the equation $k(T)=\int gP(g)\sigma(g)dg$. The rate constant is given by the shaded area. The rapid decrease of $gP(g)$ with increasing g leads to small contributions to $k(T)$ from high-velocity collisions, making it difficult to obtain information on the cross section from thermal rate data. (Weston and Schwarz, 1972, p. 86. Reprinted by permission of Prentice-Hall, Englewood Cliffs, NJ.)

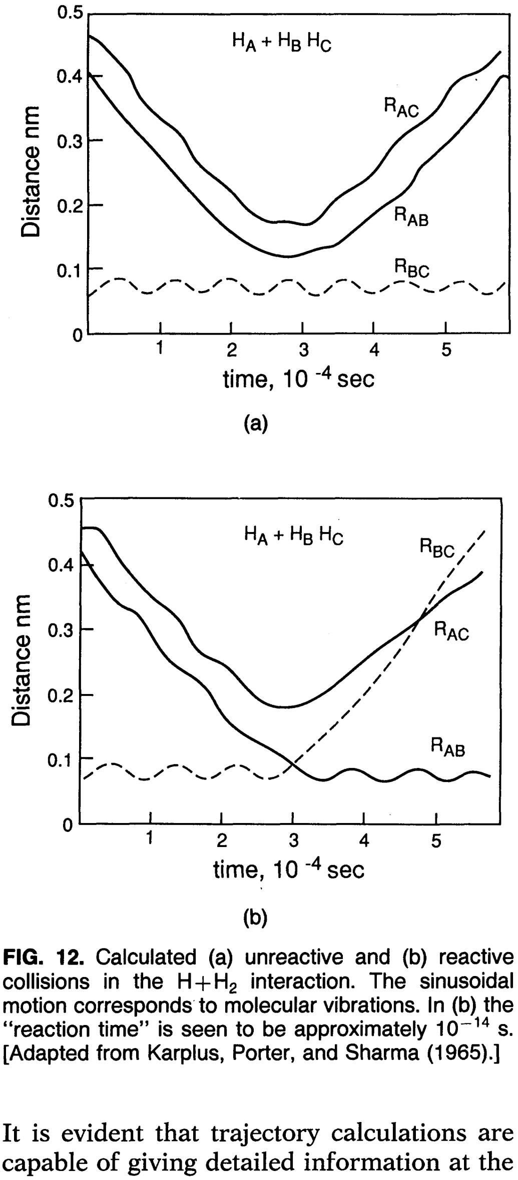
The quantities required to perform a trajectory calculation are the potential, the impact parameter, the initial kinetic energy, the vibrational energy and phase, and the rotational energy and orientation (rotational phase). Of these, the potential is of central importance. The difficulties of calculating an accurate potential-energy hypersurface have already been discussed. In a few cases good *ab initio* surfaces are available. In other cases approximate *ab initio* or semiempirical surfaces have to be used. If necessary, the potential barrier may be scaled to provide agreement with the experimental activation energy. When a surface has been selected, it must be fitted by an analytical function to obtain V as a function of position coordinates.

The next step is to choose the initial conditions for each trajectory. These are the values of b, E_0, and the internal energies. Monte Carlo procedures are used for this selection in order to approximate closely the correct statistical distribution of initial states within a relatively small set of trajectories. The minimum number of trajectories, N, that must be solved for the results to have statistical significance is of the order of 1000 or more. Examination of the trajectories shows which ones result in chemical reaction and which ones result in elastic or inelastic scattering. Figure 12 shows a reactive trajectory for an $H+H_2$ collision. The probability of reaction P_r, as a function of initial conditions, can then be obtained,

$$P_r(E_0,J,v,b)=\lim_{N\to\infty}\frac{N_r(E_0,J,v,b)}{N(E_0,J,v,b)}\,. \tag{46}$$



(a)

(b)

FIG. 12. Calculated (a) unreactive and (b) reactive collisions in the $H+H_2$ interaction. The sinusoidal motion corresponds to molecular vibrations. In (b) the "reaction time" is seen to be approximately 10^{-14} s. [Adapted from Karplus, Porter, and Sharma (1965).]

It is evident that trajectory calculations are capable of giving detailed information at the microscopic, or state-to-state, level. Reactive cross sections can be obtained by integrating over the impact parameters,

$$\sigma_r(E_0,J,v)=2\pi \int_0^{b_{\max}} P_r(E_0,J,v)b\, db, \qquad (47)$$

and microscopic thermal rate coefficients for individual vibration-rotation levels can be calculated by averaging over the Maxwell-Boltzmann distribution,

$$k(J,v)=\int_0^{\infty} \sigma(J,v)E_0\, f(E_0)dE_0. \qquad (48)$$

Finally, the thermal rate coefficient for the elementary reaction can be obtained by summing over the individual vibration-rotation states,

$$k(T)=\sum_{J,v} k(J,v). \qquad (49)$$

4. TRANSITION-STATE THEORY

4.1 Conventional Transition-State Theory

The transition-state theory (TST) was developed in the 1930s, primarily by Eyring and co-workers. A good account of the early work can be found in the book *Theory of Rate Processes* (Glasstone *et al.*, 1941). It is a statistical theory, using concepts of statistical thermodynamics to obtain an expression for the rate coefficient of an elementary reaction, and has been successfully applied to many different types of chemical reactions. The theory can be conveniently thought of as the solution to a barrier-crossing problem, where the barrier is an electronic potential maximum on the reaction path, as described in the section on potential energy. The reacting species that exists at the barrier maximum is called the transition state. The rate of crossing of the barrier can be calculated from the product of the concentration of transition states, $[A_i^{\ddagger}]$, the frequency of crossing the barrier, ν^*, and a transmission coefficient, κ :

$$r=\kappa\nu^*[A_i^{\ddagger}]. \qquad (50)$$

The derivation of the expression for the rate coefficient, which can be found in any textbook on kinetics, leads to the expression

$$k(T)=\kappa(kT/h)\frac{Q^{\ddagger}/V}{\Pi Q_i/V}\exp(-\epsilon_0/kT). \qquad (51)$$

In this equation, k is Boltzman's constant, h is Planck's constant, Q/V is the molecular partition function, and ϵ_0 is the difference in zero-point energy between the transition state and the reactants. The product in the denominator runs over all the reactant species, which in practice is usually either one or two, and the superscript double dagger (‡) denotes the transition-state. The theory assumes that there is a dividing surface between reactants and products, which locates the transition state, and beyond which there is no turning back to reactants. That is, all reactants that reach the transition-state configuration cannot return to the reactant side of the barrier, but must continue on to form products. Since some fraction is expected to turn back, TST gives an upper limit to the rate constant. Conventional TST locates the dividing surface at the barrier maximum. The reacting system is further assumed to be in thermal equilibrium. If the reaction rate is fast enough to deplete the population of reactant states above the barrier and cause deviations from a Boltzmann distribution, then the statistical arguments which lead to the incorporation of the partition functions become invalid. As a rule of thumb, if $E_a/RT \geqslant 10$, deviations from thermal equilibrium will not be severe enough to cause a problem. Finally, it is assumed that motion along the reaction path is separable. This permits factoring out a one-dimensional translational partition function that corresponds to motion of separating fragments away from one another. Thus $Q^{\ddagger}$ has one less internal degree of freedom than a stable molecule.

To evaluate the TST expression, it is necessary to calculate the partition functions. The reactants present no problem, for the usual assumption of separability into translational, rotational, and vibrational degrees of freedom is normally satisfactory. If the vibrational frequencies, moments of inertia, and electronic states are known, the computation is readily done. The evaluation of $Q^{\ddagger}$ is problematic, however. The electronic potential in the region of the transition state is only available for a few simple reactions, and we have seen that it is difficult to obtain. Furthermore, spectroscopic information is not available. Since the requisite molecular parameters are not generally calculable or measurable, they must be estimated by comparison with stable molecules. This provides sufficient latitude that agreement between theory and experiment can usually be easily obtained. It has been pointed out that since the lifetime of a transition state may be shorter than characteristic times for vibration and rotation, it is not clear whether its internal motions can be treated the same way that stationary states of stable molecules are treated (Smith, 1980). This is an issue that has not yet been addressed. Finally, TST does not provide for determination of ϵ_0, which must be obtained from other sources, either a potential surface or an experimental activation energy. (It is important to realize that ϵ_0 is not equivalent to E_a, or to V_0, but that these quantities are closely related.)

4.2 Thermodynamic Formulation

An alternative formulation of TST employs thermodynamic relationships, leading to the expressions

$$k(T)=\kappa e[kT/h(c^0)^{-\Delta\nu}]\exp(\Delta S^{0\ddagger}/R) \times\exp(-E_a/RT), \quad (52)$$

$$k(T)=\kappa[kT/h(c^0)^{-\Delta\nu}]\exp(1-\Delta n^{\ddagger}) \times\exp(\Delta S^{0\ddagger}/R)\exp(-E_a/RT), \quad (53)$$

the first of which applies to reactions in liquid solutions, and the second to reactions in the gas phase. In these equations, c^0 is a standard state concentration, conventionally taken to be 1 mol/L (solutions) or 1 molecule/cm^3 (gas phase), e is the base of natural logarithms, $\Delta n^{\ddagger}$ is 1 − (number of reactant molecules), and $\Delta S^{0\ddagger}$ is the entropy of activation, the difference between the entropy of the transition state and the entropy of the reactants. It can be seen that these are in the form of the Arrhenius equation, except that the coefficient of the $\exp(-E_a/RT)$ factor, which can be associated with the Arrhenius preexponential factor, is temperature dependent. It is common practice to ignore this, and make direct comparisons between theory and experiment whenever experimental values of $k(T)$ are available. Application of Eqs. (52) and (53) then allows calculation of $\Delta S^{0\ddagger}$. The numerical values of $\Delta S^{0\ddagger}$, which are found to encompass both negative and positive values, can be used as a guide to the general structural features of the transition state by the use of third-law molecular entropies. Johnston (1966) has summarized these ideas. It should be emphasized that a unique transition-state structure cannot be obtained, since a wide range of reasonable vibration frequencies and moments of inertia can be found that will fit a given $\Delta S^{0\ddagger}$.

4.3 The Transmission Coefficient

The transmission coefficient is a factor to correct for quantum-mechanical effects. For reactants that have total energies less than the classical barrier height, there is a probability that reaction may occur by tunneling, and if there is a surface of another electronic state nearby, there is a probability that reaction can occur by transition to that surface (nonadiabatic reaction). When tunneling is important, $\kappa > 1$, and when a nonadiabatic reaction occurs, $\kappa < 1$.

Analytical expressions for the contribution of tunneling to the transmission coefficient have been obtained for model barriers, such as the Eckert potential and the truncated parabola. For barriers of arbitrary shape, numerical calculations must be done. These are one-dimensional calculations, however, and tunneling is not a one-dimensional phenomenon. This is apparent from inspection of Fig. 6, which makes it clear that reaction paths other than the one of minimum energy will pass over higher and wider parts of the surface. Johnston (1966) has discussed this problem and tabulated some results. More recent multidimensional tunneling calculations have been done (Marcus and Coltrin, 1977), but they involve considerable effort. Tunneling will be important for light atoms, low temperatures, and thin, high barriers. In kinetics, tunneling usually only needs to be considered in reactions where the reaction coordinate involves motion of a H atom.

Electronically nonadiabatic reactions usually occur at the avoided crossing of two potential-energy curves (surfaces). The Landau-Zener model (Eyring *et al.*, 1944) gives the probability of transition between the two states in terms of the minimum-energy gap between them. It is capable of qualitatively explaining the low Arrhenius preexponential factors associated with reactions in which electron spin is not conserved, such as

$$N_2O(^1\Sigma^+) \rightleftharpoons N_2(^1\Sigma_g^+) + O(^3P),$$

which has a preexponential factor of about $10^{-11}\ s^{-1}$. The expected magnitude for a fully spin-allowed reaction would be $\geqslant 10^{13}\ s^{-1}$. The Landau-Zener treatment is a one-dimensional, classical model, and should not be considered accurate. Nikitin (1974) has given a treatment of nonadiabatic processes in chemical reactions.

4.4 Variational Transition-State Theory

As a result of dividing-surface recrossings, conventional TST leads to rate coefficients that are too large. The approach that has been taken to this problem is to relocate the dividing surface, and therefore the transition state, in a region where recrossings are minimal, since in general it may not be possible to find a location where recrossings are absent. Procedures for accomplishing this are classified as variational transition-state theories (VTST) (Truhlar and Garrett, 1980), since they have in common the minimization of some quantity. Canonical VTST minimizes the rate coefficient,

$$dk(T)/dq^\ddagger = 0, \tag{54}$$

where $q^\ddagger$ is the coordinate corresponding to the reaction path. This maximizes the Gibbs free energy. Microcanonical VTST minimizes the microcanonical rate coefficients, $k(E)$, since the number of recrossings at a given dividing surface location is most likely energy dependent:

$$dk(E)/dq^\ddagger = 0. \tag{55}$$

This defines a different transition state for each energy, and is expected to be an improvement over canonical VTST, which ignores the energy dependence of the recrossing.

5. UNIMOLECULAR REACTIONS

5.1 The Lindemann Mechanism

A unimolecular reaction is a spontaneous chemical change of an isolated molecule. The early history of unimolecular reactions centered on the question of how molecules obtain the requisite energy for spontaneous reaction, since it was thought that if collisions were responsible, the reaction would be bimolecular. The radiation hypothesis (Perrin, 1919), which claimed that absorption of blackbody radiation was the activation mechanism, was shown to be incorrect. F. A. Lindemann, at a 1922 meeting of the Faraday Society, presented a mechanism showing how collisional activation could account for first-order kinetics (Lindemann, 1922). The Lindemann mechanism is still the underlying basis for understanding unimolecular reaction kinetics. It is expressed by

$$A + M \underset{k_d}{\overset{k_a}{\rightleftharpoons}} A^* + M,$$

$$A^* \xrightarrow{k_E} \text{products}.$$

Reactant molecules A become activated by collisions with other species, or another A, here lumped together as M. The activated molecules A^* either react to form products, or become collisionally deactivated. The mechanism is an oversimplification, for it treats activation and deactivation as a one-step process, called "strong collisions," whereas multiple collisions, termed "weak collisions," are often required for an accurate description of unimolecular reactions. Also, the rate coefficient k_E for the unimolecular reaction is a strong function of energy. The steady-state approximation, applied to $[A^*]$, leads to the rate expression

$$\frac{d[P]}{dt}=\frac{k_E k_a[M][A]}{k_d[M]+k_E}=k_{\text{uni}}[A], \qquad (56)$$

and the experimentally observed first-order rate coefficient k_{uni} may be associated with $k_E k_a[M]/(k_d[M]+k_E)$, which correctly predicts that the unimolecular rate constant depends upon $[M]$, or equivalently, total pressure. When $k_d[M] \gg k_E$, the rate coefficient becomes independent of pressure, $k_{\text{uni}} \rightarrow k_E \times k_a/k_d \equiv k_\infty$, where k_∞ is the limiting high-pressure rate coefficient. At low pressures, when $k_d[M] \ll k_E$, $k_{\text{uni}} \rightarrow k_a[M] \equiv k_0$, k_{uni} becomes proportional to pressure at the low-pressure limit, and the kinetics become second order. A sketch of the pressure dependence is shown in Fig. 13, which is called a falloff plot.

If the energy dependence of k_E is taken into account, then the general expression for k_{uni} must be summed over all energies. Vibrational and, to a certain extent, rotational energy are responsible for unimolecular reactions. In molecules with enough energy to break bonds, vibrational states usually form a virtual continuum, so that summation can be replaced by integration, and the Lindemann expression for k_{uni} is replaced by

$$k_{\text{uni}}=\omega \int_{E=E_c}^{E=\infty} \frac{k_E P(E)dE}{\omega+k_E}. \qquad (57)$$

In this equation ω is the collision frequency $(\omega=k_d[M])$, $P(E)$ is the energy distribution function of the reactants, normally taken to be a Boltzmann distribution, and k_E is referred to as the microcanonical rate coefficient. The lower limit of the integral is the critical energy, a threshold energy below which reaction cannot occur. The strong-collision assumption is carried forward into this expression. Weak collisions can be empirically accounted for by replacing ω with $\beta_c\omega$, where β_c is a collision efficiency $0<\beta_c\leqslant 1$. Collisional energy transfer in unimolecular reactions has been reviewed (Tardy and Rabinovitch, 1977; Quack and Troe, 1981; Oref and Tardy, 1990).

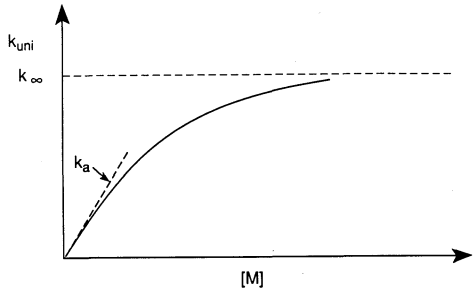


FIG. 13. Pressure dependence of k_{uni} according to Eq. (56).

5.2 Theoretical Models

Equation (57) and its modification to account for collisional inefficiency can be used for calculation of k_{uni} if a model for k_E is provided. The Rice-Ramsperger-Kassel (RRK) model, developed in the late 1920s and early 1930s (Kassel, 1932), is a statistical approach using combinational probabilities to describe randomization of vibrational energy among the s equal-frequency oscillators of the model reactant molecule. Reaction occurs when the reaction coordinate (one of the oscillators) contains energy $nh\nu$ greater than E_c. The model is successful in fitting experimental falloff data provided values of E_a and A are available. However, it is found that to obtain a satisfactory fit, s must be treated as a variable parameter, and its value usually turns out to be only one-half to two-thirds of the number of oscillators in the molecule. The model thus appears to give a contradiction between the assumption of energy randomization and the prediction that some of the oscillators are ineffective for intramolecular energy transfer.

A dynamical theory (Slater, 1959) assumes that reaction occurs when the harmonic normal-mode vibrations come into phase in such a way that the reaction coordinate extends by a critical amount. The theory was successful in application to cyclopropane isomerization, but was not able to account for some other reactions. For example, it predicts that the observed falloff curve for 1,2-dideuterocyclopropane should be shifted along the pressure axis with respect to cyclopropane, whereas no shift is found experimentally (Schlag and Rabinovitch, 1960).

The most successful unimolecular rate theory is the Rice-Ramsperger-Kassel-Marcus (RRKM) theory, an extension of RRK by incorporation of TST to replace the combinatorial statistics. These ideas (Marcus and Rice, 1951; Marcus, 1952), were further developed, primarily by Marcus and by Rabinovitch and co-workers. The RRKM theory is clearly laid out in two textbooks dealing with the theory of unimolecular reactions (Robinson and Holbrook, 1972; Forst, 1973). The book of Robinson and Holbrook is particularly useful as a tutorial in application of the theory. The incorporation of TST is made clear by the mechanism

$$A+M \underset{k_d}{\overset{k_a}{\rightleftarrows}} A^*(E)+M,$$

$$A^*(E) \underset{k_{-E}}{\overset{k_E}{\rightleftarrows}} A^\ddagger(E),$$

$$A^\ddagger(E) \xrightarrow{k_r} \text{products},$$

in which a distinction is made between activated molecules, $A^*(E)$, those that have enough energy to react, and transition states, $A^\ddagger(E)$, those that are at the critical configuration, or dividing surface. The energy dependence of the microcanonical rate coefficient is taken into account, but the strong-collision approximation is still made. Equation (57) can be used for k_{uni} with the appropriate expression for k_E and weak collisions can be taken into account by inclusion of a collision efficiency. The microcanonical rate coefficient in RRKM theory is given by

$$k_E = Q_i^\ddagger \sum G(E^\ddagger)/Q_i h N(E^*) \ , \qquad (58)$$

where Q_i are partition functions for inactive degrees of freedom of the transition state and the activated molecule, h is Planck's constant, $\Sigma G(E^\ddagger)$ is the total number of states of the active degrees of freedom of the transition state, and $N(E^*)$ is the internal state density of the activated molecules at energy E^*. Inactive degrees of freedom are those that do not couple with the reaction coordinate, and active degrees of freedom are those that exchange energy with it. Overall rotations are usually considered inactive, and taking all vibrational degrees of freedom to be active usually leads to satisfactory agreement between theory and experiment. Improved treatments of the adiabatic rotations are available (Waage and Rabinovitch, 1970).

The calculation of sums and densities of states can be done exactly on a digital computer by direct counting using the Beyer-Swinehart algorithm (Beyer and Swinehart, 1973; Stein and Rabinovitch, 1973). State sums and densities can be large numbers. For example, the relatively modestly sized molecule CH_3CN has about 10^6 states cm^{-1} at an energy of 350 kJ/mol. For computational efficiency an approximation due to Whitten and Rabinovitch (1963) is frequently used,

$$G(E^\ddagger) = (E+aE_z)^s \Big/ s! \prod h\nu_i \ . \qquad (59)$$

In Eq. (59), E is the total energy, E_z is the vibrational zero-point energy, a is an empirical correction factor that can be calculated from the vibrational frequencies, s is the number of vibrational degrees of freedom, and the product runs over all the normal vibrational frequencies. State densities at the same energy can be calculated by differentiation, $N(E^*) = dG(E^\ddagger)/dE$. This approximation is quite accurate when the nonfixed vibrational energy content is greater than an amount approximately equal to the zero-point energy, but can be appreciably in error at lower energies. In practice, direct count is used only up to energies where the Whitten-Rabinovitch approximation has acceptable accuracy.

Figure 14 shows an RRKM calculation for the thermal isomerization of methylcyclopropane compared with experiment (Topor and Carr, 1973). The calculation empoys the experimental activation energy, as the theory provides no guidance on energetics, and vibrational frequencies fitted to the experimental entropy of activation. The latter essentially provides a fit at the high-pressure limit, since it is readily shown that at the high-pressure limit, the RRKM expression for k_{uni} reduces to the TST rate coefficient. The vibrational frequency model is not unique, but falloff is

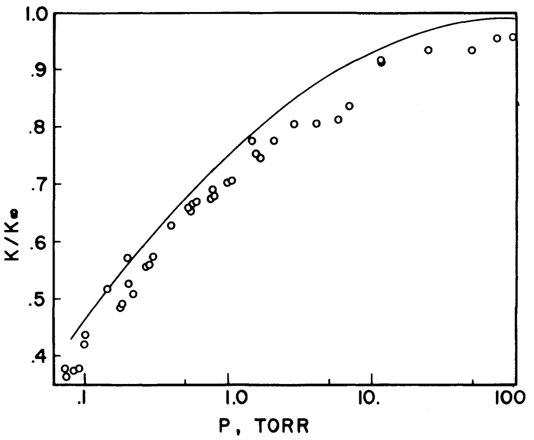

FIG. 14. Reduced (k/k_∞) unimolecular falloff plot for methylcyclopropane isomerization. Symbols are data points; the line is an RRKM calculation. Reprinted with permission from Topor and Carr (1973), p. 764.

insensitive to transition-state parameters so that any fit using reasonable values of frequencies is satisfactory. It can be seen that there is good agreement in the falloff without any further adjustment. Slightly better accord could be obtained by introducing $\beta_c < 1$, which shifts the RRKM curve to higher pressures. Figure 14 illustrates typical performance that can be expected from RRKM theory.

Troe has parameterized falloff curves to express the broadening that is observed at intermediate pressures in comparison with Lindemann-Hinshelwood predictions. This has led to a computationally efficient and reasonably accurate general procedure for calculating falloff curves. A summary of this approach has been given (Gardiner and Troe, 1984).

An alternative approach to the computation of k_E for use in situations where there is no maximum of the electronic potential, and hence there is an ambiguity in the location of the transition state, has been put forward (Quack and Troe, 1974; 1975). Termed the statistical adiabatic channel model, it takes angular momentum conservation explicitly into account as certain vibrational degrees of freedom become transformed into product overall rotations, by correlating states of reactants with states of products during passage through the transition region. The microscopic reaction coordinate is thus an adiabatic channel. A potential is constructed for each channel, involving an empirical looseness parameter. The calculations are somewhat more involved than RRKM, and agreement between calculation and experiment is good.

5.3 Chemical Activation and Photoactivation

The central assumptions of RRKM theory are that there is free-energy exchange between active degrees of freedom, that activation and deactivation occur via strong collisions, and that the activated molecules have random lifetimes and decay exponentially. These assumptions can be tested by employing the experimental techniques of chemical activation and photoactivation.

Chemical activation employs bimolecular association reactions to produce an adduct that contains enough internal energy to undergo a subsequent unimolecular reaction:

$$A+B\rightleftarrows AB^*\rightarrow \text{products},$$

$$AB^*+M\rightarrow AB+M.$$

The reverse of the association reaction may always occur, since the AB^* adduct is formed with at least enough energy to redissociate. If the reaction forming products has a lower critical energy than the reverse association reaction, then this path can dominate. Furthermore, AB^* is said to be chemically activated, since its energy distribution function is not characteristic of a thermally activated AB undergoing reaction to products. It is a distribution at the temperature of the association reaction, which may be considerably lower than the temperature needed to drive AB to products thermally, and which has been shifted to higher energy by an amount equal to the exothermicity of the AB^*-forming reaction. Figure 15 illustrates the energetics by means of a reaction-path diagram. The mean thermal energy of the adduct will be $\approx skT$, which may in some cases be only a few percent of the exothermicity of the addition reaction. Thus chemical activation may be used to probe the energy dependence of the unimolecular reaction. The second step in the above mechanism is the collisional deactivation of AB^*. In chemical activation reactions, the relative yield of the stabilized AB and the unimolecular reaction product is pressure dependent.

Photoactivation is analogous to chemical activation. Here, photon absorption produces an excited electronic state of the reactant, which must be selected to be a species that

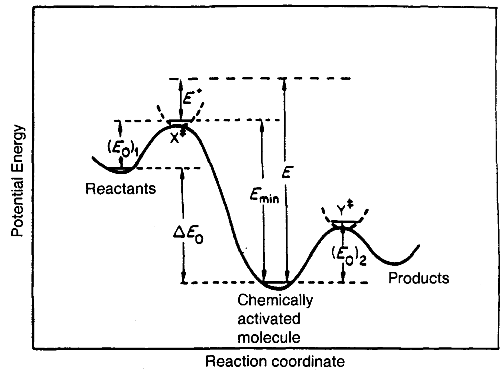

FIG. 15. Reaction-path profile for chemical activation by an exothermic reaction: $X^‡$ represents the transition state for the activating reaction and $Y^‡$ the transition state of the reaction to form products. [Reproduced from Robinson and Holbrook (1972), p. 269, with permission of the copyright holder.]

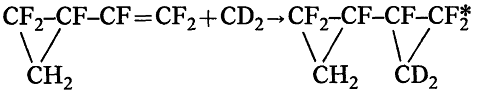
undergoes rapid intramolecular relaxation to high vibrational levels of the ground state. Photoactivation possesses the advantage that the energy of the photoactivated reactant can be varied by selecting the excitation wavelengths.

One of the first experimental tests of RRKM theory employed the addition of H and D atoms to 1-butene and *cis-* and *trans-*2-butene, which produces, in each case, a chemically activated *sec*-butyl radical capable of dissociating to form propylene and a methyl radical. The thermochemistry differs in each of the six reactions, and by varying temperature the range of energies was increased. Measurement of the unimolecular rate coefficients for these nearly monoenergetically excited radicals showed that they increased with increasing energy, as predicted by the model, and also were in very good quantitative agreement with values calculated by RRKM theory (Rabinovitch *et al.*, 1963).

The random lifetime assumption can be tested by determining the unimolecular rate constant in a chemical activation reaction over a wide range of pressure. If the decay of AB^* is exponential, the unimolecular rate constant will be independent of pressure, but if the decay is nonexponential, it will not be. In the H+2-butene reaction system, pressurized with H_2, the rate constant was independent of pressure from 55 to 203 atm, or up to a collision frequency of 5×10^{12} s^{-1} (Placzek *et al.*, 1966; Oref *et al.*, 1971). It can be concluded that energy randomization in *sec*-butyl radicals must occur on a time scale shorter than 2×10^{-13} s. This result is typical of polyatomic molecules, since a number of experiments have now been done, nearly all of which show that energy randomization occurs within the period of a few to a few tens of molecular vibrations. Organometallics having a relatively heavy metal atom bonded to lighter organic groups may be an exception (Sakai *et al.*, 1990). In these molecules the low-frequency vibrations associated with metal-ligand bonds may not couple strongly enough with portions of the molecule having higher-frequency vibrations to provide pathways for rapid intramolecular energy transfer.

Nonrandom decomposition can be diagnosed in experiments where isotopically labeled chemically activated intermediates are formed. For example, in the reaction



$$\underset{CH_2}{\underset{\diagdown\;\diagup}{CF_2-CF}}-CF=CF_2+CD_2\rightarrow\underset{CH_2}{\underset{\diagdown\;\diagup}{CF_2-CF}}-\underset{CD_2}{\underset{\diagdown\;\diagup}{CF-CF_2^*}}$$

the energy released upon addition of CD_2 to the double bond is initially localized there. Later, it may be distributed throughout the molecule. The reaction is unimolecular elimination of either CD_2 or CH_2, and the deuterium labeling permits one to distinguish which end of the molecule has reacted. Equal elimination of CH_2 and CD_2 denotes randomization, whereas any preferential elimination of CD_2 is evidence of nonrandom decomposition. In this case, 3.5% nonrandom decomposition was found, and the first-order rate constant for intramolecular energy relaxation was determined to be 1.1×10^{12} s (Rynbrandt and Rabinovitch, 1971). In other similar tests of randomization, small amounts of nonrandom reaction, amounting to a few percent, have been found.

Chemical and photochemical activation have been extensively employed for investigations of intermolecular energy transfer. As noted above, the ratio of reaction products to stabilized adducts (D/S) is pressure dependent. The strong-collision mechanism predicts that a plot of D/S vs the reciprocal of the collision frequency will be linear, whereas for weak collisions such a plot will be approximately linear for small values of D/S, but will be noticeably concave upward for $D/S > 10$ to

20. Figure 16 shows experimental data for the decomposition of methylcyclobutane (MCB), chemically activated by insertion of CH_2 into a C–H bond of cyclobutane, to propylene (P) and ethylene (McCluskey and Carr, 1976). Propylene is a decomposition product and methycyclobutane is the stabilized adduct so that $D/S = P/MCB$. It is clear that in order to diagnose weak collisional behavior, data must be taken at higher D/S. The line in the figure is a theoretical calculation, using RRKM theory in a steady-state master-equation formulation. Master-equation calculations are commonplace in the analysis of chemical and photochemical activation data. A collisional transition-probability model is required for these calculations. Simple analytical models are used since there is as yet almost no direct experimental or theoretical information on transition probabilities. The calculation presented in Fig. 16 employed equally spaced energy levels, called a stepladder model, with the spacing used as a fitting parameter. The average amount of energy removed per collision is 30 kJ/mol at an average MCB* energy of 483 kJ/mol, which is about 230 kJ/mol above the critical energy for the decomposition.

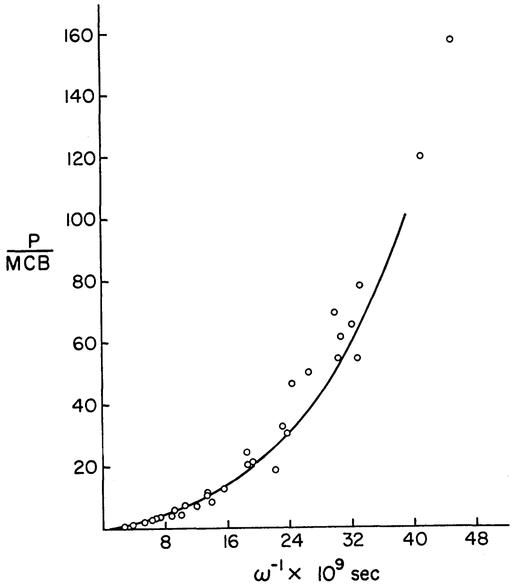


FIG. 16. The dependence of the ratio of decomposition P to collisional stabilization MCB on collision frequency ω for chemically activated methylcyclobutane MCB*. Reprinted with permission from McCluskey and Carr (1976), p. 1395. Copyright 1976, American Chemical Society.

Recent developments in unimolecular reactions center on direct detection of highly vibrationally excited molecules, primarily by application of laser spectroscopies (Crim, 1984; Reisler and Wittig, 1986). Time-resolved determination of unimolecular decay rates of molecules excited to very narrow energy distributions above the critical energy have become possible. These "almost state-resolved" experiments in dense vibrational manifolds are permitting unimolecular reactions to be examined in unprecedented detail, with direct determination of k_E and of reaction-product quantum states. Direct studies of collisional energy transfer have been pioneered by Troe and co-workers (Quack and Troe, 1981; Hippler, 1985) and by Barker (Barker, 1984).

6. ASSOCIATION REACTIONS

Association reactions are a class of reactions initiated by a bimolecular step, but which cannot be described by passage over a single potential barrier, as is done in the usual TST or collision-theory treatment of bimolecular reactions. They include atomic and free-radical combination reactions, as well as addition of atoms and free radicals to molecules. The association of atoms, and the reverse dissociation of diatomics, occurs without passage over a barrier, as the potential of the separating atoms goes asymptotically to the dissociation energy as shown in Fig. 4. The same situation holds for association of free radicals, and in these two cases a problem arises with respect to the placement of the dividing surface if TST is to be applied. In general, a chemically activated intermediate is formed in association reactions, although whether it is observed depends upon its lifetime and the total pressure. It can be seen that an association reaction is not a single elementary step, but a sequence that cannot be separated, since the subsequent steps all follow from the initial bimolecular event. The steps of an association reaction should therefore be treated as a whole. Pilling (1989) has recently reviewed association reactions of atoms and radicals.

6.1 Termolecular Combination of Atoms

The formation of diatomic molecules by combination of atoms is kinetically third order, and is commonly referred to as termolecular, although the reaction actually occurs by two bimolecular steps that must take place within about a picosecond of one another. This can be seen by the following, called the energy-transfer mechanism:

$$A+A \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} A_2^*,$$

$$A_2^*+M \xrightarrow{k_2} A_2+M.$$

A steady-state kinetic treatment of A_2^* leads to the rate expression

$$\frac{d[A_2]}{dt}=\frac{k_1k_2[A]^2[M]}{k_{-1}+k_2[M]}. \qquad (60)$$

The rate coefficient k_{-1} can be associated with the vibration frequency of the diatomic, $\approx 10^{13}\,\mathrm{s}^{-1}$, since there are no other vibrational degrees of freedom to share the energy released on formation of the bond, and redissociation will occur within a single vibrational period. Also, $k_2[M]$ may be associated with the collision frequency, assuming strong collisions. The value of $k_2[M]$ at 1 atm is about $10^{10}\,\mathrm{s}^{-1}$. Thus at virtually all pressures of interest $k_{-1} \gg k_2[M]$, and the rate expression becomes

$$\frac{d[A_2]}{dt}=\frac{k_1k_2}{k_{-1}}[A]^2[M], \qquad (61)$$

from which it is seen that the combination is kinetically third order. Pressures of the order of 1000 atm would be required to observe deviation from third-order kinetics. If collision theory is used to estimate k_1 and k_2, then $k_{\text{third}}=k_1k_2/k_{-1}$ is approximately 10^{-32} cm^6 $\mathrm{molecule}^{-2}$ s^{-1}.

Atoms may also combine by a mechanism, called the bound-complex mechanism, in which an atom forms a van der Waals cluster with M, followed by reaction of AM with another atom:

$$A+M \underset{k_4}{\overset{k_3}{\rightleftarrows}} AM,$$

$$AM+A \xrightarrow{k_5} A_2+M.$$

The rate of formation of diatomic molecules is given by

$$d[A_2]/dt=k_5[AM][A]. \qquad (62)$$

Since the atoms are normally present in a large excess of M species, the AM complexes can be considered to be in chemical equilibrium,

$$K_e=[AM]/[A][M], \qquad (63)$$

and the rate is third order,

$$d[A_2]/dt=k_5K_e[A]^2[M]. \qquad (64)$$

In this case, $k_{\text{third}}=k_5K_e$ can be evaluated by using equilibrium statistical mechanics for K_e, and computing k_5 by the collision theory. For weakly bound AM complexes, k_{third} is approximately 10^{-32} cm^3 $\mathrm{molecule}^{-1}$ s^{-1}, but for more strongly bound complexes, k_{third} will be larger. Data for first-row atoms with atomic and diatomic M species are normally found to have rate coefficients within a factor of 2 of the above estimates. Collected data for the combination of iodine atoms illustrates the much wider range of third-order rate-constant values possible for highly polarizable species (Johnston, 1966).

Measurements of the temperature dependence of k_{third} show that values decrease with increasing temperature. This is a common occurrence for association reactions with no potential barrier. The negative temperature coefficient can be rationalized for the bound-complex mechanism in terms of the temperature dependence of K_e, but is difficult to explain by the energy-transfer mechanism. Arrhenius plots of k_{third} have positive slopes, which according to the Arrhenius equation yield a negative value of E_a. Thus, termolecular atom combinations are frequently said to have negative activation energies, even though it is difficult to attach any physical significance to such a concept.

6.2 Combination of Polyatomic Radicals

The combination of radicals can be described by the mechanism

$$R\cdot+R\cdot \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} R_2^*,$$

$$R_2^*+M \xrightarrow{k_2} R_2+M,$$

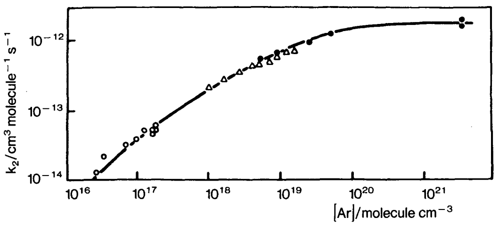

FIG. 17. The dependence of the second-order rate coefficient for the combination reaction $CH_3+O_2+Ar \rightarrow CH_3O_2+Ar$ on concentration of Ar. $k=k_2k_1[Ar]/(k_{-1}+k_2[Ar])$, where the quantities on the right-hand side are defined in Eq. (65). [Reprinted from Pilling (1989), p. 272. Copyright © 1989, John Wiley & Sons, Inc., with permission of John Wiley & Sons.]

which is formally identical to the energy-transfer mechanism of atom combination, with the rate of formation of R_2 given by

$$\frac{d[R_2]}{dt}=\frac{k_2k_1[R\cdot]^2[M]}{k_{-1}+k_2[M]}. \qquad (65)$$

In this case, however, $R_2^{\ddagger}$ is a polyatomic species, and the energy released by formation of the chemical bond between the two $R\cdot$ species can be distributed among its internal degrees of freedom, giving it a significantly longer lifetime than $A_2^{\ddagger}$. For this reason, $k_2[M]$ can no longer be neglected with respect to k_{-1}, and the pressure dependence of $d[R_2]/dt$ may be observable at conventional reaction pressures. It is correct to describe $R_2^{\ddagger}$ as a chemically activated intermediate, and to treat k_{-1} as a unimolecular rate constant. The relative magnitude of $k_2[M]$ and k_{-1} depends upon the pressure and on the lifetime of $R_2^{\ddagger}$, which is a function of the number of oscillators, the vibrational frequency pattern, and the excitation energy, or equivalently, the temperature. Figure 17 shows the pressure dependence of the combination of methyl radicals and O_2, from which it is seen that the pressure-dependent region is between a few Torr and 1 atm. As the combining species become larger (an increase in the number of oscillators) the falloff shifts to lower pressures.

A distinguishing feature of association reactions is that they proceed through the formation of an intermediate complex. This is due to the electronic potential, which has a deep well, in contrast with reactions occurring on surfaces such as depicted in Figs. 7 and 8, where the maximum corresponds to an unstable transition state with a lifetime typically less than a picosecond. Intermediate complexes larger than diatoms can have considerably longer lifetimes than this. The surfaces on which intermediate complexes are formed may have a single entrance and exit channel, such as in Fig. 4, which is correct for diatomic molecules. A curve similar to Fig. 4 may also represent the reaction path for polyatomics for which there is only one energetically accessible reaction. A reaction path profile for a two-channel reaction is sketched in Fig. 18. Here, the possibility of an entrance-channel barrier, with a transition state $X_l^{\ddagger}$, is represented by the solid line, and no barrier by the horizontal dashed line. In the forward direction, the entrance barrier is higher than the exit barrier, but the other case of a lower entrance barrier can be obtained simply by considering C and D to be the reactants. In this case we have the typical chemical activation situation of Fig. 15. The mechanism is given by

$$A+B \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} Y^* \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} C+D,$$

$$Y^*+M \overset{k_3}{\rightarrow} Y+M.$$

The overall rate coefficient is defined by $k_{\mathrm{exp}}=[A]^{-1}[B]^{-1}d[A]/dt$. If the exit barrier is high enough that k_{-2} is very small, a steady-state treatment of Y^* leads to

$$k_{\mathrm{expt}}=\frac{k_1(k_2+k_3[M])}{k_{-1}+k_2+k_3[M]}, \qquad (66)$$

which predicts that k_{expt} is pressure dependent. Several cases can be distinguished depending upon the relative magnitudes of the

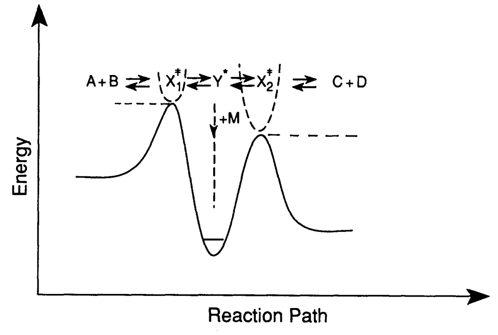

FIG. 18. Reaction-path profile for a two-channel association reaction.

rate coefficients of the elementary processes: For example if $k_3[M] \gg k_2, k_{-1}$, then $k_{\mathrm{expt}} = k_1k_2/(k_{-1}+k_2)$, independent of pressure, and further if $k_{-1} \gg k_2$, $k_{\mathrm{expt}} = k_1k_2/k_{-1}$, or if $k_{-1} \ll k_2$, $k_{\mathrm{expt}} = k_1$. Other cases can be worked out starting with $k_3[M] \ll k_2$. Values of k_{expt} can be estimated from theory by applying TST to k_1, and RRKM theory to k_{-1} and k_2.

It is worth emphasizing that although the reaction of A with B involves a bimolecular step (initially), there is only one case where application of TST alone leads to a correct interpretation of k_{expt}. Reactions that appear elementary should always be closely examined to make sure that they do not proceed by complex formation. The reaction $OH+CO = CO_2+H$, which is important in combustion, provides a case in point. It was originally thought to be an elementary atom-transfer reaction, although the temperature dependence from low- and high-temperature experiments was not in agreement. It is now known that Arrhenius plots for this reaction are strongly curved, being nearly independent of temperature at 300 K and lower temperatures, suggesting virtually no barrier, but increasing strongly with increasing temperature above 1000 K. This behavior cannot be explained if $OH+CO$ occurs as a direct reaction which can be modeled by TST. It is readily and quantitatively reproduced by postulating that the reaction involves the formation of an intermediate HOCO species. There is independent evidence from low-temperature spectroscopy in matrices for the existence of stable HOCO.

7. MOLECULAR REACTION DYNAMICS

Molecular reaction dynamics is the branch of kinetics dealing with elementary processes from the standpoint of the motions, or dynamics, of atomic and molecular motions during chemical reaction. These are most usefully investigated by examining quantum states. It would be of interest to know how microscopic rate coefficients depend upon the velocities and internal states of the reactants, and what the product velocities and internal state distributions are. A complete state-to-state description would provide an enormously detailed picture of a reaction. The accumulated results from this type of investigation would lead to deep understanding of the factors that control chemical reactivity, and to detailed tests of rate theories. Levine and Bernstein have recently published an excellent text on molecular reaction dynamics (Levine and Bernstein, 1987).

In practice, state-to-state kinetics usually falls somewhat short of these lofty aspirations. The amount of experimental effort that would be required for a complete state-to-state description of a single reaction in which the reactants are in thermal equilibrium with the surroundings would be formidable, with a number of experimental techniques most likely having to be brought to bear. Furthermore, it may not be possible to achieve complete initial-state selection in many experiments, and where possible, final-state detection sensitivity may require compromises. Most molecular-dynamics experiments that have been reported have required some concessions along these lines. Equations (17) give the relationship between microscopic rate coefficients and rate coefficients of elementary reactions. Although, in principle, the latter could be calculated from these equations, it is impractical to do so. In spite of these shortcomings, many very interesting experiments have been done, most of them with only partial state resolution. The resultant body of data has been instrumental in advancing our understanding of how chemical reactions occur.

The trajectory calculation approach discussed in Sec. 6 is capable of providing the detailed picture sought, but it must be remembered that the accuracy of these calculations depends critically upon the potential-energy surface. Since quantum-mechanical calculations of surfaces are always approximate, considerable effort must be put into evaluating the goodness of a trajectory calculation. Computational methodology has advanced to the point where good confidence can be placed in a number of surfaces.

7.1 Molecular Beams

Bimolecular reactions can be studied in crossed molecular beams. Two narrow beams of atoms or molecules are caused to intersect in a vacuum chamber. The beams are now most usually produced by supersonic nozzle expansions, although the earlier technique of effusive beams may also be used. In the individual beams, collisions are virtually absent, and the atoms or molecules move in essentially one dimension, given by the direction of the beam. However, in the volume defined by the intersection, collisions between the species of each beam occur. The forces that govern the collisional interaction cause the atoms and molecules to be scattered. A detector that can be moved about the scattering volume detects the scattered species. The angular dependence of the scattering provides information from which differential cross sections can be obtained. The detector most commonly used is the quadrupole mass filter, which provides species identification and can distinguish between reactive and unreactive scattering. Crossed–molecular-beam investigations can provide information about many aspects of bimolecular collision dynamics. The velocity dependence of the cross section, the effect of internal energy states of the reactants on the course of the reaction, and the dependence of product velocities, internal energy states, and angular momentum on initial states can all be investigated.

Molecular-beam investigations have revealed that for certain reactions, the reactive cross sections can be quite large, of the order of 100 Å^2. In these cases, there is a high probability of reaction at large impact parameters due to the dominance of long-range attractive forces, and the scattering in the center-of-mass coordinate system is predominantly in the forward direction. This behavior is observed in the reactions of alkali-metal atoms, M, with halogens, X_2, where a halogen atom is transferred to the metal,

$$M+X_2 \rightarrow MX+X;$$

this is termed a stripping reaction, since it appears that the metal strips an atom from X_2 as it passes by. In other reactions, having smaller cross sections in the vicinity of 10 Å^2, the products recoil backward in the center-of-mass system. These are said to occur by a rebound mechanism. The observed dynamics in these cases is a result of the low reaction probability for all but a range of small impact parameters. Reactive collisions are thus close interactions in which the products rebound from the repulsive wall of the potential.

In the above types of reactions, the anisotropic angular distribution of the products due to the bimolecular collision dynamics can be observed because the lifetime of the transition state is very short, of the order of 10^{-12}–10^{-13} s or less. If the lifetime is longer than the characteristic time for rotation, the angular distribution becomes one of forward-backward symmetry. Longer lifetimes are usually associated with bound collision complexes. Thus, molecular beams can be employed to study the unimolecular decay of complexes formed in bimolecular collisions. Quantities such as the relative probabilities of decay into different products, angular distributions of the products, the internal and translational energies of the products, and the dependence of these on the reactant energies can all be investigated. A very detailed picture of a unimolecular reaction may be obtained, permitting rigorous tests of unimolecular rate theories.

Orientation effects have been studied by producing beams of oriented molecules in a combination of inhomogeneous and homogeneous electric fields. Molecules with permanent dipole moments can be aligned parallel to the homogeneous field **E**, after being rotationally state selected in the inhomogeneous field. The direction of orientation can be reversed by reversing **E**, thus presenting one end or the other of the oriented molecule to the other beam. In the reaction of CH_3I with Rb atoms to form RbI and CH_3 radicals, interaction of Rb with the "I-atom end" of the molecule results in a high reaction probability, whereas interaction with the "CH_3-group end" results in no reaction when the atom is within a conical region determined by the C–H bond angle of the methyl group.

The effect of internal energy of the reactants can be studied in molecular-beam experiments by exciting one of the reactants. This was first demonstrated by Brooks and coworkers, who studied the reaction of K atoms with HCl (Odidorne *et al.*, 1971),

$$K+HCl=KCl+H,$$

in which the HCl was excited to $v=1$ by employing a pulsed HCl laser. It was found that the reactive cross section was larger by more than two orders of magnitude when the HCl was in $v=1$, compared with $v=0$. Furthermore, it was found that translational energy was less effective than vibrational energy in facilitating this reaction. Subsequent research has shown other cases where vibrational energy is more effective than translational energy in promoting reaction, and others where translational energy is the dominant factor, vibrational energy having little influence. These findings have been rationalized in terms of the position of the barrier maximum on the potential-energy surface.

Laser spectroscopies are now being used for quantum-state-specific detection of reaction products in crossed–molecular-beam experiments. In the reaction

$$D+H_2 \rightarrow HD+H,$$

measurements of differential cross sections for the HD product in $J=1$, 2, and 3 of $v=1$ have recently been made. These are extremely sensitive to subtle details of the potential-energy surface, and are expected to lead to refinement of the potential for this reaction. The prospects are that the interplay between theory and experiment will be exploited further in the future, leading to improvements in the calculation of accurate potentials.

7.2 Energy Disposal in Chemical Reactions

Energy disposal addresses how the energy brought to the reaction by the reactants, and in exothermic reactions by thermochemistry, is distributed among the products. There are several experimental methods for probing energy distributions.

One of the earliest and most successful methods is infrared chemiluminescence (IRC) (see CHEMILUMINESCENCE). IRC is the spontaneously emitted IR radiation from reaction products produced in vibrationally excited states. In small enough molecules that the emission, dispersed by a monochromator, can be resolved into individual vibration-rotation bands, the internal energy distribution of the products can be determined. The relatively long radiative lifetimes in the IR require low background pressures and large reaction chambers in order to avoid relaxation of the distribution by gas-phase and wall collisions, and to ensure that the nascent distribution, which contains the information on dynamics, is observed. This technique was pioneered by Polanyi and co-workers in studies of atoms reacting with diatomic molecules (Polanyi and Schreiber, 1974),

$$A+BC \rightarrow AB(v,J)+C.$$

Comparison of the vibrational and rotational energy of AB with the total internal energy change accompanying the reaction permits the relative translational energy of AB and C to be determined by difference for each v,J state formed, and a map of total-energy disposal is obtained. In the reaction of F atoms with H_2, which is exoergic by 130 kJ/mol, the fraction of total reaction energy that goes into vibration, rotation, and translation is 0.66, 0.08, and 0.26, respectively. Furthermore, there is a population inversion of the vibrational states, which is the basis of the HF chemical laser.

A drawback of IRC is that the population in $v=0$ is not observable. This may be circumvented by probing the product energy distribution with laser-induced fluorescence (LIF). In LIF, a pulsed, tunable, narrow-band laser is used to excite a molecular species into a fluorescent electronic state. The fluorescence intensity, which is related to the population of the state that is excited, is measured. In cases where the molecule of interest does not fluoresce, the multiphoton ionization technique can be used to good advantage.

Laser spectroscopies have been extensively employed to probe the population of product states in chemical reactions. Levine and Bernstein (1987) cover many examples of this type of experiment in bimolecular reactions, while Crim (1984) and Reisler and Wittig (1986) review recent developments in state-resolved experimentation in unimolecular reactions. Recent texts on gas-phase kinetics also give some coverage of the many experimental approaches to product distributions, as well as some important results.

GLOSSARY

Activation Energy: An energy defined by the equation $E_a \equiv -Rd\ln k(T)/d(1/T)$, where R is the gas constant, $k(T)$ is the rate coefficient, and T is the absolute temperature. It is also given by the difference between the average energy of those reactant molecules that have enough energy to react, and the average energy of all reactant species.

Arrhenius Equation: An empirical equation giving the temperature dependence of the rate coefficient $k(T)$, $k(T)=A\exp(-E_a/RT)$. A is the Arrhenius preexponential factor.

Association Reaction: Association of two molecules to form an energized intermediate complex which may be collisionally stabilized, redissociate to the reactants, or undergo unimolecular reaction(s) to form new product(s).

Chemical Activation: The formation of a highly internally excited molecule by either an exothermic addition reaction, or an endothermic addition reaction proceeding over a potential barrier.

Chemical Dynamics: The study of chemical reaction kinetics at the quantum-state–resolved (or partially quantum-state–resolved) level.

Collision Theory: Any theory that treats reactions as occurring via the dynamics of collisions, as opposed to statistical considerations.

Cross Section: The effective target area presented by two colliding species in either elastic scattering, inelastic scattering, or reaction.

Elementary Reaction: A chemical reaction viewed as it occurs as an isolated molecular event. Spontaneous reaction of a single molecule is a unimolecular reaction, a reaction requiring interaction of two molecules is bimolecular, and one involving three molecules is termolecular.

Empirical Kinetics: The determination of rate expressions for complex overall reactions by laboratory measurements of rates of change of reactants and products. No information on short-lived, reactive intermediates is obtained.

Mechanism: The list of elementary reactions that make a non-negligible contribution to the rate of an overall reaction.

Microcanonical Rate Coefficient: A rate coefficient for an elementary reaction at a specified total energy. Thermal rate coefficients $k(T)$ are thermally averaged microcanonical rate coefficients.

Microscopic Kinetics: The kinetics of quantum state-to-state processes.

Microscopic Reversibility: The principle that all reactions are reversible, and that therefore cyclic equilibria are not permitted.

Molecularity: The number of molecules involved in a specified elementary reaction.

Order: For reactions that have a rate expression of the form $r = k(T)\Pi[A_i]^{\alpha_i}$, where $[A_i]$ is the concentration of the ith chemical species, the order is defined as $\Sigma\alpha_i$.

Overall Reactions: A complex reaction written to show the stoichiometric relationship between reactants and products, but containing no information on the elementary reactions involved, or on any reactive intermediates.

Photochemical Activation: The formation of highly internally excited ground electronic-state molecules by photoexcitation to an excited electronic state, followed by a radiationless transition to the ground state.

Potential-Energy Surface: The electronic potential of a reacting system as a function of the relative positions of the atoms. For the three-atom system, the potential can be represented in three dimensions, but for any larger number of atoms, a potential-energy hypersurface in a higher-dimensional space is required.

Rate: The time derivative of a chemical species concentration in a reacting system.

Rate Coefficient: Proportionality coefficient appearing in rate expressions. Properly determined rate coefficients $k(T)$ are functions of temperature only.

Rate Expression: An equation expressing the dependence of the rate upon reactant (and product) concentrations, as well as any other parameters that influence the rate.

Steady-State Approximation: An approximation made in the kinetic analysis of a mechanism, whereby the net rate of formation of a highly reactive intermediate is set equal to zero, thus converting a differential equation into an algebraic equation.

Stoichiometric Reaction: An overall reaction.

Transition State: The assembly of atoms that exists at the dividing surface between reactants and products in a chemical reaction. This concept is used in transition-state theory.

Transition-State Theory: A statistical theory of reaction rates in which the rate of passage over a potential barrier is calculated by assuming dynamic equilibrium between the transition state and the reactants.

Variational Transition-State Theory: A version of transition-state theory in which the dividing surface is placed either to minimize the Gibbs free energy of the transition state (canonical variational transition-state theory) or to minimize the microcanonical rate coefficient (microcanonical variational transition-state theory).

INTRODUCTION

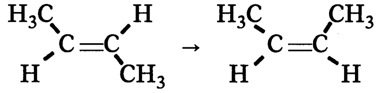
A chemical reaction can be defined as any process in which the chemical bonds, and hence the valence electrons, of one or more chemical species undergo rearrangement. Thus, this definition includes reactions such as

1. an electron transfer reaction,

$$Fe^{3+} + {}^{*}Fe^{2+} \rightarrow {}^{*}Fe^{3+} + Fe^{2+}$$

(where the asterisk indicates a radioactive label),

2. a geometrical isomerization,



3. or a metathesis,

$$Cl + H_2 \rightarrow HCl + H.$$

A substantial fraction of the entire science of chemistry involves the study, in one way or

another, of chemical reaction—chemists seek to determine what chemical species react with each other, the rates at which the reactions take place, the energetics of the process, and, ultimately, the detailed reaction mechanism at the atomic level. The ultimate goal of such studies is to provide a basis from which the analogous properties of other hypothetical reactions can be predicted without the necessity of carrying out the actual measurements of reaction properties. The chemical equation expressing a chemical reaction, i.e., reactants → products, indicates the stoichiometry of the reaction, but may give a very misleading and oversimplified impression of the actual reaction mechanism. Many elementary reactions, involving intermediates that are not among the reactants or products, may be taking place simultaneously. For example, the reaction of hydrogen and bromine to form hydrogen bromide is described by the net reaction

$$H_2+Br_2 \rightarrow 2HBr,$$

but the actual mechanism consists of the elementary reactions

$$Br_2 \rightarrow 2Br,$$

$$Br+H_2 \rightarrow HBr+H,$$

$$H+Br_2 \rightarrow HBr+Br,$$

$$H+HBr \rightarrow H_2+Br,$$

$$Br+Br \rightarrow Br_2.$$

Throughout this article, the emphasis, whenever possible, will be on elementary reactions.

Many of the features of chemical reactions are treated under other headings in this *Encyclopedia*. For example, general characteristics of reaction rates and mechanisms are discussed in CHEMICAL KINETICS. Specific types of reactions are treated in greater detail under headings such as COMBUSTION, POLYMER REACTIONS, PHOTOCHEMISTRY, etc. Therefore, this article can only attempt to catalog major types of chemical reactions, whenever possible emphasizing those related to important technical applications.

1. GAS-PHASE REACTIONS

Gas-phase reactions play a very important role in the understanding of all chemical reactions. They are the simplest, in the sense that the reactants are isolated and are not perturbed by interactions with adjacent solvent or surface molecules. In principle, the simplest possible chemical reaction is that of a single isolated molecule, a unimolecular reaction. In fact, the understanding of unimolecular reactions followed that of bimolecular reactions, as is discussed below. As will be discussed later in this section, many reactions of practical importance take place in the gas phase.

1.1 Bimolecular Reactions

A bimolecular reaction, as its name implies, involves two reactants, one or both of which may be atoms, radicals, ions, or molecules. The reactants may simply combine to form a larger molecular entity, i.e.,

$$A+A \rightarrow A_2,$$

or can undergo a metathesis of the form

$$A+BC \rightarrow AB+C,$$

where A , B, and C may be atoms or larger groups. The rate of this reaction is given by the expression

$$\begin{aligned} -d[A]/dt &= -d[BC]/dt \\ &= d[AB]/dt = d[C]/dt \\ &= k[A][BC]. \end{aligned} \tag{1}$$

In this equation, t is time, the brackets indicate concentrations or pressures, and k is the rate constant or rate coefficient. The basic mechanism for such a reaction is easily understood, involving the approach of the reactive species to some distance at which chemical forces leading to product formation overcome the bonding forces in the original reactant molecules. For the sake of simplicity, such an encounter is called a "reactive collision," although it is somewhat ill-defined. A reaction may be either exothermic (heat evolved) or endothermic (heat absorbed), but in either case there is usually an energy barrier that must be surmounted before reaction takes place (see CHEMICAL KINETICS).

1.1.1 Reactions in Molecular Beams. Atomic beams were produced as early as 1911, and the techniques were extensively applied in atomic physics during the 1920s, earning Otto Stern a Nobel Prize for Physics in 1943. However, crossed-molecular-beam studies of chemical reactions were not carried out until the 1950s (Bull and Moon, 1954; Taylor and Datz, 1955). The experimental difficulties are exemplified by the fact that the density of product species is many orders of magnitude less than that of the reactants.

From the standpoint of understanding the detailed mechanism of a bimolecular reaction, one would like to study the following process:

$$A\ (v_{\mathrm{rel}}) + BC(v, J) \rightarrow AB(v', J') + C(v'_{\mathrm{rel}}). \quad (2)$$

Here, the atomic species A, with collision velocity relative to BC of v_{rel}, reacts with the diatomic molecule BC in internal energy states specified by rotational and vibrational quantum numbers J and v. The products separate with a relative velocity v'_{rel}, and with internal energy states of AB again specified.

Usually, chemical reactions occur under much less well-defined conditions, with a broad thermal distribution of both velocity and internal energy. Molecular beams permit an approach to the ideal reaction written above (Bernstein, 1982). First of all, the reaction takes place under single-collision conditions, ensured by working at very low pressures, and the relative velocity of the reactants can be controlled by the use of mechanical velocity selectors. The usually broad thermal distribution of internal energy states of the molecule BC can be greatly reduced by using a supersonic jet expansion that converts internal energy into translational energy, and effectively lowers the vibrational and rotational temperatures. Excitation of specific v, J levels can be achieved by using appropriate infrared lasers. To probe the internal energy states of the products, sensitive and selective detection methods are required; these include infrared chemiluminescence, laser-induced fluorescence, multiphoton ionization, bolometric detection, surface ionization, mass spectrometric analysis, etc. Another mechanical velocity selector, or a time-of-flight mass spectrometer, is used to determine product velocity over a range of scattering angles. By taking advantage of the principle of energy conservation, precise measurements of the relative kinetic energy of fragments can then be used to determine their internal energy states, if the energy of reaction is known.

The 1986 Nobel Prize for Chemistry was awarded to D. R. Herschbach, Y. T. Lee, and J. C. Polanyi for their contributions to the understanding of molecular reaction dynamics, and both Herschbach and his one-time postdoctoral student Lee used molecular-beam techniques to achieve this goal.

1.1.2 Atom and Radical Abstraction Reactions. A large number of bimolecular gas-phase reactions of the type $A + BC \rightarrow AB + C$ are metathetical reactions in which A and C are atoms or free radicals, and BC and AB are molecules. A free radical is an atom or molecular fragment that has at least one unpaired electron. Since chemical bonds usually are formed by paired electrons, the radical is an inherently reactive species. This type of reaction is also called an "abstraction" reaction, since the A species "abstracts" an atom or molecular fragment from the molecule BC. The energetics of this type of reaction are shown schematically in Fig. 1. It should be noted that even when the reaction is energetically "downhill," there is often an energy barrier to be surmounted for the reaction to occur. This barrier is closely related to the activation energy E_a, which can be derived from the temperature dependence of the rate constant, often expressed in the form first used by Arrhenius in 1889:

$$k(T) = A(T)\exp(-E_a/RT), \quad (3)$$

where T is the absolute temperature and R is the gas constant. The term $A(T)$ is known as the pre-exponential factor. Methods for estimating both $A(T)$ and E_a from molecular and thermodynamic properties have been extensively developed (Benson, 1976).

As the general chemical equation above indicates, the reactant free radical forms a stable molecule, but produces another radical in the process. This can lead to a chain reaction, exemplified by the one historically the first to be studied:

$$Br + H_2 \rightarrow HBr + H, \quad (4)$$

$$H + Br_2 \rightarrow HBr + Br. \quad (5)$$

Such a process can proceed indefinitely, until the chain is broken by the intervention of some other reaction that consumes one of the radical species.

1.1.3 Ion–Molecule Reactions. In reactions involving uncharged species, as discussed above, the forces between the reactants

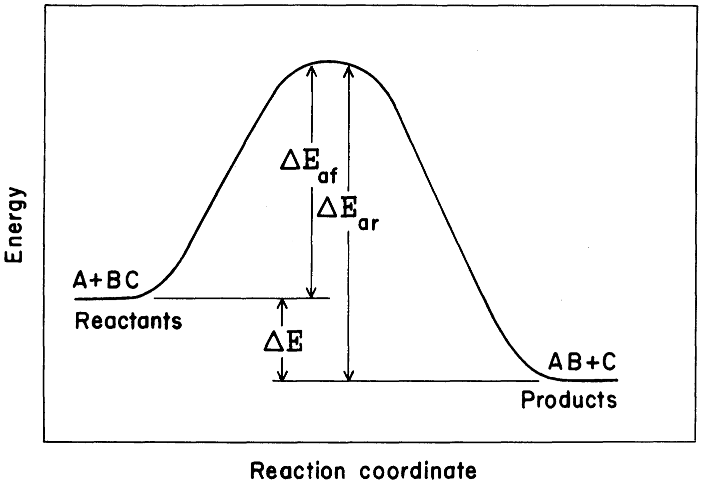

FIG. 1. Energy vs reaction coordinate for the hypothetical reaction $A+BC \rightarrow AB+C$, showing the transition state at the top of the energy barrier. ΔE is the energy of reaction, which in this case is exoergic; E_{af} and E_{ar} are the energy barriers for the forward and reverse reactions, respectively. They are closely related to the activation energies (Sec. 1.1.2).

are very short range (0.1–1.0 nm) chemical forces. Another class of reactions important in radiation chemistry, mass spectrometry, electric discharges, and the upper atmosphere involves ions. The interaction of a charged molecule or atom with an uncharged species involves much longer range electrostatic forces than does the interaction of two uncharged species. If the uncharged reactant is a dipolar molecule, such as HCl or NH_3, there is an attractive potential with an inverse dependence on the square of the distance between the two reactants. Even in the case of a nonpolar molecule, the dipole induced by the approaching ion will lead to a potential with a $1/r^4$ dependence. As a result of these attractive forces, the rate constants for ion–molecule reactions of the abstraction type are much larger than those for neutral species.

1.1.4 Atom and Radical Recombinations. In the discussion of chain reactions above, the termination of the chain was briefly mentioned. One obvious termination step involves the bimolecular reaction in which two atoms or radicals recombine. These reactions are exothermic by an amount corresponding to the bond dissociation energy, and typically have very small or zero activation energies. The only barrier to reaction is that imposed by the conservation of angular momentum, and the rate constants can be estimated reasonably well using a hard-sphere collision model. The exothermicity of the reaction results in a highly energetic product, which, unless stabilized by a simultaneous or subsequent collision with another species, has a finite probability of dissociation. In fact, the recombination process is just the microscopic reverse of a unimolecular dissociation discussed in Sec. 1.2.

1.2 Unimolecular Reactions

Although in principle a unimolecular reaction is the simplest possible chemical reaction (as it involves a single molecule), the understanding of such processes actually came later than the understanding of bimolecular reactions. The puzzle is: If an isolated molecule can react, how can it exist as a stable species? The clue to the answer is found in the observation that unimolecular reactions proceed more rapidly as the temperature is increased, indicating that some sort of excitation or activation of the reactants is required. After experiments showed that this excitation could not result from the absorption of radiation, it was recognized that collisions with other molecules were the source of the required energy. This collision mechanism for activation was proposed by Lindemann in 1922, and a simplified version is as follows:

$$A+M \rightarrow A^*+M \quad \text{(activation by collision),} \tag{6}$$

$$A^*+M \rightarrow A+M \quad \text{(deactivation by collision),} \tag{7}$$

$$A^* \rightarrow \text{products} \quad \text{(spontaneous reaction of activated molecule).} \tag{8}$$

In this mechanism, A is the reactant molecule, A^* is an activated reactant molecule, and M may be either another molecule of reactant or of any other species present in the reaction mixture. Although the first two steps are actually bimolecular reactions, at sufficiently high pressures a quasiequilibrium is reached so that the concentration of activated molecules A^* is maintained and the rate-determining step is its spontaneous reaction. At lower pressures, the activation step becomes the rate-limiting process. Thus, the apparent rate constant is a function of total pressure. This pressure dependence can be used to determine the relative energy transfer efficiencies of various added species M. More realistic models for unimolecular reactions take into account the energy dependence of the rate constants for the elementary reactions.

1.2.1 Isomerizations. Many unimolecular reactions are isomerizations, i.e., changes in molecular structure with no change in the elemental formula of the reactant. Examples are

$$\text{cyclopropane } (C_3H_6) \rightarrow \text{propene } (CH_2{=}CH\text{–}CH_3), \qquad (9)$$

$$CH_3CN \rightarrow CH_3NC. \qquad (10)$$

Note that such reactions may involve bond rupture and new bond formation with the reactant molecule.

1.2.2 Bond Rupture Reactions. A much larger number of unimolecular reactions result in the formation of atoms or radicals by fragmentation of the reactant. Thus, they may be considered the microscopic reverse of the bimolecular reactions considered in Sec. 1.1.4. For example,

$$H + H \rightarrow H_2^* \quad \text{(formation of activated molecule by recombination)}, \qquad (11)$$

$$H_2^* \rightarrow H + H \quad \text{(dissociation of activated molecule)}. \qquad (12)$$

The activation energies of such processes are closely related to the enthalpies of dissociation into the fragments (bond dissociation energies), and in fact, experimental determinations of such activation energies are frequently used to derive bond energies.

1.3 Some Practical Applications of Gas-Phase Reactions

1.3.1 Combustion Chemistry. Many fuels are solids or liquids at room temperature, but at the high temperatures of combustion, gas phase reactions are all-important. The burning of organic material is the source for over 90% of the energy we use. The objectives of combustion chemistry are to provide the knowledge needed to carry out this conversion of chemical energy to thermal energy as efficiently as possible and, simultaneously, to minimize the production of deleterious byproducts such as soot, carbon monoxide, nitrogen oxides, and sulfur oxides. The data base for this understanding is provided by a determination of the complicated reaction mechanisms of combustion and measurements of the rate constants of the elementary reactions involved in the mechanism (Miller and Fisk, 1987).

The methods of investigation rely upon the usual techniques of chemical kinetics (*q.v.*), with the special methods demanded by the fact that reactions must be studied at high temperatures (1000–2000 K). High-temperature experiments are necessary because there are numerous examples of reactions for which data obtained in experiments at lower temperatures cannot be extrapolated to combustion temperatures with useful accuracy. Shock tubes are often used to obtain temperatures as high as 5000 K. In the shock tube, a diaphragm separating a low-pressure reaction mixture from a high-pressure driver gas (such as helium) is suddenly ruptured and the resulting shock wave initiates reaction by heating and compressing the reaction mixture. An alternative approach, especially suitable for reactions initiated by an atom or radical species, is to use the shock wave only for heating, with the reactive species produced by flash photolysis of a suitable substrate. High-temperature flow systems are also used.

Theoretical approaches are also important for investigating combustion chemistry. At the macroscopic level of understanding, sophisticated methods for solving coupled differential equations are used to model the kinetics of the combustion process, including the chemical reactions, the convective fluid motion, and the molecular diffusion of the major chemical species. On the molecular level, quantum-mechanical calculations of the potential energy surface governing the interaction of the reactants are made using either semiempirical or *ab initio* methods. The potential energy surface thus obtained can be used either for classical trajectory calculations of the reaction rate constant, or for a simpler statistical mechanical method known as transition-state theory. Once the rate constants for elementary reactions have been measured or calculated, another major step is required to relate these to the processes actually taking place in a flame. Not only are chemical reactions taking place, but fuel and oxygen are flowing into the flame, while heat and reaction products flow out of the flame. Using laser-based spectroscopy as a diagnostic tool, it has recently become possible to measure concentration distributions of some of the major reactants and products within the flame, as well as the temperature profile.

The simplest hydrocarbon fuel, and one that has been extensively studied, is methane (CH_4). Nevertheless, even for this simple molecule, the reaction mechanism of combustion is fairly complicated, involving many steps (Fig. 2). The determination of the corresponding reaction mechanism for a larger fuel molecule, such as octane (C_8H_{18}), or for aromatic hydrocarbons, such as benzene (C_6H_6), is a formidable problem. However, the problem is somewhat simplified by the fact that many of the elementary reactions in the overall mechanism are also found in mechanisms for smaller fuel molecules. Thus a kind of "bootstrap" approach can be used. The general steps involved in the combustion of a saturated hydrocarbon such as methane are as follows:

1. Abstraction of a hydrogen atom from the hydrocarbon by an atomic or radical reactant such as H, O, OH, HO_2, CH_3O, or CH_3O_2, to form a hydrocarbon radical.
2. Alternatively, formation of a hydrocarbon radical by dissociation of a hydrocarbon molecule.
3. Formation of oxygenated species by reactions of hydrocarbon radicals with oxygen atoms or molecules. The oxygenated species are further oxidized, with CO as the final product of the sequence.
4. Recombination and disproportionation of hydrocarbon radicals to form larger hydrocarbons, larger hydrocarbon radicals, or unsaturated hydrocarbons.
5. Simultaneously occurring, a number of reactions that do not involve organic species at all, with reactants such as H, O, OH, HO_2, H_2, O_2,CO, and H_2O.

Two of the most important reactions in the combustion scheme are the chainbranching step

$$H+O_2 \rightarrow OH+O \qquad (13)$$

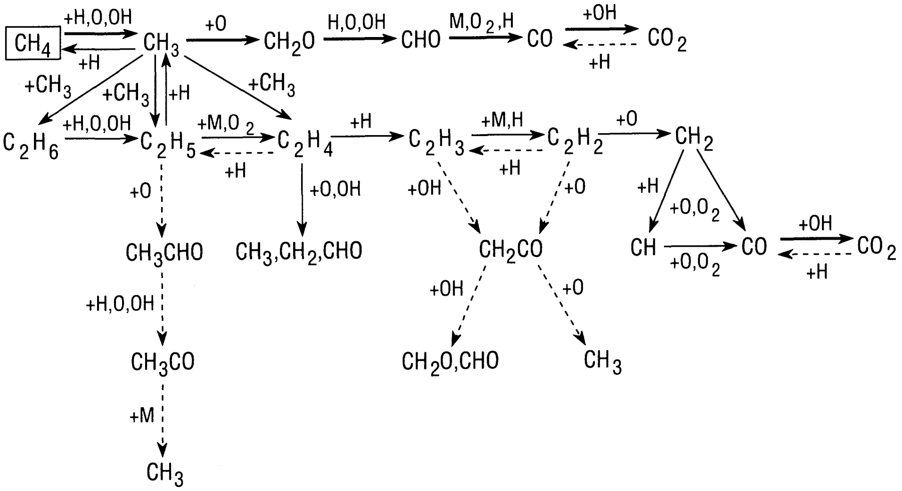

FIG. 2. A diagram that shows the mechanism of combustion of methane in a stoichiometric methane/air flame at atmospheric pressure. Only reactions involving carbon-containing species are indicated. Thickness of arrows indicates the importance of the reaction step, with the least important reactions indicated by dashed arrows. [Reprinted from Miller and Fisk (1987). Published 1987 by the American Chemical Society.]

and the step that converts CO to the final oxidation product CO_2:

$$OH + CO \rightarrow H + CO_2. \qquad (14)$$

Both of these reactions have been extensively studied, experimentally and theoretically, and there is substantial agreement between the rate constants obtained by various methods.

Of course, it is an oversimplification to consider only hydrocarbons as constituents of fuels, which in the real world also may contain significant amounts of oxygenated species, sulfur-containing compounds, and nitrogen-containing compounds. The latter two classes of compounds are important as sources of the nitrogen and sulfur oxides involved in air pollution. Major research efforts are directed towards an understanding of the additional reactions of these nonhydrocarbon species, as well as the combustion of alternative fuels such as methyl and ethyl alcohols.

1.3.2 Air Pollution: Photochemical Smog. Major cities of the world that are blessed with abundant sunshine are often cursed with urban air pollution that has come to be known as "photochemical smog," a specific form of air pollution first recognized in the Los Angeles area during the mid-1940s, but not unique to that locality. The factors that contribute to this problem are abundant sunshine, frequent temperature inversions that effectively place a lid on the lower atmosphere, a geography in which winds from the Pacific are blocked by mountain ranges to the east of the urban area, and a transportation system that relies on large numbers of private automobiles (see AIR POLLUTION: COMPONENTS, CAUSES, AND CURES). Other cities that share some of these characteristics may also suffer from photochemical smog. The term "smog" (=smoke+fog) was invented to describe London air pollution and, as the name implies, particulate matter is an important constituent of smog. Nonetheless, homogeneous gas-phase reactions also play a significant role in the generation of photochemical smog (Finlayson and Pitts, 1976; Okabe, 1978; Wayne, 1985).

The laboratory study of these reactions has relied extensively on the use of "smog chambers"—very large (thousands of liters) reaction vessels that can be filled with a mixture of gases to simulate a polluted atmosphere and then illuminated with sunlight or a powerful arc lamp as its surrogate. The resulting chemical changes can be measured by taking samples of the reaction mixture as reaction proceeds, or in a more sophisticated approach, spectroscopic methods can be used to follow changes in reactant and product concentrations continuously. Once specific reactions have been identified, they can be studied in isolation, using more conventional laboratory techniques. Direct studies of the polluted atmosphere rely on air samples taken at many locations, or on remote sensing methods such as long-path infrared absorption spectroscopy. Aircraft may be used either to collect air samples at various altitudes, or to carry analytical instrumentation aloft for *in situ* measurements. Theoretical modeling utilizes measured or estimated reactant concentrations and rate coefficients, together with data describing air mass motion to predict the spatial and temporal distribution of pollutants.

Measurements of pollutant concentrations in the atmosphere show a pronounced diurnal variation, which can be explained by the rates of dark reactions compared with those initiated by sunlight, and by the variation in traffic load during the day (Fig. 3). Typically, nitric oxide (NO) concentrations increase during the night and early morning, with nitrogen dioxide (NO_2) lagging somewhat behind. By the middle of the day there are high concentrations of nitrogen dioxide and other oxidants such as ozone (O_3) and PAN (peroxyacetyl nitrate). The latter species is in equilibrium with NO_2 and the peroxyacetyl radical and, therefore, can serve as a reservoir for nitrogen dioxide. The source of NO is the reaction of nitrogen and oxygen from the air at the high temperatures of the internal combustion engine, especially diesel engines. Other constituents of automobile exhaust are carbon monoxide and dioxide, partially oxidized and unburned hydrocarbons, and sulfur dioxide from sulfur-containing fuels. The reaction of NO with oxygen in the atmosphere is too slow to account for the formation of NO_2, but the rapid reaction with ozone could be significant. However, as we have seen, the ozone concentration peaks long after that of NO and NO_2. Evidently, other oxidants, such as hydroxyl and organic peroxy radicals, formed from constituents of automobile exhaust, must be important:

$$HO_2 + NO \rightarrow OH + NO_2, \qquad (15)$$

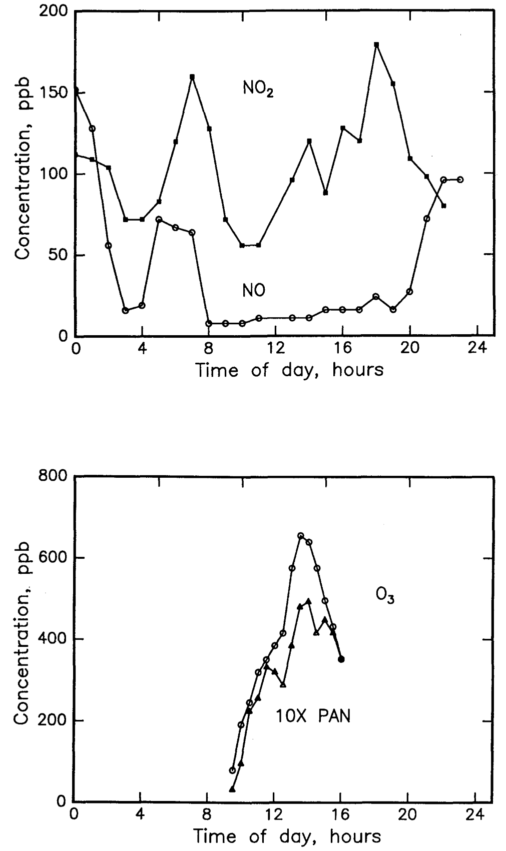

FIG. 3. Diurnal variation of some primary and secondary pollutants in Pasadena, California, on 25 July 1973. (Data from Finlayson and Pitts, 1976.)

$$CH_3O_2 + NO \rightarrow CH_3O + NO_2. \quad (16)$$

The radical initiators may be formed by reactions such as

$$NO + NO_2 + H_2O \rightarrow 2HONO \text{ (nitrous acid)}, \quad (17)$$

$$HONO + \text{light} \rightarrow OH + NO \quad (18)$$

and

$$HCHO + \text{light} \rightarrow H + HCO, \quad (19)$$

$$HCO + O_2 \rightarrow CO + HO_2, \quad (20)$$

$$H + O_2 + M \rightarrow HO_2 + M, \quad (21)$$

$$\text{Net: } HCHO + 2O_2 + \text{light} \rightarrow 2HO_2 + CO. \quad (22)$$

Ozone buildup is hindered by its reaction with NO until most of the free NO has reacted. Then it can be formed by the sequence

$$NO_2 + \text{light} \rightarrow NO + O, \quad (23)$$

$$O + O_2 + M \rightarrow O_3 + M. \quad (24)$$

In the reactions above, M indicates any collision partner that removes enough energy to stabilize the product molecule (cf. Sec. 1.2). It should be noted that the direct photodissociation of oxygen and subsequent reaction of O atoms to form ozone does not take place in the troposphere because the short-wavelength ($\lambda < 200$ nm) UV radiation required for this dissociation does not penetrate through the upper atmosphere. In addition to providing a reservoir for NO_x, PAN is of primary importance as a powerful lachrymator. Its formation involves aldehydes:

$$OH + CH_3CHO \rightarrow CH_3CO + H_2O, \quad (25)$$

$$CH_3CO + O_2 \rightarrow CH_3CO \cdot O_2, \quad (26)$$

$$CH_3CO \cdot O_2 + NO_2 \rightarrow CH_3CO \cdot O_2 \cdot NO_2 \text{ (PAN)}. \quad (27)$$

The reduction in visibility caused by photochemical smog is due mainly to particulate matter, principally organic aerosols formed in secondary reactions. Final products that have been identified include organic nitrates, carboxylic acids and their esters, carbonyl compounds, alcohols, and polymers of peroxides. Inorganic nitrates and sulfates, the latter originating from sulfur-containing fuels, are also found. The mechanism for formation of the organic constituents is not yet clear; however, it seems likely that unsaturated hydrocarbon precursors are oxidized by OH and peroxy radicals.

The deleterious effects of photochemical smog are manifold. Respiratory problems are caused by the oxidants such as ozone and nitrogen dioxide, and the lachrymatory effect of PAN has already been mentioned. Major cities now experience fairly frequent pollution alerts triggered by high ozone levels. The reduction in visibility from aerosols leads to a greater probability of automobile and aircraft accidents. The oxidant species also have a harmful effect on vegetation with serious implications for the agricultural economy. California, as befits its historic role in the understanding of photochemical smog, has taken the lead in measures to control harmful emissions from automobiles, gas stations, dry cleaning establishments, paint solvents, etc. Needless to say, the economic repercussions of such controls are themselves considerable, and it remains to be seen just how extensively they can be applied to the U.S. as a whole.

1.3.3 Homogeneous Catalysis: Destruction of Ozone in the Stratosphere. The triatomic allotrope of oxygen, ozone (O_3), is an important constituent of the earth's upper atmosphere, despite the fact that its maximum partial pressure (at an altitude of about 25 km) is of the order of 10^{-7} bar, corresponding to a mixing ratio of about 10 ppm (Wayne, 1985; Cicerone, 1987). Ozone absorbs biologically deleterious solar radiation between the wavelengths 240 and 320 nm. In addition to experiments showing that such short-wavelength ultraviolet radiation destroys DNA, there is strong epidemiological evidence for a correlation between exposure to solar UV and the incidence of skin cancer, including a frequently fatal form, melanoma. In absorbing the short-wavelength UV radiation, ozone plays an important role as a heat source. The recognition within the past two decades that the ozone concentration could be reduced by man-made pollutants has led to an active research effort to study the reactions involving this relatively unstable species.

The steady-state model proposed in 1930 by Chapman to account for the ambient stratospheric ozone concentration involves only allotropes of oxygen:

$$O_2+h\nu\rightarrow O+O, \tag{28}$$

$$2(O+O_2+M\rightarrow O_3+M)\quad (M=\text{ any molecule}), \tag{29}$$

$$O_3+h\nu\rightarrow O_2+O, \tag{30}$$

$$O+O_3\rightarrow O_2+O_2. \tag{31}$$

Laboratory measurements of the rate constants for these reactions could be combined with known solar UV flux and pressures of major atmospheric constituents to model the ozone concentration in the stratosphere. By about 1964, comparison of such model calculations with stratospheric measurements showed that the measured concentrations were significantly lower than those predicted by the Chapman model. It was apparent that an additional sink for O_3 or O must exist, and it was suggested by Crutzen in 1970 that the nitrogen oxides NO and NO_2 (collectively designated NO_x) could serve as catalysts to remove ozone itself. In this specific example, the proposed mechanism is

$$NO+O_3\rightarrow NO_2+O_2 \tag{32}$$

$$NO_2+O\rightarrow NO+O_2 \tag{33}$$

$$\overline{O+O_3\rightarrow O_2+O_2\text{ (net reaction)}.} \tag{34}$$

A major source of NO_x is nitrous oxide, N_2O, which results from biological sources, some of them man-made. The nitrous oxide reacts with electronically excited oxygen atoms in the ^1D state, produced by photodissociation of ozone or oxygen:

$$O(^1D)+N_2O\rightarrow NO+NO. \tag{35}$$

Reactions (32) and (33) constitute a "chain reaction," one that can go through many cycles before the catalyst is removed by some competitive process. The number of cycles per catalyst molecule is called the "chain length." In this particular example, the most important reaction for removal of NO_2 is

$$NO_2+OH+M\rightarrow HNO_3+M, \tag{36}$$

and in fact, nitric acid serves as a reservoir for the nitric oxides, which are regenerated by the relatively slow photolysis of the nitric acid. To complicate this scheme, the hydroxyl radical itself can enter into *another* catalytic cycle by reactions such as

$$OH+O_3\rightarrow HO_2+O_2 \tag{37}$$

$$HO_2+O_3\rightarrow OH+O_2+O_2 \tag{38}$$

$$\overline{2O_3\rightarrow 3O_2\text{ (net reaction)}.} \tag{39}$$

Coupling between different catalytic cycles like this, together with the large number of reservoir species that must be considered, leads to a very complicated set of chemical reactions (Wayne, 1985).

Harold S. Johnston recognized in 1971 that the NO_x catalytic cycle could be exacerbated by the injection into the stratosphere of large amounts of NO_x from the fleet of supersonic transport aircraft being planned for construction in the U.S. As a result of this insight, an extraordinary scientific effort was set into motion. As one participant said a few years later: "More has been learned about the stratospheric chemistry of ozone in the past few years than in all preceding time."

An even more significant anthropogenic threat to stratospheric ozone is now known to be the family of organic chemicals called chlorofluorocarbons or CFC's, such as CF_2Cl_2. (These are often called "Freons," actually a

DuPont trade name.) Their practical uses as aerosol propellants, plastic foaming agents, and refrigerants have led to an exponential growth in the manufacture of these compounds over the past few decades. The concentration of these compounds in the atmosphere was found to indicate that roughly the total amount that had been manufactured was still intact, if very dilute (Lovelock, Maggs, and Wade, 1973). This evident inertness even led to the suggestion that these compounds would be valuable as atmospheric tracers. However, Molina and Rowland (1974) realized that because of the chemical inertness of CFC's, the only escape route was diffusion into the stratosphere, where the short-wavelength solar UV has not yet been filtered out by ozone, followed by photodissociation:

$$CF_2Cl_2 + \text{light} \rightarrow CF_2Cl + Cl. \qquad (40)$$

The chlorine atoms then enter into a catalytic cycle:

$$Cl + O_3 \rightarrow ClO + O_2 \qquad (41)$$

$$\underline{ClO + O \rightarrow Cl + O_2} \qquad (42)$$

$$O + O_3 \rightarrow 2O_2 \quad (\text{net reaction}). \qquad (43)$$

This cycle is coupled to the NO_x cycle by reactions such as

$$ClO + NO_2 + M \rightarrow ClONO_2 + M, \qquad (44)$$

which *remove* active chlorine species. Dramatic confirmation of this Cl atom cycle was obtained in 1987, based on simultaneous high-altitude measurements of ozone and ClO in the Antarctic. These measurements were part of a major effort to understand the ozone depletion in this region revealed by both airborne and land-based measurements over the preceding two decades. Not only was there a slow decrease of about 30% from 1959 to 1986, but there was a striking drop in ozone in the Antarctic spring of each year. It became apparent that the chemical processes are closely coupled to large-scale atmospheric movements, and the darkness prevailing during the Antarctic winter. A stream of air—the polar vortex—circles Antarctica at this time, trapping air that reaches temperatures as low as −90 °C, cold enough to form clouds even in the very dry stratosphere. These clouds provide a mechanism for heterogeneous reactions that both sequester NO_x and convert chlorine reservoirs such as HCl (hydrochloric acid) and $ClONO_2$ (chlorine nitrate) into active species of chlorine. As Fig. 4 shows, high-altitude measurements with instruments aboard a NASA aircraft demonstrate the simultaneous increase in ClO and decrease in O_3 that would be predicted from reactions (41) and (42).

This brief and simplified description of the atmospheric ozone problem indicates the utility of basic information about chemical reactions, obtained in laboratory experiments, for understanding large-scale phenomena of great practical importance. In the present example, as a result of this understanding, the Montreal protocol of 1987 binds a number of countries to an agreement to cut CFC emissions in half by the end of the century. Major producers of

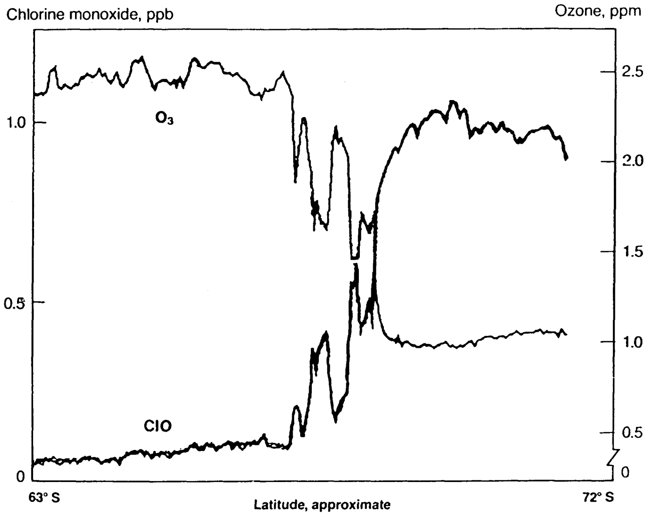

FIG. 4. Concentrations of ozone and chlorine monoxide as measured by instruments aboard a NASA research plane flying from Punta Arenas, Chile (53° S), to 72° S. The ozone "hole" is shown by the precipitous drop in ozone concentration. [Reprinted from Zurer (1988). Published 1988 by the American Chemical Society. Figure used by permission of Prof. J. G. Anderson.]

CFC's are at the present time vigorously searching for suitable substitutes.

2. REACTIONS IN THE LIQUID PHASE AND IN SOLUTION

The effect of a solvent on a chemical reaction can range from trivial to profound. In the latter category are many ionic reactions, which take place readily in polar solvents, but occur in the gas phase only under extreme conditions. The basic reason for this is made apparent by a comparison of heats of ionization in the gas phase with those in water:

$$\mathrm{HCl(g)} \rightarrow \mathrm{H^+(g)} + \mathrm{Cl^-(g)} \quad \Delta H^0 = 1360\ \mathrm{kJ/mol}, \tag{45}$$

$$\mathrm{HCl(aq)} \rightarrow \mathrm{H^+(aq)} + \mathrm{Cl^-(aq)} \quad \Delta H^0 = -104\ \mathrm{kJ/mol}. \tag{46}$$

The large difference between the enthalpies of ionization results from the highly exothermic solvation of the ions compared with a small enthalpy of solvation of the undissociated HCl.

Another important difference between reactions in the gas phase and those in the liquid phase is that in a bimolecular reaction, the reacting species must diffuse towards each other by a series of encounters with solvent molecules until they reach a distance at which a charge transfer or atomic rearrangement can take place. Of course, an important exception to this situation is a reaction involving the solvent itself. This will be discussed below, particularly for the case of acid–base reactions in water.

2.1 Ionic Reactions

Although difficult to define precisely in a condensed phase, the mean free path of a molecule or ion is small compared to molecular dimensions, in contrast to the situation in the gas phase. The random Brownian motion of a solute through a solvent can be treated with Fick's laws of diffusion, leading to a rate constant for binary encounters of species A and B (Weston and Schwarz, 1972):

$$k_D = 4\pi(D_A + D_B) d_{AB}(N^0/1000). \tag{47}$$

In this expression, D_i is the diffusion coefficient for species i, d_{AB} is the encounter distance, and the last term includes Avogadro's number N^0 to give a rate constant in units of $M^{-1}\ s^{-1}$. Reasonable values for the diffusion coefficients and d_{AB} lead to a rate constant of about $5 \times 10^9\ M^{-1}\ s^{-1}$. Thus, an upper limit is set on the rate at which binary encounters can take place, and a reaction occurring with a rate constant of this order of magnitude is said to be diffusion-controlled. Of course, other factors such as energy barriers or geometric factors will often reduce the rate constant to a lower value. Examples of reactions that appear to be diffusion-controlled are

$$\mathrm{I} + \mathrm{I} \rightarrow \mathrm{I_2}\ \text{in}\ \mathrm{CCl_4} \quad (13, 8.2), \tag{48}$$

$$\mathrm{OH} + \mathrm{OH} \rightarrow \mathrm{H_2O_2}\ \text{in}\ \mathrm{H_2O} \quad (6, 5). \tag{49}$$

The numbers in parentheses are the calculated and observed rate constants, respectively, in units of $10^9\ M^{-1}\ s^{-1}$.

Reactions between ions can also be treated by the diffusion equations, provided the electrostatic potential energy is taken into account. This introduces into Eq. (47) for the rate constant an additional factor

$$-z_A z_B r_0/d_{AB}[1 - \exp(z_A z_B r_0/d_{AB})],$$

where z_i is the ionic charge. The constant r_0 depends on the dielectric constant of the solvent and the temperature; in water at 25 °C the value is 7.1×10^{-8} cm. With this modification, the diffusion model is again found to be appropriate for many reactions such as those of solvated electrons in water with both positive and negative ions. Also, all reactions of hydrated protons (hydronium ions) with strong bases that have been studied have proven to be diffusion limited.

The situation becomes more complicated if the ionic solution cannot be assumed to be infinitely dilute. In this case the electrostatic potential of the entire ionic atmosphere must be taken into account. This leads to a dependence of the rate constant on the ionic strength of the solution, defined as

$$\mu = 0.5 \sum_i c_i z_i^2, \tag{50}$$

where c_i is the concentration and z_i is the charge of the ion. The sum is over all ionic species present. In terms of the rate constant at infinite dilution k^0, the rate constant is given by

$$\log k(\mu) = \log k^0 + [1.02\, z_A\, z_B\, \mu^{1/2}/(1+\mu^{1/2})] \quad (51)$$

in water at 25 °C. It can be seen from this expression that reactions between ions of like charge are facilitated by an increase in ionic strength, whereas the opposite effect is observed for reactions between ions of opposite charge (Fig. 5). There may also be small effects due to specific interactions such as ion pair formation, or due to interactions of ions with neutral but dipolar molecules.

2.2 Acids and Bases: Proton Transfer Reactions

In 1923, Brönsted and Lowry introduced a theory of acid–base reactions in which an *acid* was defined as any species capable of donating a proton to a *base*, a species capable of accepting a proton. Thus, the general reaction can be written as

$$AH + B \rightleftharpoons A + BH. \quad (52)$$

AH and A represent an acid and its conjugate base, while B and BH represent a base and its conjugate acid. A more concrete example is provided by the ionization of a strong acid such as hydrochloric acid, in water:

$$HCl + H_2O \rightarrow H_3O^+ + Cl^-. \quad (53)$$

Notice that this expression tacitly assumes that the proton exists in water as the hydronium ion, H_3O^+. In fact, further solvation may take place, but this formulation at least conveys the desired impression that the bare proton itself does not exist in aqueous solution. The solvent, water, has unique properties in that it can act as both acid and base, according to the equilibrium

$$H_2O(\text{acid}) + H_2O(\text{base}) \rightleftharpoons H_3O^+(\text{acid}) + OH^-\ (\text{base}). \quad (54)$$

The equilibrium constant for this reaction, expressed as the ion product

$$K_w = [H_3O^+][OH^-],$$

is 1×10^{-14} at 25 °C. Somewhat surprisingly, this autoionization reaction is apparently not diffusion controlled, as the observed rate constant is $5\times10^{-7}\ M^{-1}\,s^{-1}$. In this example, water is weak both as an acid and as a base; reactions involving either proton transfer from a strong acid or to a strong base do tend to be diffusion controlled. Rapid proton transfer reactions such as these can be studied by the technique of nuclear magnetic resonance (NMR) spectroscopy. This utilizes the fact that in a magnetic field, the separation of the energy levels (i.e., the transition frequency) of a magnetic nucleus such as a proton depends on the chemical environment of the proton. This environmental effect is known as the "chemical shift." Thus, in the acid–base reaction (52), the chemical shift for H will be different in AH and BH, and two peaks will be observed in the NMR spectrum. As the rate increases, the spectral features become broadened, and finally, if the exchange is rapid enough, a new narrow peak that is a statistically weighted average of those for AH and BH is observed.

Brönsted and Pedersen (1924) studied the decomposition of nitramide,

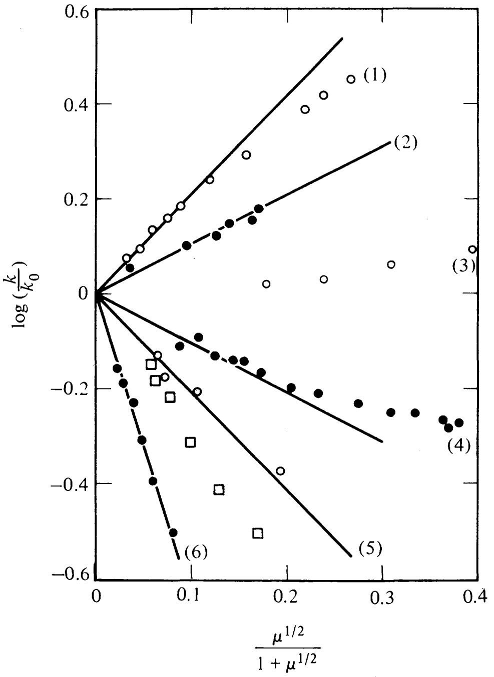

FIG. 5. Effect of ionic strength (μ) on rate constants. The ordinate is the logarithm of the rate constant at ionic strength μ relative to that at $\mu=0$. The reactions are (1) $BrCH_2COO^- + S_2O_3^{2-}$; (2) $e^-(aq) + NO_2^-$; (3) $H_3O^+ + C_{12}H_{22}O_{11}$ (inversion of sucrose); (4) $H_3O^+ + Br^- + H_2O_2$; (5) $OH^- + Co(NH_3)_5Br^{2+}$ [ionic strength varied with NaBr (circles) and Na_2SO_4 (squares)]; (6) $Fe(H_2O)_6^{2+} + Co(C_2O_4)_3^{3-}$. The lines are calculated according to Eq. (51). [From Weston and Schwarz (1972), p. 170. Reprinted by permission of Prentice-Hall, Inc., Englewood Cliffs, NJ.]

$$H_2N_2O_2 \rightarrow H_2O + N_2O, \qquad (55)$$

catalyzed by various bases B. They found a correlation between the base dissociation constant and the rate constant for the reaction. (Actually, they observed an *inverse* correlation with the acid dissociation constant of the conjugate acid, which is related to the base dissociation constant by $K_{HB}K_B = K_w$.) Brönsted further noted that a similar correlation applied to many acid-catalyzed reactions as well as other base-catalyzed reactions. The dependence of the rate constants on equilibrium constants can be expressed as follows:

$$(k_{HA}/p) = A(K_{HA}\,q/p)^{\alpha}$$

for acid catalysis and

$$(k_B/q) = B(K_B\,p/q)^{\beta} \qquad (56)$$

for base catalysis. In these expressions, A and B are constants, and p and q are statistical factors, i.e., the number of equivalent protons on the acid and the number of equivalent sites for accepting protons on the base, respectively. The rate constants k_i are related to the acid and base dissociation constants for the reactions

$$H_2O + HA \rightleftharpoons H_3O^+ + A^-, \quad K_{HA},$$

and

$$H_2O + B \rightleftharpoons HB^+ + OH^-, \quad K_B. \qquad (57)$$

An example of the dependence is shown in Fig. 6, where data for the acid-catalyzed dehydration of acetaldehyde hydrate are plotted. It is seen that the correlation between rate constant and dissociation constant is valid over several orders of magnitude, for the three general classes of compounds for which data are shown. Reactions that obey these rate laws are considered subject to either general acid or general base catalysis. In some other reactions, for example, if the coefficient α is large, the effective catalysis by the hydronium ion will mask acid catalysis by other, weaker, acids. This is a case of specific hydronium ion catalysis, and can be detected by noting that the rate does not depend on the concentration of buffer solutions of HA and A^- in which the concentration of H_3O^+ is kept constant. Other types of acid and base catalysis may not follow the Brönsted rate laws; for example, if K_{HA} is very large, the reaction may be diffusion limited.

2.3 Oxidation–Reduction Reactions

These reactions, often called redox reactions, include some of the most important biochemical reactions, such as those involved in photosynthesis. An oxidation reaction was originally defined as one in which a substance combined with oxygen, and a reduction was one in which oxygen was removed from a compound, as, for example, in the reaction of a metal ore such as Fe_2O_3 with a reducing agent to give the elemental metal. These definitions have been expanded to include all reactions in which the oxidation number of an element is changed. In a simple binary ionic compound, the oxidation number of an element is equal to the number of electrons gained or lost when the compound was formed. In a monatomic ion, the oxidation number is

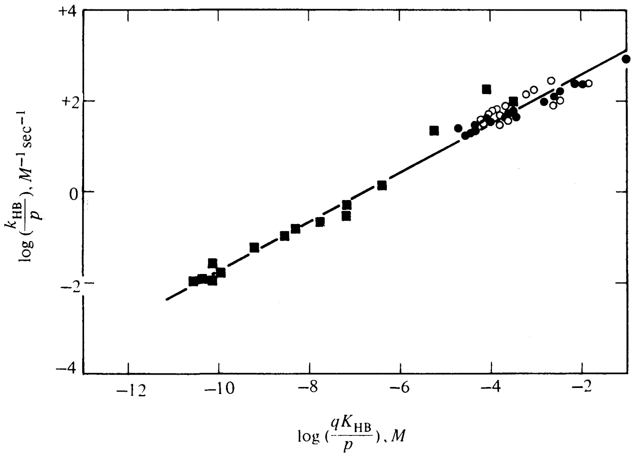

FIG. 6. The Brönsted relation [Eq. (56)] between acid dissociation constant K_{HA} and rate constant k_{HA} for the acid-catalyzed dehydration of acetaldehyde hydrate. Open circles, carboxylic acids; closed circles, substituted benzoic acids; filled squares, phenols. [From Weston and Schwarz (1972), p. 193. Reprinted by permission of Prentice-Hall, Inc., Englewood Cliffs, NJ.]

equal to the charge on the ion. The oxidation numbers of elements in covalent compounds are defined in a more formalistic way, but they still represent shifts of electron density. With these additional rules, an oxidation is now defined as an algebraic increase in the oxidation number (corresponding to a loss of electrons), and a reduction corresponds to a gain of electrons and an algebraic decrease in the oxidation number.

The simplest form of an oxidation–reduction reaction, at least in principle, is provided by the electron transfer process exemplified by

$$\mathrm{Fe}^{3+} + {}^{*}\mathrm{Fe}^{2+} \rightarrow \mathrm{Fe}^{2+} + {}^{*}\mathrm{Fe}^{3+}, \qquad (58)$$

where the asterisk indicates an isotopic label that makes it possible to follow such a reaction. The ferrous–ferric exchange was one of the first electron transfer reactions to be studied in detail (Silverman and Dodson, 1952), and it has the obvious attraction of a system in which no net chemical change takes place and there is no energy of reaction. The reaction follows a bimolecular rate law, but is not as simple as is indicated above, because the ferrous and ferric ions form coordination complexes in aqueous solution. Even in the absence of added ligand species, the ions will be complexed by six water molecules from the solvent. The study of a large number of electron transfer reactions involving transition-metal complexes indicates that they can be roughly divided into "inner sphere" and "outer sphere" processes (Sykes, 1967). Outer sphere reactions are those in which the reaction path does not involve the sharing of a ligand between the two metal atom centers. This mechanism must apply when the rate of ligand substitution on both centers is slower than the rate of the electron transfer process, as in the example:

$$\begin{aligned} &{}^{*}\mathrm{Ru(NH_3)}_6^{2+} + \mathrm{Ru(NH_3)}_6^{3+} \\ &\quad \rightarrow {}^{*}\mathrm{Ru(NH_3)}_6^{3+} + \mathrm{Ru(NH_3)}_6^{2+}. \qquad (59) \end{aligned}$$

The initial step in these reactions is the approach of the two reactants to a distance at which the electron transfer can take place, and this step is subject to the same considerations as those applicable to the reaction of two ions discussed in Sec. 2.1. The time scale for electronic motion ($\sim 10^{-15}$ s) is very rapid compared with that for nuclear motion (10^{-11} to 10^{-13} s), and according to the Franck–Condon principle, internuclear distances and nuclear momenta do not change during an electronic transition (see, for example, Berry, Rice, and Ross, 1980). The theoretical problem to be faced in considering electron transfer reactions is how they can be relatively slow when electronic motion is so fast. The answer lies in the fact that nuclear rearrangements *must* occur in these reactions: metal–ligand bond lengths depend on the metal atom charge, and the dipolar water molecules of the solvent must rearrange themselves to minimize the potential energy after the electron transfer has taken place (Fig. 7). A detailed theory that takes these factors into account has been developed and widely applied (Marcus, 1963; Sutin, 1983). Without going into the detailed formulation of this theory, some of the important factors can be indicated here. These include the equilibrium constant for the reaction (unity if there is no net chemical reaction), and contributions from the energy changes due to the solvent reorganization and the difference in metal–ligand bond length. The solvent reorganization energy can be calculated from a classical electrostatic model, while the inner shell energy depends on the force constant for metal–ligand vibrations and the change in bond length. It has recently become possible to estimate this latter term by measuring the metal–ligand bond lengths of complexes in solution, using EXAFS. The bond-length differences are very small; for example, in the hexa-aquo ferrous–ferric system, the difference is about 10 pm. Nevertheless, when the other factors entering the expression for the electron transfer rate constant

The circles represent the inner coordination shells of the metal complexes. The wedges represent water molecules. [From Sutin and Creutz (1983). Reproduced by permission of the Division of Chemical Education, American Chemical Society.]

are taken into account, a good correlation is found between these bond-length differences and the exchange rate constant (Brunschwig *et al.*, 1982).

The Marcus theory also leads to a relationship between the rate constants for self-exchange reactions of the type exemplified in Eqs. (58) and (59), and that of the cross reaction obtained by combining these two reactions:

$$\mathrm{Fe(H_2O)_6^{3+} + Ru(NH_3)_6^{2+} \rightarrow Fe(H_2O)_6^{2+} + Ru(NH_3)_6^{3+}}. \qquad (60)$$

The rate constant for the cross reaction k_{12} is approximately given by

$$k_{12} = (k_{11}k_{22}K_{12})^{1/2}, \qquad (61)$$

where k_{11} and k_{22} are the rate constants of the two self-exchange reactions, and K_{12} is the equilibrium constant for the cross reaction. The validity of this expression is demonstrated by the data in Table 1.

The mechanism of an inner-sphere reaction requires that the reactants combine to form a single primary bond system with a ligand bonded simultaneously to both metal centers. Various types of indirect evidence for such a mechanism have been offered, but the most persuasive argument is provided when an actual ligand transfer from one metal center to another is established, as in the following example:

Table 1. Comparison of experimental rate constants for cross-reactions with rate constants calculated from the Marcus expression.[a]

[a] Data from Bennett (1973).

$$\mathrm{Co(NH_3)_5X^{2+} + Cr(H_2O)_6^{2+} \rightarrow [(NH_3)_5Co..X..Cr(H_2O)_5]^{4+} + H_2O \rightarrow Co(NH_3)_5(H_2O)^{2+} + Cr(H_2O)_5X^{2+}} \quad (\mathrm{X{=}halide\ ion}). \tag{62}$$

The rate of such a reaction is found to depend on the specific halide ion, being determined by the relative strengths of the metal–halide bond being broken and that being formed.

The limiting case of the inner-sphere mechanism is provided by an intramolecular electron transfer within a compound containing two metal atoms. An extension of the Marcus theory to this case indicates a strong dependence of the rate constant on the distance between the metal centers, due to the effect of the charge separation on the solvent reorganization energy and also due to the distance dependence of the electronic coupling between the metal atoms. This dependence has been demonstrated experimentally by measuring electron transfer rates for a series of compounds of the type

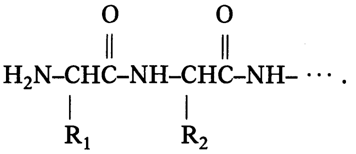
$$\mathrm{[(NH_3)_5Os(III)...(L)_{\mathit{n}}...Co(NH_3)_5(III)]^{5+}},$$

where L_n is a peptide bridge of varying length (Isied *et al.*, 1985, 1988). Pulse radiolysis in aqueous solution leads to rapid reduction of Os(III) to Os(II), followed by intramolecular oxidation of Os(II) and reduction of Co(III). The rate constant for electron transfer varies over seven orders of magnitude for L=proline as n increases from zero to four.

2.4 Catalysis by Enzymes

Earlier in this section, acid and base catalysis in aqueous solution is discussed; in Sec. 1.3.3 an example of catalysis in the gas phase is given, and in Sec. 3.2.5 the important topic of heterogeneous catalysis on surfaces is treated briefly. The importance of these types of catalysis pales by comparison with enzyme catalysis which is essential to life itself, as it is involved in numerous biochemical reactions. The effects of enzymes on chemical reactions are profound—increases in reaction rates by factors of 10^{10} to 10^{14} over the uncatalyzed reaction are possible. Moreover, this type of catalysis (unlike industrial heterogeneous catalysis) takes place at ambient temperatures and atmospheric pressure in neutral aqueous solutions.

Enzymes are proteins—copolymers of amino acids with the general formula $\mathrm{RCH(NH_2)COOH}$ or $\mathrm{RCH(NH_3^+)COO^-}$ that are fastened together by peptide linkages:



$$\mathrm{H_2N{-}\underset{\displaystyle R_1}{\underset{|}{C}}H\overset{\displaystyle O}{\overset{\|}{C}}{-}NH{-}\underset{\displaystyle R_2}{\underset{|}{C}}H\overset{\displaystyle O}{\overset{\|}{C}}{-}NH{-}} \cdots .$$

The number of amino acid units in these proteins is very large, of the order of hundreds, and the molecular weights are of the order of 10^4–10^5 daltons. Nevertheless, they are specific chemical compounds that can be obtained in pure form, and can even be crystallized in some cases. Only a very small part of the very large enzyme molecule, the "active site," is intimately involved in the catalytic reaction. The rest of the molecule may serve as a skeleton which constrains the active site to the appropriate geometry.

A complete description of the mechanism of action of an enzyme contains the following information (Fersht, 1977):

1. The sequence of amino acids in the protein. Automated methods can now be used for this determination.
2. The detailed structure of the active site and of the enzyme–substrate complex. The first x-ray determinations of protein structures (myoglobin and hemoglobin) were carried out in the 1950s, and this pioneering work is described in the 1962 Nobel Prize lectures (Kendrew, 1963; Perutz, 1963). Since that time the structures of some 500 to 1000 proteins, including many enzymes, have been determined by diffraction methods. Enzyme–substrate complexes have a fleeting existence along the reaction path, but it is sometimes possible to determine structures of less reactive analogs, or of enzymes blocked with inhibitors that occupy the active site. Only a limited number of functional groups can be used by an enzyme in the catalytic process, and it is not surprising, therefore, that the active site regions of different enzymes may be very similar.
3. The chemical mechanism of the enzyme action, and a determination of the rate constants for the individual reaction steps. The basic approach to this problem is outlined below.

4. An understanding of the magnitudes of the rate constants based on thermochemistry and stereochemistry.
5. The specificity of substrates, and the mechanism by which an enzyme can discriminate between substrates of similar structure competing for the active site.

The basic understanding of the rates of enzyme reactions was developed by Michaelis and Menten (1913). Experimentally, it is found that the initial rate of the enzymatic reaction is proportional to the enzyme concentration. At low concentrations of substrate, the rate is also proportional to substrate concentration. However, as the substrate concentration increases, a saturation effect becomes evident, and the rate reaches a maximum value (Fig. 8). This effect can be expressed by the rate equation

$$v=k_{\mathrm{cat}}[E]_0[S]/(K_m+[S]), \tag{63}$$

where v is the rate, k_{cat} is a rate constant, K_m is essentially an equilibrium constant, called the Michaelis constant, $[E]_0$ is the initial concentration of free enzyme, and $[S]$ is that of the substrate. An observed rate constant can be defined from the expression

$$v=k_{\mathrm{obs}}[E]_0,$$

from which

$$k_{\mathrm{obs}}=k_{\mathrm{cat}}[S]/(K_m+[S]). \tag{64}$$

At very high substrate concentrations such that $[S]\gg K_m$, the limit on the rate is

$$v_{\max}=k_{\mathrm{cat}}[E]_0 \quad \text{and} \quad k_{\mathrm{obs}}^{\infty}=k_{\mathrm{cat}}. \tag{65}$$

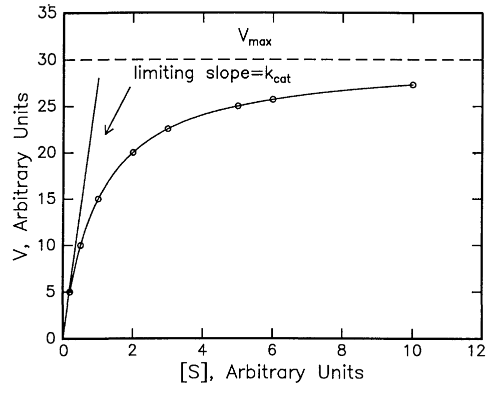


FIG. 8. Reaction rate plotted against substrate concentration for a reaction obeying Michaelis–Menten kinetics.

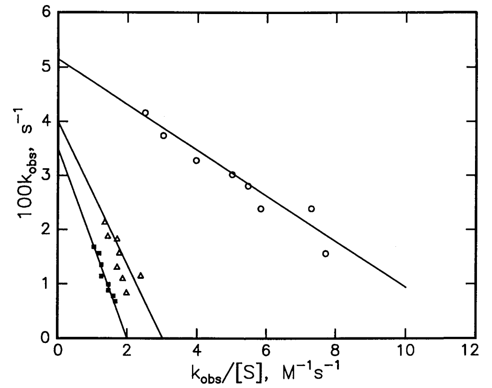

FIG. 9. Data for the α-chymotrypsin–catalyzed hydrolysis of N-acetyl-*L*-tryptophanamide, plotted according to Eq. (67). Circles, *p*H 7.9, $[E]_0=5$ μmol; squares, *p*H 9.6, $[E]_0=5$ μmol; triangles, *p*H 9.6, $[E]_0=20$ μmol. Data from Himoe *et al.* (1967).

The Michaelis constant is given by the substrate concentration at which $v=v_{\max}/2$. At low concentrations of the substrate, where $[S]\ll K_m$, the rate is

$$v=(k_{\mathrm{cat}}/K_m)[E]_0[S],$$

and

$$k_{\mathrm{obs}}^{0}=k_{\mathrm{cat}}[S]/K_m. \tag{66}$$

Rearrangement of Eq. (64) leads to a form linear in $1/[S]$:

$$k_{\mathrm{obs}}=k_{\mathrm{cat}}-K_m k_{\mathrm{obs}}/[S]. \tag{67}$$

A plot of the data in the form of k_{obs} vs $k_{\mathrm{obs}}/[S]$ gives a straight line with an intercept of k_{cat} and a slope of $-K_m$ (Fig. 9). This expression is also written in the form (the Eadie–Hofstee equation)

$$v=v_{\max}-K_m v/[S]. \tag{68}$$

The rate expression of Eq. (63) can be derived from a mechanism

$$\mathrm{E+S\rightarrow ES}, \quad k_1, \tag{69}$$

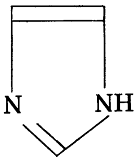
$$\mathrm{ES\rightarrow E+S}, \quad k_{-1}, \tag{70}$$

$$\mathrm{ES\rightarrow P}, \quad k_{\mathrm{cat}}, \tag{71}$$

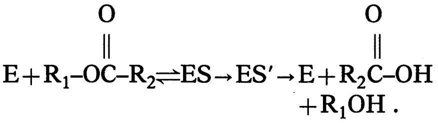
where ES is an enzyme–substrate complex and P is the product. Under steady-state conditions (valid when the concentration of ES is much smaller than that of E or S), this mechanism leads to a rate expressed by Eq. (63), with $K_m=(k_{-1}+k_{\mathrm{cat}})/k_1$. Thus, it is seen that the Michaelis constant is a measure of the stability of the enzyme–substrate complex; in fact, if $k_{cat} \ll k_{-1}$, the constant is just the dissociation constant of the complex.

Some of the above general considerations may become more concrete when applied to a specific enzyme, α-chymotrypsin. This compound belongs to a family of enzymes, the serine proteases, that have in common a reactive serine residue, $\text{-NH-CH(CH}_2\text{OH)-C(O)-}$; they catalyze the hydrolysis of peptides and synthetic ester and amide substrates. Chymotrypsin consists of 246 amino acid residues, and their sequence has been determined. The enzyme is produced in the pancreas by the action of another enzyme, trypsin, on the precursor, chymotrypsinogen.

Examples of data for chymotrypsin that fit the Michaelis–Menten mechanism are shown in Fig. 9. A clue to the location of the active site in this enzyme is given by the *p*H dependence of the reaction, which indicates that k_{cat} is sensitive to groups with acid dissociation constants of $\sim 10^{-7}$ M and $\sim 10^{-10}$ M (pK_a's of 7 and 10), whereas K_m is affected by groups with a *p*K of about 9. There are three groups in the enzyme with a pK_a of about 7: a terminal -NH_3^+ group, unlikely to be active, and two histidine residues containing imidazole rings:



Imidazole is known to have a pK_a of 7.09 in aqueous solution. Thus, at least one of these groups is at the active site. Further reaction studies indicate that this group is histidine-57 (the 57th amino acid residue in the chain). Some substrates, such as *p*-nitrophenyl acetate, form stable acyl–enzyme complexes, and the amino acid sequencing of the complex shows that the acetyl group is linked to serine-195. The acid and alcohol products are not released by the enzyme simultaneously, indicating a slightly more complicated mechanism,



$$E + R_1\text{-}O\overset{\overset{O}{\|}}{C}\text{-}R_2 \rightleftharpoons ES \rightarrow ES' \rightarrow E + R_2\overset{\overset{O}{\|}}{C}\text{-}OH + R_1OH . \qquad (72)$$

Thus, the surprising conclusion is that two amino acid residues separated by 137 other residues are both at the active site. The fact that these two groups are actually close together has been proven by x-ray diffraction studies (Fig. 10). In addition, these structural determinations indicate hydrogen-bonding between the histidine and aspartic acid-102. In fact, some evidence now indicates that the *p*H ~ 7 dependence is due to involvement of this aspartate group in a proton transfer from histidine-57. The effect of higher *p*H mentioned above is now known to be due to the α-amino group of isoleucine-16, which affects the conformation of the enzyme but does not directly influence k_{cat}. This specific example of α-chymotrypsin shows that the combination of structural studies (x-ray diffraction, NMR spectroscopy, infrared spectroscopy) and mechanistic studies can be combined to elucidate the action of an enzyme at the most detailed level.

2.5 Polymerization Reactions

Polymers are very large molecules, made up of recurring structural units, frequently identical. In the discussion of enzyme catalysis in the preceding section, proteins were briefly mentioned as an example of naturally

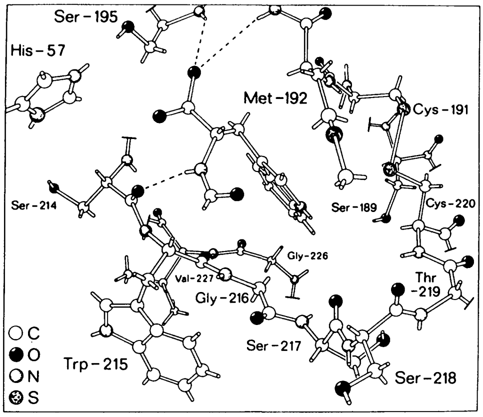


FIG. 10. The active site structure of chymotrypsin. Amino acids are abbreviated as follows: Cys, cysteine; Gly, glycine; His, histidine; Met, methionine; Ser, serine; Thr, threonine; Trp, tryptophan, Val, valine. (From *Enzyme Structure and Mechanism*. By Alan Fersht. © 1977 by W. H. Freeman and Company. Reprinted by permission.)

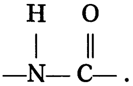
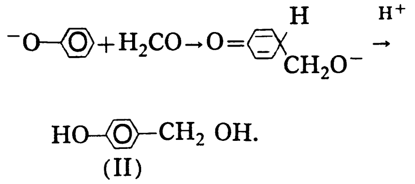
occurring copolymers, consisting of amino acid residues held together by the amide linkage,



$$\overset{\displaystyle H}{\overset{|}{—N}}—\overset{\displaystyle O}{\overset{\|}{C}}— .$$

Other polymers also occur in nature: starch, cellulose, natural rubber, silk, wool, and DNA (deoxyribonucleic acid) are examples. However, the number of these is overwhelmed by the number of man-made polymers. Only a few of these will be discussed here as examples of general types of polymerization reactions.

Condensation Polymers. One of the oldest synthetic polymers is *Bakelite,* produced by the condensation of phenol, C_6H_5OH, with formaldehyde, H_2CO. The reaction is induced by a basic catalyst that removes a proton from phenol to form the phenoxide ion. Subsequent reactions are:

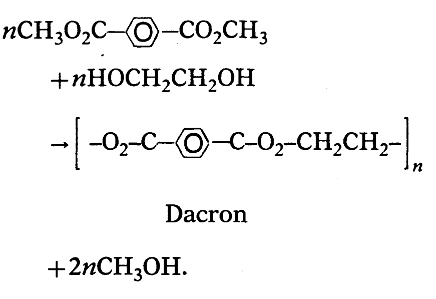


(73)

Further condensation of (II) with another molecule of phenol and loss of a water molecule leads to

Continuation of this process leads to a cross-linked three-dimensional polymer, with each aromatic ring linked through methylene (CH_2) groups at the 1, 3, and 5 positions of the ring.

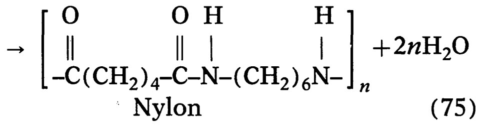
Polyester condensations lead to a variety of polymers. For example,



(74)

Polyamides, with linkages like those of proteins, can be made by condensing diamines with dicarboxylic acids:

$$n\mathrm{HO_2C(CH_2)_4CO_2H} + n\mathrm{H_2N(CH_2)_6NH_2}$$



$$\rightarrow \left[-\overset{\displaystyle O}{\overset{\|}{C}}(CH_2)_4-\overset{\displaystyle O}{\overset{\|}{C}}-\overset{\displaystyle H}{\overset{|}{N}}-(CH_2)_6\overset{\displaystyle H}{\overset{|}{N}}- \right]_n + 2n\mathrm{H_2O}$$

Nylon (75)

Addition Polymers. Hydrocarbons containing a double bond (alkenes or olefins) typically form polymers in chain reactions; for example, styrene polymerizes to form polystyrene:

$$n\mathrm{C_6H_5{-}CH{=}CH_2} \rightarrow [-(\mathrm{C_6H_5})\mathrm{CH{-}CH_2}]_n. \quad (76)$$

Free-radical catalysts to initiate these reactions are frequently produced by thermal or photochemical decomposition of organic peroxides, which form alkyl radicals: e.g.,

$$\mathrm{(CH_3)_3C{-}O{-}O{-}C(CH_3)_3} \rightarrow 2\mathrm{(CH_3)_3CO}\bullet \rightarrow 4\mathrm{CH_3}\bullet + 2\mathrm{(CH_3)_2C{=}O}. \quad (77)$$

This chain-initiation step is followed by addition of the radical to the alkene to form a larger radical that can add to yet another alkene molecule; this process is repeated until a chain-terminating step intervenes:

$$\mathrm{R}\bullet + n\mathrm{CH_2{=}CH(C_6H_5)} \rightarrow \mathrm{R[-CH_2{-}CH(C_6H_5)-]}_n. \quad (78)$$

The chain length is large enough so that the product is essentially polystyrene, even if the initiating radical is still part of the polymer molecule. Other alkenes, such as isobutylene (2-methylpropene), undergo acid-catalyzed polymerizations in which a proton adds to the alkene to form a positively charged (cationic) growing chain.

3. REACTIONS INVOLVING THE SOLID PHASE

Chemical reactions that take place entirely in the solid phase are much less common than those taking place in the gas or liquid phase. As in the case of liquid-phase reactions, transport within the condensed phase is often the rate-determining process. From a technological standpoint, the most important class of reactions involving solids is that in which the solid serves as a heterogeneous catalyst for reactions of gases or liquids. Other important reactions of solids, such as corrosion and electrochemical reactions at the surface of metal electrodes, will be discussed in Sec. 4.3.

3.1 Solid–Solid Reactions

In the solid phase, unlike the gas or liquid phase, reactants are restricted from access to each other. Diffusion of one or more reactants is required, through a solid phase that may include both reactant and product species. Mass transfer may take place by bulk diffusion, or may occur along grain boundaries, etc.

Addition reactions are the simplest type of solid–solid reaction. Examples are found in the formation of spinels:

$$\mathrm{ZnO(s)+Fe_2O_3(s)\rightarrow ZnFe_2O_4(s)}, \qquad (79)$$

$$\mathrm{MgO(s)+Al_2O_3(s)\rightarrow MgAl_2O_4(s)}. \qquad (80)$$

In the latter reaction, both Mg^{2+} and Al^{3+} ions diffuse.

In double decomposition reactions, such as

$$\mathrm{AgCl(s)+NaI(s)\rightarrow NaCl(s)+AgI(s)}, \qquad (81)$$

there may be as many as four solid phases involved. In this example, they might be AgCl/NaCl/AgI/NaI, corresponding to diffusion of Ag^+ through NaCl and AgI to react at the AgI/NaI interface, and motion of Na^+ through AgI and NaCl to react at the AgCl/NaCl interface.

3.2 Gas–Solid Reactions

3.2.1 Tarnishing of Metals. Tarnishing is the reaction of a solid metal with a liquid or a gas, typically to form an oxide or a sulfide. An example that again illustrates the importance of material transport is provided by the reaction of silver with molten sulfur at a temperature of 200 °C. An experiment was carried out with the silver surface separated from the liquid sulfur by two separate layers of silver sulfide, Ag_2S, and it was found that the weight of the silver layer decreased as reaction occurred, the weight of the sulfide layer closest to silver remained relatively constant, but the sulfide layer next to sulfur gained weight corresponding to the loss of weight in silver. Thus, the reaction involves diffusion of Ag^+ through the sulfide to react at the silver sulfide–sulfur interface. Electrons flow in the opposite direction to maintain electrical neutrality.

The formation of thick ($\geqslant$100 nm) tarnish films often obeys a linear rate law

$$X=At, \qquad (82)$$

where X is the film thickness, t is the time, and A is a rate constant. The mechanism involves reaction of the gas or liquid with the solid to form a film that does not adhere, so that open surface of the solid is always accessible to the other reactant. Hence, the rate is independent of time and film thickness. Examples are the oxidation of alkali metals and alkaline earth metals. On the other hand, if diffusion through a product forming a coherent solid is rate-limiting, the formation rate follows a parabolic law:

$$X^2=At. \qquad (83)$$

This expression can be derived from the equations for the concentration gradient of metal atoms diffusing to the surface, which is inversely proportional to the film thickness.

The growth of thin films ($<$100 nm) follows several possible rate laws, depending on specific metals and on film thickness. These rate laws reflect the electrostatic effects of space charges in the surface regions, which now represent a significant fraction of the total film thickness. Also, in thin films material transfer occurring at the gas–surface interface may be rate-determining, rather than transport through the film itself. However, the film thickness determines the electric field through which the metal ions move. As the film thickness increases, the potential decreases and the rate of growth slows down. This is the case for the oxidation of aluminum, and indeed, were it not so, aluminum would be virtually useless for practical applications. After an oxide film of about 20 Å is formed (at room temperature), the rate of oxidation decreases to a very low value, and the metal is "passivated" against further reaction.

3.2.2 Chemical Vapor Deposition of Thin Films on Semiconductor Substrates. Chemical vapor deposition (CVD) is a process in which vapor-phase components react to form a solid thin film on some surface. The use of this method for the formation of thin films has become a major process in the production of solid-state electronic devices. It is an extremely versatile technique that permits the formation of solid phases with a wide range of controllable composition at relatively low reaction temperatures. The solids formed, with a high degree of purity and perfection, may be either crystalline or glassy. An indication of the economic significance of CVD is given by the production of silicon for use in solid-state electronics, using the reduction of trichlorosilane ($SiHCl_3$) by hydrogen. The polycrystalline silicon thus produced is grown into single crystals with an impurity content of one part in 10^{11}. About 30 000 metric tons (3×10^7 kg) are produced every year, worldwide (Yablonovitch, 1989).

The chemical reactions taking place in a CVD process can be investigated by determination of the vapor composition *in situ*, using techniques such as mass spectrometry, Raman and absorption spectroscopy, and gas chromatography. In addition, the composition of the solid phase must be determined using techniques such as XPS, Auger spectroscopy, and IR reflectance spectroscopy. Reactors designed for use at both normal and reduced pressures, at ambient and elevated temperatures (1000–1300 °C), are available. At normal pressures, the rates of transport processes and surface chemical reactions are comparable. For this reason, both types of rate-limiting steps must be optimized to ensure uniformity of film characteristics over extended surfaces. The recent innovation of reactors designed for low-pressure CVD has proven to be a significant advance in the semiconductor industry. The advantage is that gas flow is no longer a consideration in the reactor design, since diffusion is no longer the rate-determining step in the process, and the gas-phase composition is more homogeneous. The longer mean free path of the reactants means that limitations on the loading and positioning of the solid substrates are reduced (see CVD).

3.2.3 Vapor Etching of Semiconductors.

The increasing demands on spatial resolution in integrated circuit wafers have made conventional chemical etching with liquids unsuitable. In spite of the name, plasma etching is predominantly a chemical process in which the reactants are produced by an electrical discharge in a low-pressure gas. The reactive species thus produced diffuse to the substrate surface and react to form volatile products. The electrical discharge is typically a microwave rf discharge at a frequency of ~14 MHz and a power level of 0.1 to 1 W/cm^3 of reactor volume.

The chemistry of plasma etching is very complicated and not yet well understood (Jasinski, Meyerson, and Scott, 1987). In the discharge, high-energy electron impact produces charged species by direct and dissociative ionization. Also, lower energy electrons dissociate molecules by processes such as

$$e^- + O_2 \rightarrow e^- + O + O$$

and

$$e^- + CF_4 \rightarrow e^- + CF_3 + F. \tag{84}$$

Electron impact may also lead to electronically excited molecules that dissociate rapidly before they can lose energy in collisions or by radiation.

A specific example is provided by the CF_4–O_2 plasma, which is useful in etching Si, SiO_2, and Si_3N_4. Tetrafluoromethane (CF_4) is itself a very inert gas, which in a discharge produces reactive species such as F, CF, CF_2, and CF_3. The addition of O_2 up to a content of ~30% to the discharge increases the etch rate of silica, but the rate then decreases as more oxygen is added. This is apparently caused by a parallel dependence of the F atom concentration on oxygen pressure, and it is believed that the reaction of oxygen with the CF_3 radical is responsible. The reactor effluent contains CO, CO_2, COF_2, and SiF_4 as stable products. It is important that the gaseous products be relatively stable, since otherwise they may dissociate and redeposit on the substrate. For example, SiH_4 (silane) is volatile, but decomposes in a plasma to form solid deposits of SiH_x. Halocarbons are widely used as sources of halogen atoms and halocarbon radicals because they are relatively inexpensive, easy to handle, noncorrosive, volatile, and relatively nontoxic. (For the deleterious effect of chlorofluorocarbons on the stratospheric ozone layer, cf. Sec. 1.3.3.) Table 2 (from Vossen and Kern, 1978) shows some of the plasma etching reactants and the observed products (see PLASMA ETCHING).

As indicated above, the addition of oxygen to the halocarbon has an important effect on the etching rate. This is in part due to increased concentrations of halogen atoms, and also because the formation of polymers that deposit on the substrate is hindered. Substrate

Table 2. Halocarbon gases for plasma etching.

Etching gas	Etchable materials	Principal fragments and relative intensities from mass spectra					
CF_4	Si,SiO_2,Si_3N_4,Ti, Mo,Ta,W	CF_3	CF_2	F	CF		
		100	12	7	5		
C_2F_6	SiO_2,Si_3N_4	CF_3	C_2F_5	CF_2	CF	C	F
		100	41	10	10	2	1
$CClF_3$	Au,Ti	CF_3	$CClF_2$	CF_2	Cl	CF	
		100	21	10	7	4	
$CBrF_3$	Ti,Pt	CF_3	$CBrF_3$	$CBrF_2$	Br		
		100	15	14	5		
C_3F_8	SiO_2,Si_3N_4	CF_3	CF	C_3F_7	CF_2	C_2F_5	C_2F_4
		100	29	25	9	9	7
CCl_4	Al,Cr_2O_3,Cr	CCl_3	Cl	CCl	CCl_2		
		100	41	41	29		

temperature is another variable that affects the etching rate, as most of the chemical reactions involved have activation energies of 10–50 kJ/mol. For this reason, temperature control is important in establishing reproducible etching conditions.

3.2.4 Adsorption of Gases on Solids. Reactions occurring at the surfaces of solids are extremely important in the production of many industrial chemicals, and in the refining of crude oil into useful fuels and into a variety of feedstocks for other chemical processes. The initial step in any of these heterogeneous catalytic reactions is the adsorption of gases on the solid substrate. The potential chemical reactivity of a surface can be understood if it is imagined that the surface is formed by cleaving or breaking off a fragment of the solid (Fig. 11). In a covalent solid, the surface then contains broken bonds and unsatisfied valencies. (This same principle leads to the excess free energy of a liquid surface, demonstrated by the phenomenon of surface tension.) In a similar way, the surface of an ionic solid has unbalanced electrostatic forces. Chemisorption results when a molecule interacts with the unsatisfied valencies of the solid surface; in effect, this is a chemical reaction since the electronic configurations of the surface and the adsorbed molecule are changed in the process. The process is spontaneous, and hence the free energy change ΔG is negative:

$$\Delta G = \Delta H - T\,\Delta S < 0. \tag{85}$$

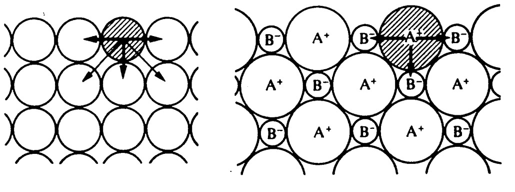


FIG. 11. A schematic representation of the surface energy of a covalent solid (left), and an ionic solid (right). (From Bond, 1987. © 1987 by Oxford University Press. Reproduced by permission of the publishers.)

The adsorbed molecule loses some degrees of freedom when it is confined to the surface, and the entropy change ΔS is negative. Therefore, the enthalpy of adsorption ΔH must also be negative, i.e., the reaction is exothermic. Typical values are -40 to -800 kJ/mol. However, the process is very specific, depending on the metal and even the particular surface plane exposed, and also depending on the adsorbed species. The reverse process of desorption is highly endothermic, and for this reason, chemisorbed layers are stable up to relatively high temperatures. Since the valence forces involved in this adsorption process are short-range forces, only a single layer may be considered to be chemisorbed, although additional layers may accumulate by physical adsorption. In many cases the electronic structure of the adsorbed molecule must be drastically altered to permit reaction with the "broken bonds" of a metal surface. Dissociation may be necessary, as in the case of hydrogen:

$$2M + H_2 \rightarrow 2H\text{-}M. \tag{86}$$

Unsaturated hydrocarbons with a π-electron cloud, such as alkenes or aromatics, can interact by adding on to the "free valencies" of the metal, with subsequent rehybridization of their molecular orbitals. Chemisorption on metal oxide surfaces is less well understood than that on metal surfaces, and differs somewhat between semiconductor and insulator oxides.

Physical adsorption involves forces very similar to those acting between molecules in a liquid or condensed gas: van der Waals forces resulting from dipolar or multipolar interactions, or forces between multipoles induced by fluctuations in electron density. As would be expected, the enthalpies of physisorption are considerably smaller than those associated with chemisorption, and are similar in magnitude to enthalpies of vaporization of liquids (8–20 kJ/mol). The temperatures at which physical adsorption occurs are related to the boiling points of the adsorbates, but aside from this there is not the degree of specificity found in chemisorption. Finally, another distinction from chemisorption is that more than a single layer of adsorbed species can form.

The relation between the amount of adsorbed material and the pressure of the gas phase from which it is adsorbed is known as an adsorption isotherm. In spite of the multitude of known gas–solid interactions, all isotherms appear to be contained within five families (Fig. 12). The simplest of these, the Langmuir isotherm, is based on the following assumptions:

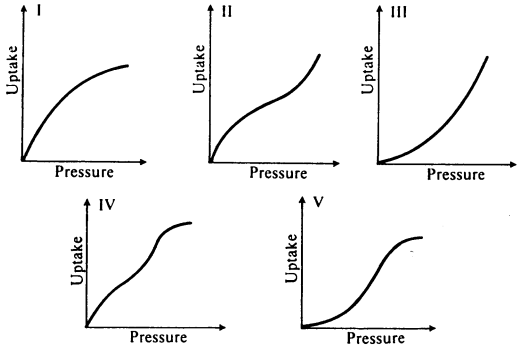

FIG. 12. The five different types of adsorption isotherm. I is typical of a Langmuir isotherm, and II is that for a BET isotherm (see text). (From Bond, 1987. © 1987 by Oxford University Press. Reproduced by permission of the publishers.)

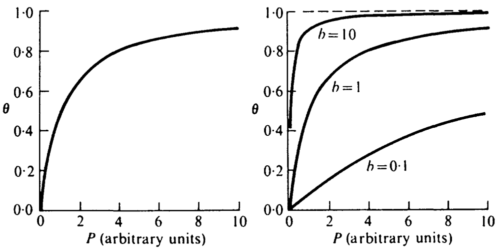

FIG. 13. Langmuir adsorption isotherms, showing the effect of the equilibrium constant for adsorption b. (From Bond, 1987. © 1987 by Oxford University Press. Reproduced by permission of the publishers.)

1. The surface is homogeneous.
2. The surface contains a fixed number of adsorption sites, each of which can be occupied by only a single molecule of adsorbate. (This limits the coverage to a monolayer.)
3. All sites are equivalent, and the adsorption of a single molecule is independent of all surrounding molecules.

These conditions lead to an equilibrium between A, the gas-phase adsorbate, M, the adsorption site, and A–M, the adsorbed species:

$$\mathrm{A(g)+M(s)\rightleftharpoons A\text{–}M(ads)}.$$

The equilibrium constant for this reaction can be expressed in terms of p, the pressure of A at equilibrium, and the fractional surface coverage θ. The ratio [A–M]/[M] is simply $\theta/(1-\theta)$, from which the equilibrium constant is

$$b=\theta/p(1-\theta)$$

and hence,

$$\theta=bp/(1+bp). \qquad (87)$$

The adsorption coefficient b indicates the strength of the interaction (Fig. 13). A convenient way of plotting a Langmuir isotherm is provided by identifying θ with the ratio V/V_m. The volumes V and V_m are those of the adsorbed gas and the equivalent of an adsorbed monolayer, respectively. Then the Langmuir expression can be written in the form (Fig. 14)

$$P/V=(1/bV_m)+(P/V_m). \qquad (88)$$

Another widely used isotherm is the BET (Brunauer, Emmet, and Teller, 1938) isotherm, which is particularly applicable to

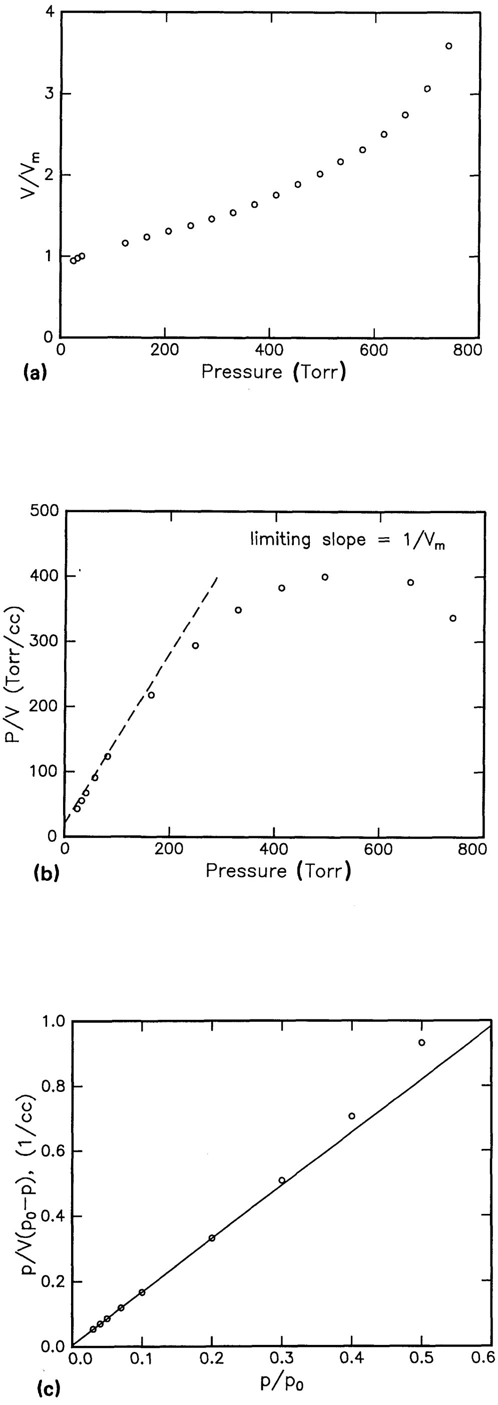

FIG. 14. The adsorption of nitrogen on KCl at 78 K. (a) Adsorption isotherm in the form of $\theta = V/V_m$ vs pressure. (b) Plotted as a Langmuir isotherm; this gives values of 0.77 cm^3 for V_m and 49.4 atm^{-1} for b; (c) plotted as a BET isotherm, yielding 0.58 for V_m and 344 for the constant C. Data from Keenan and Holmes (1949).

physisorption. It assumes neither a monolayer coverage of the surface nor a constant heat of adsorption. Instead, it is assumed that the first layer has an enthalpy of adsorption H_0 while that of subsequent layers is equal to the heat of vaporization of the adsorbate species H_L. The BET isotherm can be derived by considering the equilibrium between each adsorbed layer and the gas phase, with the result

$$\frac{p}{V(p_0-p)} = \frac{1}{V_m C} + \frac{(C-1)p}{V_m C p_0}\,. \tag{89}$$

In this equation, the BET constant is given by $C = \exp(H_0 - H_L)/RT$, where R is the gas constant and T is the absolute temperature. The pressures p and p_0 are the equilibrium pressure and the vapor pressure of the adsorbate at the temperature of the experiment. The BET expression is widely used to obtain the surface areas of catalysts, etc. An inert gas such as Ar or Kr is used as the adsorbate, and measurements of the volume and pressure are made as pressure is changed. A plot of $p/V(p_0-p)$ vs p/p_0 (up to low values of p/p_0) gives a straight line with intercept $1/V_m C$ and slope $(C-1)/CV_m$ (Fig. 14) from which the heat of adsorption for the first layer (from C) and a value of V_m can be derived. With assumptions about the size of adsorbed molecules and their packing on the surface, the volume V_m can be converted to a surface area. In the case of physisorption, where H_0 and H_L are comparable, the BET isotherm gives reasonable results. An expression similar to the BET isotherm can also be derived for a finite number of adsorbed layers. When the number of layers in such an expression is reduced to one, and with the identification of θ with V/V_m, the isotherm becomes identical to the Langmuir adsorption with the equilibrium constant b equal to C/p_0.

The experimental requirements for studies of adsorption, surface chemistry, and heterogeneous catalysis are very demanding. For example, the surfaces to be studied must be prepared under ultra-high vacuum (UHV) conditions. The reason for this can be understood on the basis of the rate at which ambient gaseous molecules collide with a surface. At 298 K, this rate for a gas of mass 28 (N_2 or CO) is 3.8×10^{20} collisions $cm^{-2}\,s^{-1}\,Torr^{-1}$ (1 Torr = 133.3 Pa). A typical metal surface has of the order of 10^{15} sites per square centimeter, and if half the collisions lead to adsorption, the rate at which surface sites are covered is 1.9×10^5 surface layers s^{-1} $Torr^{-1}$. Obviously, if the experiment is to extend over a time period of minutes, the ambient pressure must be of the order of 10^{-8} to 10^{-10} Torr to prevent surface coverage by background gas from blocking the adsorption of the desired species.

The surface scientist has a number of analytical tools at his disposal and seems to delight in designating them with a bewildering collection of acronyms (Gasser, 1985). LEED (low-energy electron diffraction) utilizes the scattering of 20–500 eV electrons from a metal surface to determine the lattice structure, or in some cases, the arrangement of an adsorbed layer. Typically, about 2% of the incident electrons are scattered quasi-elastically, with a penetration depth of the order of one nanometer (i.e., a few atomic layers). In clean metals the lattice spacing is usually within about ±10% of that found for the bulk metal. When a gas is adsorbed on the metal surface, a new electron scattering pattern is observed, which may be due to the metal lattice itself changed by adsorption, or may be caused by scattering from the adsorbate. Several electron emission spectroscopic techniques are used to obtain information about the elemental composition of the adsorbed species and the changes in its electronic configuration upon adsorption. UV photoelectron spectroscopy (UPS), using photons with energies less than 100 eV, provides information about the energy levels of valence electrons. The energy analysis is made by determining the kinetic energy of ejected electrons, given by

$$E_k=h\nu-I-E_{\text{int}}, \tag{90}$$

where the first term is the energy of the UV photon, I is the ionization potential, and E_{int} is the internal (vibrational and rotational) energy of the molecule. According to a theory due to Koopmans, the ionization potential is equal in magnitude to the orbital energy of the electron. Although this is not rigorously correct, it is a useful working approximation. XPS (x-ray photoelectron spectroscopy), also known as ESCA (electron spectroscopy for chemical analysis), is very similar to UPS, except that a monochromatic x-ray source now provides the excitation photons, and the energy is sufficient to eject electrons from core levels of the atom. Auger electron spectroscopy (AES) uses an electron or x-ray source that need not be monochromatic to ionize from core levels. The energy of the primary photoelectron thus ejected is not analyzed. The empty core level with energy E_1 is refilled with an electron from an outer shell, having energy E_2. However, there is still sufficient excitation energy to eject a secondary electron from a level with energy E_3. The energy of this electron is measured, and is given by

$$E_k=E_1-E_2-E_3, \tag{91}$$

so that it is independent of the excitation energy. In principle, Auger electron spectroscopy can also provide information about the chemical bonding of the atom that is ionized, but in practice, spectral resolution limits this application. Instead, Auger spectroscopy is used to determine surface "cleanliness," or the amount of adsorbate on the surface. Other techniques useful in studying chemisorption are EELS (electron energy loss spectroscopy) to determine vibrational energy levels of adsorbed species, and several types of microscopy: field emission microscopy (FEM), scanning tunneling microscopy (STM), etc. Also, EXAFS (extended x-ray absorption fine structure) and related x-ray techniques can be used to obtain information about interatomic distances.

3.2.5 Heterogeneous Catalysis. From an industrial standpoint, the most important chemical reactions that involve solids are those taking place on the surface of catalysts (Bond, 1987; Sinfelt, 1983). Industrial catalysts are produced in many forms: pellets, rings, spheres, tablets, granules, spaghettilike extrudates, etc. The solid phase is not necessarily uniform, as it may consist of a mechanical support, the catalyst itself, and a "promoter" that increases the catalytic activity by a mechanism not always understood. (There is more than a modicum of empiricism in the art of chemical catalysis.) These industrial catalysts may be subjected to extreme conditions of temperature (up to 1600 K) and pressure (350 atm), and yet may have a useful life of several years before they either deteriorate mechanically or are chemically "poisoned" by impurities in the feedstock or products. Catalytic reaction vessels are broadly classified into fixed-bed reactors, in which the catalyst is confined and the reactant gases flow through it, and fluid-bed reactors in which the catalyst consists of fine particles that are sufficiently agitated by flowing gas to behave like a liquid phase.

Some important industrial processes utilizing heterogeneous catalysis are discussed briefly below (see also CATALYSIS).

3.2.5.1 Catalytic Processes Used in the Petroleum and Petrochemical Industry. Many crude oils contain significant amounts (a few percent) of sulfur compounds, such as thiophene, C_4H_4S. These sulfur compounds are undesirable because when burned they produce the air pollutant sulfur dioxide and because the sulfur poisons catalysts used in "cracking" reactions (see below). They can be removed by hydrogenation over catalysts such as Mo–Co sulfides, Ni–Mo sulfides, or Ni sulfide–tungsten, supported on alumina.

Low molecular weight alkanes, such as methane or ethane, can be catalytically oxidized to synthesis gas, a mixture of hydrogen, carbon monoxide, and carbon dioxide. The general reaction is exemplified by that for methane:

$$CH_4+H_2O \rightleftharpoons 3H_2+CO. \qquad (92)$$

About 90% of the world production of hydrogen uses this type of reaction, which is catalyzed by Ni on alumina or magnesia. Depending on the stoichiometry, the water–gas shift reaction

$$CO+H_2O \rightleftharpoons CO_2+H_2 \qquad (93)$$

may also be important. This second step is catalyzed by Fe_3O_4 and Cr_2O_3.

Synthesis gas can be converted to hydrocarbons by a reaction that is essentially the reverse of reaction (92). This Fischer–Tropsch synthesis was used in Germany during World War II to produce liquid hydrocarbon fuels from synthesis gas derived from coal, and it is still used in South Africa. Catalysts for the Fischer–Tropsch synthesis of hydrocarbons are ruthenium and palladium. Other catalysts (Cu–Zn oxides) change the product to oxygen-containing compounds, such as methanol from methane.

A very important class of catalysts is the zeolites, which are aluminosilicates with the general formula $M_v(AlO_2)_x(SiO_2)_y \cdot zH_2O$, where M is a cation. The catalytic properties of these zeolites depend on three factors:

1. their crystal structure forms cavities of a size that depends on the specific zeolite and which can contain only molecules below a certain size;
2. strongly acid hydroxyl groups are exposed on the crystal surface;
3. electrostatic fields of the cations can induce reactivity.

These catalysts are widely used in cracking reactions, which break up large hydrocarbon molecules into smaller ones and also cause some isomerization of normal alkanes to branched-chain alkanes. Thus, the volatility of the hydrocarbons is increased and their antiknock ratings (octane numbers) are enhanced.

As the compression ratio of automobile engines increased, there was a demand for gasoline of higher octane ratings to prevent knocking. This demand could not be met solely by fuels produced in the catalytic cracking process. Needed were catalysts to effect the following general reactions:

1. dehydrogenation of alicyclic molecules such as cyclohexane to aromatics (e.g., benzene);
2. enlargement of cyclopentane rings to cyclohexanes;
3. isomerization of normal (straight-chain) alkanes to branched-chain alkanes;
4. conversion of normal alkanes to alicylics and thence to aromatics;
5. fragmentation (cracking) of alkanes to lower molecular weight alkanes.

This process is called *catalytic reforming*. Typical changes in a hydrocarbon feedstock are:

	Alkanes	Alicyclics	Aromatics	Octane number
Initial %	60	25	15	60
Final %	32	2	66	100

In the 1950s, bifunctional catalysts of ~1% platinum on alumina supports were developed for this purpose. The platinum serves to dehydrogenate alkanes and cycloalkanes to alkenes plus hydrogen. These unsaturated species then migrate to an acidic site on the alumina where a proton transfer reaction converts them to carbonium ions, i.e., molecular cations with the positive charge on carbon. These carbonium ions can undergo isomerization (ring closure or enlargement). After losing a proton, the isomerized species migrates to another Pt site, where it is hydrogenated. More recently (since 1970), bimetallic catalysts of platinum–rhenium or platinum–iridium on alumina have been introduced. In some cases, both of these catalysts are used at different stages of the reforming process. At least part of the beneficial effect of rhenium or indium is due to the inhibition of carbonaceous deposition on the catalyst.

3.2.5.2 Heterogeneous Catalysis in the Heavy Chemical Industry. The synthesis of ammonia by the inorganic fixation of nitrogen

$$N_2+3H_2 \rightarrow 2NH_3 \qquad (94)$$

is an important application of heterogeneous catalysis. The hydrogen for this reaction may be produced from alkanes as described above. Early attempts to find a suitable catalyst were made around the turn of century, and in an "Edisonian" research mode, tests were made of many iron ores reduced to metallic iron. Minor impurities in the ore had significant effects on the catalytic activity. It was eventually realized that alumina and potassium oxide were important constituents. The necessary catalyst is now made by reducing magnetite, Fe_3O_4, together with promoters that may include alumina, magnesia, potassium oxide, calcium oxide, silica, and traces of titanium, zirconium, and vanadium oxides. Large amounts of the ammonia thus produced are destined for use as an agricultural fertilizer, while another major use is in the production of nitric acid. Ammonia is catalytically oxidized to nitric oxide, NO, which is oxidized by air to nitrogen dioxide. This dissolves in water to form nitric acid, HNO_3.

$$3NO_2+H_2O \rightarrow 2HNO_3+NO. \qquad (95)$$

A patent for the catalysis by platinum sponge of the ammonia oxidation was first obtained as long ago as 1838, and the catalyst of choice today remains platinum or a platinum alloy in the form of a finely woven gauze.

4. ELECTROCHEMICAL REACTIONS

Electrochemistry was originally limited to the chemistry of processes taking place at electrodes in aqueous solutions. It is now a wider discipline, including all charge-transfer processes at membranes, which may be biological as well as inorganic (see ELECTROCHEMISTRY).

4.1 Electrochemical Cells

In Sec. 2.3 we described oxidation–reduction, or redox, reactions as those in which an electron is transferred from a reducing agent to an oxidizing agent. If the Gibbs free-energy change ΔG is negative for the reaction, it will occur spontaneously, and it may therefore be possible to obtain useful work from the process. The key to practical implementation is to intercept the electrons in some external circuit and to use the electron flow (or electric current) to do the work. The schematic diagram shown in Fig. 15 depicts a galvanic cell, an electrochemical cell, or simply, a battery. (This specific arrangement is known as the Daniell cell.) Each side of this device comprises a half-cell, with its cell reaction:

Left half-cell:

$$Zn(s) \rightarrow Zn^{2+}(aq)+2e^-, \qquad (96)$$

Right half-cell:

$$2e^-+Cu^{2+}(aq) \rightarrow Cu(s), \qquad (97)$$

Net reaction:

$$Zn(s)+Cu^{2+}(aq) \rightarrow Zn^{2+}(aq)+Cu(s). \qquad (98)$$

Thus, copper ion is reduced to the metal at the cathode (by convention, the right half-cell), while zinc metal is oxidized to the ion at the anode. To prevent the mixing of the copper and zinc sulfate solutions, which would lead to equilibrium and no driving force for the

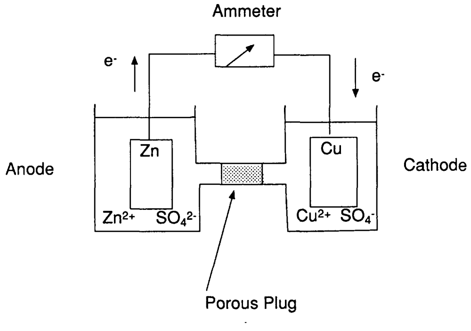

FIG. 15. Schematic diagram of an electrochemical or galvanic cell. This specific cell is known as the Daniell cell.

reaction, a porous barrier that permits electrical contact but not mixing of solutions is interposed between the two half-cells. If the voltage across this cell is measured at 25 °C, it is found to depend on the concentrations of both copper and zinc ions according to the empirical expression

$$\Delta E(\mathrm{V}) = 1.100 - 0.0128 \ln([Zn^{2+}]/[Cu^{2+}]). \qquad (99)$$

However, the measured voltage obviously depends on the combinaton of half-cells, either of which could be combined with some half-cell other than the one used in this example. To establish a reference standard, the potential of the half-cell described by the reaction

$$2\mathrm{H}^+(\mathrm{aq},\ 1m) + 2e^- \rightarrow \mathrm{H}_2(\mathrm{g},\ 1\ \mathrm{atm}) \qquad (100)$$

is *defined* to be zero volts at 25 °C. This voltage scale is entirely arbitrary, but since only relative voltages are important, the absolute voltage of the hydrogen electrode is not important. Relative to this cell, the half-cell potentials (E^0) of the Daniell cell are found to be 0.763 V for the Zn oxidation and 0.337 V for the Cu reduction, when each solution has a concentration of 1 molal (the standard state). The standard half-cell potentials for a large number of reactions have been determined and are tabulated in many reference works. By convention, the cell potential is defined as $\Delta E =$ (cathode potential) − (anode potential), where in each case the reaction is written as a reduction. Thus, in the present example,

$$\mathrm{Zn}^{2+}(\mathrm{aq}) + 2e^- \rightarrow \mathrm{Zn}(\mathrm{s}) \quad E^0 = -0.763\ \mathrm{V}\ (\mathrm{Anode}) \qquad (101)$$

$$\begin{array}{ll} \mathrm{Cu}^{2+}(\mathrm{aq}) + 2e^- \rightarrow \mathrm{Cu}(\mathrm{s}) & E^0 = 0.337\ \mathrm{V}\ (\mathrm{Cathode}) \\ \hline & \Delta E^0 = 1.100\ \mathrm{V}. \end{array} \qquad (102)$$

If the cell voltage is positive, the reaction takes place spontaneously, and electrons flow in an external circuit from the anode to the cathode.

The general expression for the cell potential can be derived from the thermodynamic relation between the Gibbs free energy ΔG and the reversible work done by the cell, dw_{rev}:

$$\Delta G = -dw_{\mathrm{rev}}, \qquad (103)$$

together with

$$\Delta G = \Delta G^0 + RT \ln Q. \qquad (103')$$

In this expression, R is the gas constant (in units of energy/K), T is the absolute temperature, and the quantity Q is given by

$$Q = [C]^c [D]^d / [A]^a [B]^b \qquad (104)$$

for a hypothetical reaction

$$a\mathrm{A} + b\mathrm{B} \rightleftharpoons c\mathrm{C} + d\mathrm{D}. \qquad (105)$$

The quantities in brackets are thermodynamic activities, which become equal to concentrations in infinitely dilute solutions. The reversible work done by the electrochemical cell is related to the cell potential ΔE according to

$$dw_{\mathrm{rev}} = nF\ \Delta E, \qquad (106)$$

where n is the number of electrons transferred in the net cell reaction and F is the charge in coulombs on one mole of electrons, 96 496 [cf. Eq. (124)]. Thus,

$$-nF\ \Delta E = \Delta G^0 + RT \ln Q. \qquad (107)$$

If all reagents are in their standard states, the last term disappears, and $\Delta G^0 = -nF\ \Delta E^0$. Finally,

$$\Delta E = \Delta E^0 - (RT/nF) \ln Q. \qquad (108)$$

This expression, the Nernst equation, is one of the two most basic equations in electrochemistry. At 25 °C, the constant term RT/F has the value 0.025 69 V, thus accounting for Eq. (99). The determination of a cell potential may serve in some cases as a method for determining the equilibrium constant for a reaction.

4.1.1 Batteries. Although many possible half-cell reactions can be combined to give a net reaction with a positive potential, there are obvious restrictions that eliminate most of these from use as practical methods of generating or storing electrical energy (see ENERGY STORAGE). Usually, but not always, the most important requirement is that the cell process be reversible, so that the battery serves as a storage device for electrical energy, and can be easily recharged from an external power source. Mobile electrical energy applications, such as in electric automobiles, place a high priority on the available energy per unit weight. Other factors are economic—the widespread use of platinum electrodes or chemical reactions of rare metals in batteries is hardly practicable.

The lead–sulfuric acid storage battery is very widely used. It has almost complete conversion of chemical to electrical energy and vice versa. The internal resistance is low, enabling it to produce large currents for short periods, and the construction is relatively simple. The chemical reactions of this cell are:

$$PbO_2(s)+HSO_4^-(aq)+3H^+(aq)+2e^- \rightarrow PbSO_4(s)+2H_2O \quad \text{(Cathode)}, \qquad (109)$$

$$Pb(s)+HSO_4^-(aq) \rightarrow PbSO_4(s)+2e^-+H^+(aq) \quad \text{(Anode)}, \qquad (110)$$

$$Pb(s)+PbO_2(s)+2HSO_4^-(aq)+2H^+(aq) \rightarrow 2PbSO_4(s)+2H_2O \quad \text{(Net reaction)}. \qquad (111)$$

The cathode of this cell is made of a lead grid with interstices filled with PbO_2. The anode is a similar grid, with interstices filled with spongy lead to provide a larger surface area. The electrodes are immersed in aqueous sulfuric acid, about 35% H_2SO_4 by weight. The cell potential of this battery, when fully charged, is $\sim$2.0 V, and in typical automotive use, six cells are connected in series to give a total voltage of 12 V. Upon discharge, sulfuric acid is converted to solid lead sulfate and water, decreasing the electrolyte density, which can be monitored as an indication of the state of charge. Typical storage capacities are 90–200 A h. The major disadvantage of the lead storage batttery is its relatively low energy density, about 40 W h/kg.

Another rechargeable battery that has widespread use in small calculators and hand tools depends upon the reactions

$$Cd(s)+2OH^- \rightarrow Cd(OH)_2(s)+2e^- \text{(Anode)}, \qquad (112)$$

$$NiO_2(s)+2H_2O+2e^- \rightarrow Ni(OH)_2(s)+2OH^- \quad \text{(Cathode)}, \qquad (113)$$

$$Cd(s)+NiO_2(s)+2H_2O \rightarrow Cd(OH)_2(s)+Ni(OH)_2(s) \quad \text{(Net reaction)}. \qquad (114)$$

Since the reactants are solids, their concentration does not change with the state of charge, and the cell potential is a constant 1.30 V. The energy density is comparable to that of the lead storage battery, about 30 W h/kg.

The mercury cell is another battery that maintains a constant voltage. The cell reactions, producing a voltage of 1.34 V, are

$$Zn(Hg)+2OH^- \rightarrow ZnO(s)+H_2O+2e^- \quad \text{(Anode)}, \qquad (115)$$

$$HgO(s)+H_2O+2e^- \rightarrow Hg(l)+2OH^- \quad \text{(Cathode)}, \qquad (116)$$

$$Zn(Hg)+HgO(s) \rightarrow ZnO(s)+Hg(l) \quad \text{(Net reaction)}. \qquad (117)$$

The anode consists of a zinc–mercury amalgam. At the cathode, solid mercuric oxide is reduced. The electrolyte is a paste of zinc hydroxide in a strongly alkaline KOH solution. This battery is not rechargeable.

The two batteries just described are "dry cells," which, unlike the lead storage battery, contain no liquid electrolyte. A more ubiquitous dry cell is the LeClanché cell, with a voltage of 1.5 V, provided by the cell reactions

$$Zn(s) \rightarrow Zn^{2+}+2e^- \quad \text{(Anode)}, \qquad (118)$$

$$2MnO_2(s)+2NH_4^++2e^- \rightarrow Mn_2O_3(s)+2NH_3+H_2O \quad \text{(Cathode)}, \qquad (119)$$

$$Zn(s)+2MnO_2(s)+2NH_4^+ \rightarrow Mn_2O_3(s)+Zn^{2+}+2NH_3+H_2O \quad \text{(Net reaction)}. \qquad (120)$$

The anode is a zinc cylinder or cup that serves as a container for the electrolyte, a moist paste of NH_4Cl and $ZnCl_2$ in an inert filler, essentially an aqueous solution in the form of a gel. The cathode is an inert carbon rod in the center of the cylinder, surrounded by a paste of MnO_2 and powdered graphite to provide electrical conductivity. One disadvantage of this cell is that the ammonium ion is a Brönsted acid, and as such it attacks the zinc casing slowly and ultimately may cause leakage.

Recently, interest in electrically powered vehicles has been revived because of environmental concerns: urban air pollution, and the "greenhouse effect" resulting from the combustion of hydrocarbons. As a result, new types of rechargeable batteries are being investigated, with a goal towards achieving higher energy densities than those obtainable with the lead–acid storage battery. For example, the sodium–sulfur battery with a net reaction of $2Na(l)+S(l) \rightarrow Na_2S(s)$ consists of an anode of liquid sodium separated from the cathode of liquid sulfur by a porous β-alumina membrane, acting as a solid electrolyte. This battery generates a potential of 1.8–2.1 V, and has an energy density of 140 W h/kg, considerably better than that of the lead battery. However, it has the significant drawback of requiring an operating temperature of 300–400 °C. Further research in this area will surely lead to new developments.

Another type of battery, not rechargeable and requiring a constant supply of reactants, is the fuel cell. Essentially, this utilizes a combustion (oxidation) reaction as its source of energy, but unlike an electric generator driven by a heat engine, the reaction generates electricity directly. A major advantage of this direct production of electricity over a heat engine-driven generator lies in the relative efficiency. The thermodynamic limit on a heat engine imposed by the second law of thermodynamics leads to a theoretical efficiency of ~40% for engines operating at achievable temperatures, with real-life efficiencies of about 25%. But the fuel cell is *not* a heat engine, and efficiencies of 60%–80% are obtained.

The most highly developed fuel cell, which has been widely used in space vehicles, is the hydrogen–oxygen cell, using the reactions

$$2H_2 \rightarrow 4H^+ + 4e^- \quad \text{(Anode)}, \tag{121}$$

$$4H^+ + O_2 + 4e^- \rightarrow 2H_2O \quad \text{(Cathode)}, \tag{122}$$

$$2H_2 + O_2 \rightarrow 2H_2O \quad \text{(Net reaction)}. \tag{123}$$

The electrodes of this cell include catalytic substances such as finely divided Pt or Ag, and are separated by an ion-exchange membrane such that protons are the current carrier. Fuels other than hydrogen (such as methanol, hydrocarbons, ammonia, and hydrazine) have been used. The oxygen (in terrestrial applications) can simply be obtained from the atmosphere (Bockris and Srinivasan, 1969).

4.2 Electrolysis

The chemical action of the cell in Fig. 15 can be reversed if the ammeter is replaced by an external voltage source with its positive pole connected to the copper electrode. As the external voltage is increased to 1.100 V, the cell current decreases to zero, and a further voltage increase will lead to a reversal in the flow of current. As a result, the direction of the cell reaction will also be reversed and the copper electrode will dissolve, while zinc plates out on the zinc electrode. This is an example of electrolysis, further applications of which are discussed below. In an electrolysis reaction, the relation between the current, the time during which it flows, and the extent of reaction serves to provide a macroscopic experimental determination of the charge on the electron, according to Faraday's laws (1834), which can be written in the form:

$$F = it/n(m/W), \tag{124}$$

where i is the current in amperes, t is the time during which it flows in seconds, m is the weight of material deposited or reacted, and W is its molecular weight. The faraday F is the charge in coulombs on one mole of electrons.

4.2.1 Electroplating. As discussed above in connection with the Cu–Zn or Daniell cell, application of an external voltage greater than the cell potential reverses the spontaneous cell reaction and can lead to oxidation of a metal to its ion at the anode, with migration of the cation through the electrolyte to the cathode, where the ion is reduced and the metal in its elemental form is deposited. A typical example is silver plating, in which the anode is metallic silver (anode reaction, $Ag \rightarrow Ag^+ + e^-$) and the cathode is the object to be plated (cathode reaction, $Ag^+ + e^- \rightarrow Ag$). The electrolyte is a solution of a silver salt, usually silver cyanide, mixed with sodium or potassium cyanide. Similar methods are used for many other metals, from antimony to zinc (Mantell, 1960).

Although given a different name, "electrorefining," the production of pure metals by electrolysis, is another form of electroplating. Copper refining provides a good example. The invention of the dynamo in the latter part of the 19th century created an increasing demand for copper wire, which must be quite pure to have the necessary ductility and electrical conductivity. There is a somewhat symbiotic relationship between the growth in the electric power industry and the electrochemical refining of copper, which uses very large quantities of electric energy. The anodes in this electrorefining process are crude copper, actually 99.0%–99.5% pure copper! A large number of these anodes are interleaved with the cathodes of pure copper (less than 1 mm thick) in an electrolyte of copper sulfate containing other additives. The electrical energy demands are impressive, about 200 kW h/ton of pure copper produced. The raw copper contains, among other impurities, significant amounts of gold and silver which are unoxidized during the electrochemical process and can be regained from the material settling to the bottom of the electrolysis cells. The final stages of purification of these noble metals again rely upon electrorefining.

Electrorefining is also used in the production of nickel, cobalt, lead, antimony, bismuth, indium, mercury, and tin.

"Electrowinning" is a similar process for obtaining pure metals from their ores. The ore is initially leached with a solution that either dissolves or forms a soluble complex with the metal. The resulting solution is purified and modified before it is used as the electrolyte in an electrochemical process that plates out the desired metal. In some applications, the spent electrolyte can be recycled into the leaching step.

4.2.2 Electrolytic Production of Hydrogen and Deuterium. There is a considerable interest in the use of hydrogen as a medium for both storage and transport of energy (Bockris and Nagy, 1974). Over very long distances, the cost per unit of energy is less for the pipeline transport of hydrogen than for electrical transmission by overhead cables. This proposed "hydrogen economy" is usually dependent on the production of hydrogen by the electrolysis of water, using electric power from a nuclear power plant. The advantage of this method over the usual production by chemical reduction of water is that the latter method uses a nonrenewable energy source, such as methane. Aside from these considerations, the only advantage of electrolytic production is in regions where electricity is extremely inexpensive, or in applications where very high purity hydrogen is needed; for example, in the hydrogenation of oils to solid fats, or in the catalytic production of ammonia. The by-product oxygen may also make electrolysis economically feasible.

The electrolyte in this process is usually an alkali hydroxide. Nevertheless, this does not imply that the alkali metal is produced at the cathode, because the potential required to reduce the alkali metal ion is greater than that required to reduce protons or water itself to hydrogen. The relative potentials are 2.714 V for the reduction of Na^+ to Na, and only 0.828 V for the reduction of water to hydrogen and hydroxide ion. The cell reactions are

$$2(2H_2O + 2e^- \rightarrow H_2 + 2OH^-) \quad \text{(Cathode,} \quad -0.828\ \text{V)}, \tag{125}$$

$$2H_2O \rightarrow O_2 + 4e^- + 4H^+ \quad \text{(Anode,} \quad -1.229\ \text{V)}, \tag{126}$$

$$4H^+ + 4OH^- \rightarrow 4H_2O, \tag{127}$$

$$2H_2O \rightarrow 2H_2 + O_2 \quad \text{(Net reaction)}. \tag{128}$$

Thus, the theoretical potential needed to carry out the electrolysis is 0.427 V, but usually an "overvoltage" is required because the electrode processes are not truly reversible. Metal electrodes of steel or nickel are used, separated by a diaphragm of asbestos or perforated metal. It is of some practical interest to note that deuterium, the heavy hydrogen isotope of mass 2, is enriched in the residual water remaining in the electrolysis cell after most of the water has been decomposed. This was noted by Washburn and Urey shortly after the discovery of the deuterium isotope (Urey, Brickwedde, and Murphy, 1932). Soon thereafter, Lewis and MacDonald produced concentrated heavy water (D_2O) by this process. A plant producing heavy water in kilogram amounts operated in Norway before the beginning of World War II. The demand for heavy water as a neutron moderator for nuclear reactors used in the Manhattan Project during World War II led to an investigation of the electrolytic method of isotope separation (Murphy, 1955). A plant in Trail, British Columbia, that produced large amounts of hydrogen for the catalytic synthesis of ammonia was used for this purpose. Actually, the initial enrichment in deuterium to 2%–3% was carried out by means of a chemical exchange, and this was followed by electrolysis to extend the enrichment to 99.8% D. This plant produced about 500 kg of heavy water per month for a period of 2.5 yr, and a total of slightly less than ten tons was produced by the end of World War II. At the present time, electrolysis is generally used only for the final stages of any deuterium enrichment process, because of the high cost of electricity.

4.2.3 Electrolysis in Molten Salts. As pointed out above, many metals cannot be produced from aqueous solutions of their salts, because their reduction potentials are higher (i.e., more negative) than those of hydrogen, i.e., the metals are stronger reducing agents. However, this problem can be overcome by electrolysis in a nonaqueous solvent, or more frequently in a molten salt. Ionic solids are not good electrical conductors because the ions are fixed in a crystal lattice, but in a molten salt they are relatively free to move to the electrode of opposite sign. In fact, the conductivities are considerably higher than those of the same salts in solution.

This property is utilized in the production of metallic sodium and gaseous chlorine from sodium chloride. Molten NaCl at a temperature of about 600 °C is contained in an iron vessel lined with refractory brick. A graphite anode in the center of this cell oxidizes Cl^- to Cl_2, which is collected in a funnel or dome above the anode. Steel cathodes enter through the sides of the vessel, and molten sodium collects in an inverted trough above the molten electrolyte. To prevent the violent recombination of sodium and chlorine, the anode and cathode are separated by an iron screen. The heat required to keep the salt molten is provided by the current flow through the cell.

Aluminum is another metal produced on an even larger scale by electrolysis. This metal is easily oxidized and consequently does not occur in nature as the metal; a major ore is bauxite, hydrated Al_2O_3. This ore is first purified to alumina, with the removal of oxides of iron, silicon, and titanium. The pure alumina is dissolved in a bath of cryolite (Na_3AlF_6), which has a melting point around 1000 °C, considerably lower than that of alumina itself ($\sim$2000 °C). Both the cathode and anode of the electrolysis cell are carbon; however, the anode is gradually consumed by the reaction $C(s)+2O^{2-}\rightarrow CO_2(g)+2e^-$, while Al^{+3} is reduced to the metal at the cathode. The reaction of the anode provides some of the heat required to maintain the high cell temperature. The aluminum produced in this way usually has a purity of only 99.5%–99.8%, and further electrolytic refining is used, with a molten electrolyte consisting of a mixture of fluorides of aluminum, sodium, barium, and calcium in various proportions.

4.3 Corrosion of Metals

The practical aspects of electrochemistry described above have all been applications with desirable economic consequences. Another electrochemical phenomenon, corrosion, has very undesirable economic consequences, leading to losses of billions of dollars per year in the destruction of metal products. The effects of corrosion may be relatively superficial, such as tarnishing, or extremely profound, leading to structural weakening and ultimate failure. Corrosion is the oxidation (in the general sense of the word) of a metal; the oxidizing agent may be a gas (oxygen or air pollutants such as nitrogen and sulfur oxides), water, or an aqueous solution such as seawater. In rare cases, corrosion is actually desirable; as pointed out in Sec. 3.2.1, aluminum forms an oxide film that prevents further reaction. Corrosion is not always an electrochemical process: The example above of aluminum oxide formation, and the formation of other films on metals in contact with a reactive gas or liquid, are more properly described as surface reactions (Sec. 3.2.1).

However, corrosion by water or aqueous solutions definitely is an electrochemical process. For example, in salt water containing oxygen, iron is oxidized according to the cell reactions

$$Fe\rightarrow Fe^{2+}+2e^- \quad \text{(Anode)}, \qquad (129)$$

$$\tfrac{1}{2}O_2+H_2O+2e^-\rightarrow 2OH^- \quad \text{(Cathode)}. \qquad (130)$$

Iron forms a ferrous hydroxide, which reacts further with oxygen to form hydrated ferric oxide. It has been found that the areas where oxide forms tend to act as an anode, while the bare exposed metal is the cathode. Even differences in the metal surface, such as local mechanical stresses, temperature gradients, impurity inclusions, etc., may serve to establish a potential difference leading to electrochemical attack.

The possibility of electrochemical reaction is exacerbated if two dissimilar metals are in electrical contact and are immersed in an electrolyte solution. In fact, the example of the Daniell cell in Sec. 3.1 illustrates this principle. Copper ion is a stronger oxidizing agent than is zinc ion, so the spontaneous reaction will lead to attack on the surface of the zinc electrode. The same principle can be used to protect steel, by connecting it electrically to a more easily oxidized metal, such as magnesium or zinc, which acts as a "sacrificial anode," while the less active steel (i.e., iron) acts as the cathode and is not attacked. This principle is widely used in maritime applications. "Galvanized" steel, made by dipping steel in molten zinc, is protected in the same way. Electroplating may also be used to form the zinc coating.

ACKNOWLEDGMENTS

This research was carried out at Brookhaven National Laboratory under Contract No. DE-AC02-76CH00016 with the U.S. Department of Energy and supported by the Division of Chemical Sciences, Office of Basic Energy Science.

GLOSSARY

***Ab Initio* Method:** Quantum chemical calculations of molecular properties, without using empirical methods.

Activation Energy: An indication of the energy barrier to reaction, which can be determined from the temperature dependence of the rate constant.

Adsorption Isotherm: The relation between the pressure of a gas and the surface coverage of a solid on which it is adsorbed.

Bimolecular Reaction: A reaction involving two molecules interacting during the reaction process.

Brönsted Acid: A compound that readily loses a proton.

Brönsted Base: A compound that readily accepts a proton.

Catalyst: A substance that increases the rate of a chemical reaction, without itself being consumed in the reaction.

Chemical Shift: The change in the energy levels of a nucleus with a magnetic moment in a magnetic field due to the screening effect of orbital electrons. As such, it is sensitive to the chemical environment of the nucleus.

ESCA: Acronym for electron spectroscopy for chemical analysis; see "XPS" below.

EXAFS: Acronym for extended x-ray absorption fine structure. A technique by which the structure of the x-ray absorption spectrum near the absorption edge can be used to determine interatomic distances.

Gibbs Free Energy: A thermodynamic property that indicates the tendency for a chemical reaction to take place.

Isomerization: A reaction that leads to atomic rearrangement within a molecule.

Ligand: An atom or group of atoms that are coordinatively bonded to a central metal atom.

Metathesis Reaction: A chemical reaction involving an atom or radical transfer, of the form: $A + BC \rightarrow AB + C$.

Oxidation Number: An indication of the number of valence electrons in an atom or molecule. In a monatomic ion, it is numerically equal to the ionic charge.

Reaction Rate Constant or Coefficient: A fundamental indicator of chemical reactivity which, combined with concentrations of reactants, allows the rate of reaction to be calculated.

Reaction Mechanism: The combination of elementary reactions that leads to the observed overall reaction.

Redox Reaction: A reaction in which the oxidation numbers of the reactants change.

Unimolecular Reaction: A reaction involving a single, isolated molecule in the rate-determining step.

XPS: Acronym for x-ray photoelectron spectroscopy, also known as ESCA . A method for determining binding energies of electrons (usually core electrons) by measuring the kinetic energy of electrons ejected upon excitation by x-ray irradiation.

INTRODUCTION

Chemiluminescence (CL) refers to emission from excited molecules generated as products of a chemical reaction. If this reaction is derived from biological organisms such as bacteria, fungi, and insects, the luminescence is called bioluminescence. Although CL phenomena were reported more than a half century ago (Albrecht, 1928), only in the last ten years have there been extensive basic studies as well as practical applications. The dynamic field of CL is experiencing considerable growth due to the advent of new instrumentation, sensitive detection methods, and efficient automation technology. The use of CL is also receiving increased interest due to its simplicity, sensitivity, and dynamic range. This article provides an overview of the basic principles of CL, the instrumentation commonly used for detection, and several applications of this unique molecular process in a wide variety of fields ranging from environmental monitoring to protein analysis, food product screening, immunological assays, and DNA sequencing.

1. BASIC PHOTOPHYSICAL AND PHOTOCHEMICAL PRINCIPLES

1.1 Background

1.1.1 Electronic Transitions and Luminophores. Luminescence is an emission process that involves transitions between electronic states of an atom or a molecule. The technique deals with optical detection and spectral analysis of light emitted by a substance, often referred to as a luminophore, which undergoes a radiative transition from an excited electronic state to a lower electronic state. Most organic molecules contain an even number of electrons. In the ground state, the electrons fill the various atomic orbitals with the lowest energies in pairs. According to the Pauli exclusion principle, two electrons in one given orbital must have spins in opposite directions and the total spin is equal to 0. For this reason, the ground state has no net electron spin. Such a state is called a singlet state. Excitation of a molecule usually results in the promotion of one electron from the highest occupied orbital to a previously unoccupied orbital having a higher energy. Figure 1 shows a diagram, known as the Jablonskii diagram, illustrating the photophysical processes that ensue from excitation of a molecule into a singlet (spin equal to 0) excited state S_n. At equilibrium, molecules have the greatest probability of having the thermal energy of the lowest vibrational and rotational levels of the ground state S_0 in accordance with the Boltzmann distribution. In condensed media, a molecule in the S_n state deactivates rapidly to lower vibronic levels of S_n within 10^{-13} to 10^{-11} s via vibrational relaxation (VR) processes and acquires the thermal energy distribution of the lowest vibrational levels of S_n. This VR process is faster than electronic transitions. The VR excess energy is released as thermal energy to the surrounding medium. From the S_n state, the molecule deactivates rapidly to the isoenergetic vibrational level of a lower electronic state such as S_{n-1} via a process known as internal conversion (IC). By a succession of VR and IC processes, the molecule deactivates rapidly to the lowest excited singlet state S_1. From S_1 the molecule may

1. further deactivate to the ground state S_0 in a radiationless fashion (i.e., no photon emitted) via IC and VR processes, or
2. emit a photon.

This emission process is known as fluorescence.

From S_1, the molecule may also undergo a transition to some vibrational level of one of the lower triplet states (states with spin equal to 1) via a mechanism known as intersystem crossing (ISC). The molecule undergoes deactivation to the lowest excited triplet state T_1 via VR and IC processes. From T_1, the molecule may return to the ground state S_0 in a radiationless fashion via an ISC process or by emitting a photon. This latter process is known as phosphorescence. Both fluorescence and phosphorescence processes are referred to as luminescence (Harmony, 1972; Vo-Dinh, 1984).

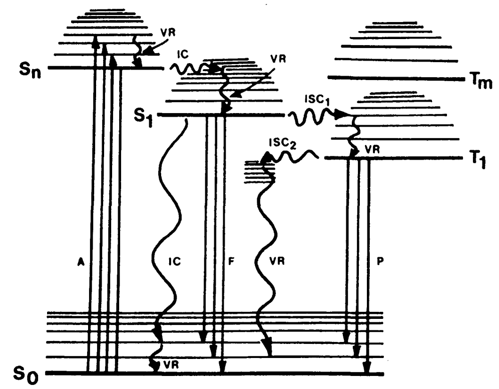

FIG. 1. Jablonskii diagram for molecular photophysical processes. S_0, singlet ground state; S_1, first excited singlet state; S_n, *n*th excited singlet state; T_1, first excited triplet state; T_m, *m*th excited triplet state; *A*, absorption; *IC*, internal conversion; *F*, fluorescence; *VR*, vibrational relaxation; *P*, phosphorescence; *ISC*, intersystem crossing.

The nature of the orbitals involved in an electronic transition is an important factor in determining the luminescent properties of the molecule. Organic compounds that are known to be strongly luminescing are molecules with extensive π-electron systems. It is noteworthy that, in the gas phase, fluorescence may be observed from higher vibrational levels of the excited state. These emission mechanisms, known as single-vibronic-level (SVL) luminescence processes, do not occur in solution.

1.1.2 Chemiluminescence. Chemiluminescence emission is usually a fluorescence process (from the excited singlet state) rather than a phosphorescence process (from an excited triplet state). This is because the triplet state has a relatively long lifetime and is subject to radiationless deactivation by other molecules present such as oxygen. Chemiluminescence in solution generally involves an oxidative reaction. Molecular oxygen and hydrogen peroxide are most often involved.

The production of chemiluminescence usually requires three conditions:

1. adequate chemical energy to populate an excited state of a molecule,
2. an efficient chemical reaction with high yield, and
3. deactivation of the excited state via radiative CL emission.

In some cases the excited molecule does not emit radiation but transfers the energy to another molecule that subsequently emits CL. The efficiency of CL emission may be determined by the number of photons produced per molecule undergoing a chemical reaction, defined as follows:

$$M \xrightarrow{\Omega_E \Omega_C} M^*, \tag{1}$$

$$M^* \xrightarrow{\Omega_L} M + h\nu(\text{CL photon}), \tag{2}$$

$$\Omega_{\text{CL}} = \Omega_E \times \Omega_C \times \Omega_L, \tag{3}$$

where M denotes a molecule in the ground state, and M^*, a molecule in the excited state.

The excitation yield Ω_E, which denotes the proportion of molecules promoted to the excited state, depends on the chemical reaction mechanism. A high CL yield Ω_{CL} depends on a high chemical yield Ω_C and an efficient luminescence yield Ω_L. The values of Ω_{CL} vary from 10^{-8} up to 0.88, the latter for the *in vitro* firefly reaction, which has one of the most efficient CL yields (Seliger and McElroy, 1960).

1.2 Chemiluminescent Systems in the Gas Phase

When a reagent gas is mixed with another gas in a reaction cell, and if the reaction is sufficiently exothermic, one or more of the products may be promoted to an excited electronic state, which can subsequently decay to the ground state with emission of CL. By use of different reagent gases, a wide variety of CL reactions may be induced. Chemiluminescence reagents are not limited to stable molecules. Highly exothermic reactions of atoms, radicals, ions, and electronically excited species can be produced in gas discharges and detected by photometric detectors.

1.2.1 Hydrocarbon Reactions With Active Nitrogen. An active-nitrogen detector has been developed by Sutton *et al.* for monitoring hydrocarbons (Sutton *et al.*, 1979). High-energy electrical discharges (e.g., electrical or microwave discharges) can be used to produce a mixture of nitrogen atoms and highly excited nitrogen molecules $N_2(A\,^3\Sigma_u^+)$. These excited-state nitrogen molecules (active nitrogen) can induce collisional energy transfer to analyte molecules present, providing a pathway to electronic and vibrational excitation of the analytes. For example, active nitrogen reacts with hydrocarbons to produce an excited state of the cyanogen radical (CN*), which emits intense CL emission corresponding to the following transition:

$$B\,^2\Sigma^+ \rightarrow X\,^2\Sigma^+. \tag{4}$$

Since carbon compounds are found to react with active nitrogen to produce excited states of cyanogen radicals, the active-nitrogen detector can be used as a universal monitor for hydrocarbons. Possible reactions capable of producing excited-state cyanogen are

$$CH_2 + N \rightarrow CN^* + 2H, \tag{5}$$

$$CH + N \rightarrow CN^* + H. \tag{6}$$

Figure 2 shows the CL spectrum of CN* obtained when hydrocarbons were added to the active-nitrogen monitor (Sutton *et al.*, 1979). The most intense band of this emission is the violet-blue emission at approximately 385 nm. This system is often used as the universal response to hydrocarbons, and is based on the fact that virtually all carbon compounds react with active nitrogen to produce an excited state of cyanogen radicals. In general, CL emission from saturated hydrocarbons is much less intense than that from the corresponding alkene reactions. Addition of HCl has been found to enhance catalytically the reactions of saturated hydrocarbons. For example, the detection limit of methane was 4 and 200 ng with and without HCI catalysis, respectively (Sutton *et al.*, 1979; Birks, 1989).

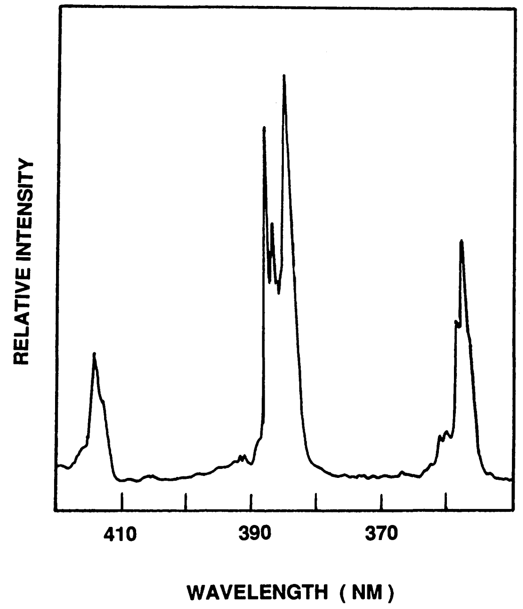

FIG. 2. Chemiluminescence spectrum of CN* for hydrocarbons added to active nitrogen 1979 (from Sutton *et al.*, 1979).

1.2.2 Chemiluminescent Reactions With Ozone.

Ozone (O_3) is one of the most widely used CL reagents since most gas-phase reactions with ozone have been found to be chemiluminescent. The basis of ozone CL reactions is attributed to the weak O–O bond (24.9 kcal/mol), which is broken to form the strong O=O bond (119 kcal/mol) in molecular oxygen and strong C=O bonds (172 kcal/mol) in reactions with many organic compounds (Birks, 1989).

Ozone reacts rapidly with olefins, producing CL emission from various species. Figure 3 shows the CL emission spectrum for the reaction of O_3 (2% in O_2) with ethylene (Finlayson *et al.*, 1974).

Various nitrogen-containing compounds, oxygenated compounds, and reduced sulfur compounds can be detected by use of ozone CL reactions. The basic reaction involved in the detection of nitrogen and oxygenated compounds is

$$NO + O_3 \rightarrow NO_2^* + O_2. \tag{7}$$

Sulfur compounds and their interactions with ozone have also been extensively investigated. Reduced sulfur compounds usually become oxidized to produce electronically excited SO_2^* ($^3B_1$), which exhibits CL emission between 300 and 400 nm (Birks, 1989). Figure 4 shows the CL spectrum of SO_2^* ($^3B_1$) produced by the reaction of O_3 with CH_3SH (Glinski *et al.*, 1981).

The gas-phase reaction between ozone and simple sulfides, e.g., H_2S, CH_3SH, and CH_3SCH_3, has been found to produce strong CL emission under flow-tube conditions (Pitts *et al.*, 1972). The results indicated that SO_2^* was the chemiluminescent species produced by the reaction

$$SO + O_3 \rightarrow SO_2^* + O_2, \tag{8}$$

where SO is produced in a previous step. Glinski *et al.* (1981) reported that, at low pressures, the excited singlet state is quenched to the triplet manifold to yield phosphorescence.

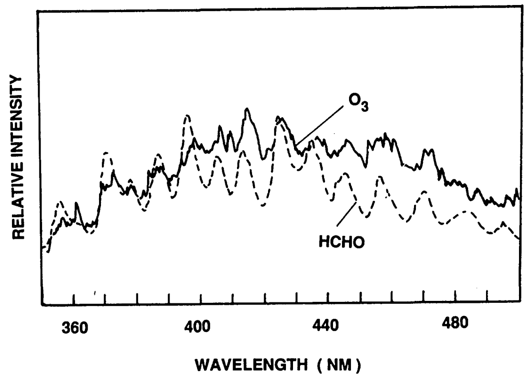

FIG. 3. Chemiluminescence spectra for the reaction of O_3 (2% in O_2) with ethylene (from Finlayson *et al.*, 1974).

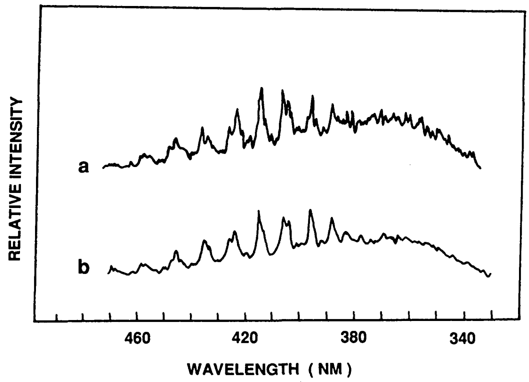

FIG. 4. Chemiluminescence of SO_2 from the reaction of O_3 with CH_3SH: *a*, 20 mTorr O_3; 7 mTorr CH_3SH; *b*, 30 mTorr O_3, 15 mTorr CH_3SH; with 520 mTorr of He in both cases (from Glinski *et al.*, 1981).

1.2.3 Other Gas-Phase CL Reactions. Fluorine molecules, F_2, react with reduced sulfur compounds to produce several chemiluminescent species, providing an important detection method highly selective to organosulfur compounds (Mishalanie and Birks, 1986). When fluorine atoms are used in place of fluorine molecules, the reactions occur at a much faster rate, and the chemical processes are similar to those occurring with active nitrogen. Fluorine atoms can be produced via various methods such as microwave discharges of F_2, CF_4, and SF_6 (Birks, 1989). Other compounds that have been used as gas-phase CL reagents include sodium atoms (Yamada *et al.*, 1982) and chlorine dioxide (Spurlin and Yeung, 1982).

1.3 Chemiluminescent Systems in Liquid Solution

1.3.1 Luminol. Luminol or 5-amino-2,3-dihydrophthalazine-1,4-dione is one of the most investigated CL systems. The oxidation process of luminol has been extensively investigated although the mechanisms have not yet been completely elucidated. In aqueous alkaline solution, luminol is oxidized to produce an excited-state species, viz. 3-aminophthalate, which exhibits CL emission centered at approximately 425 nm (Seliger and Lee, 1972). This reaction is depicted in Fig. 5. Various oxidants (e.g., permanganate, hypochlorite, iodine, and perhaps the most common oxidant, hydrogen peroxide) can be used. When peroxide is used as the oxidant, a catalyst (e.g., peroxidase, hemin, ferricyanide, and transition-metal ions, such as Co^{2+}, Cu^{2+}, Fe^{3+}, etc.) is required. The CL luminol reaction may be summarized as follows:

$$\text{Luminol} + H_2O_2 + \text{Catalyst} + OH^- \rightarrow \text{Product} + \text{Light}. \qquad (9)$$

The above equation indicates that the CL emission depends upon the concentrations of luminol, H_2O_2, and the catalyst. Since the measurement of the CL signal intensity can be used to quantitate any of these species, the luminol CL method can be used to determine the following species:

1. luminol or species labeled with luminol,
2. peroxide or species that can be converted to peroxide, or
3. catalysts (e.g., Cu^{2+}, Co^{2+}, Ni^{2+}, Fe^{3+}, etc.) or species labeled with catalysts.

The wavelength maximum of the luminol CL emission changes with the solvent used. The CL quantum yield has been found to vary also with solvent polarity and, in water, with *p*H, with the maximum CL intensity occurring between *p*H values 10 and 11 (Seliger and Lee, 1972). Although the CL quantum yield of luminol, which is only about 1%, is low in comparison to typical luminescence quantum yields of strong fluorophors, it is one of the more efficient nonenzymatically coupled CL systems. To date, extensive studies have been devoted to investigation of properties of luminol and many of its analogs (Gundermann, 1968; Roswell and White, 1978). The reaction rates of some intermediates of the luminol system have also been investigated by flash photolysis spectroscopy (Meneryi and Lind, 1980). Other luminol derivatives that are commonly used as CL systems include isoluminol and aminobutylethylisoluminol (ABEI). Coupling of these compounds to an analyte is usually performed via the primary amine group. Although the quantum efficiency of luminol is greater than that of isoluminol, substitution at the primary amine group on luminol often decreases the quantum efficiency. On the other hand, substitution at the primary amine group on isoluminol increases the quantum efficiency.

1.3.2 Peroxyoxalates. Some commonly used CL reactions are peroxyoxalate reactions which involve the hydrogen peroxide oxidations of aryl oxalate esters. The quantum efficiencies of these reactions are very high (usually 20%–30%), with the production of a

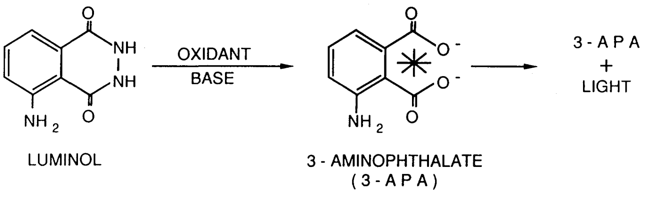

FIG. 5. Chemiluminescence reaction for luminol (asterisk indicates luminescent excited state).

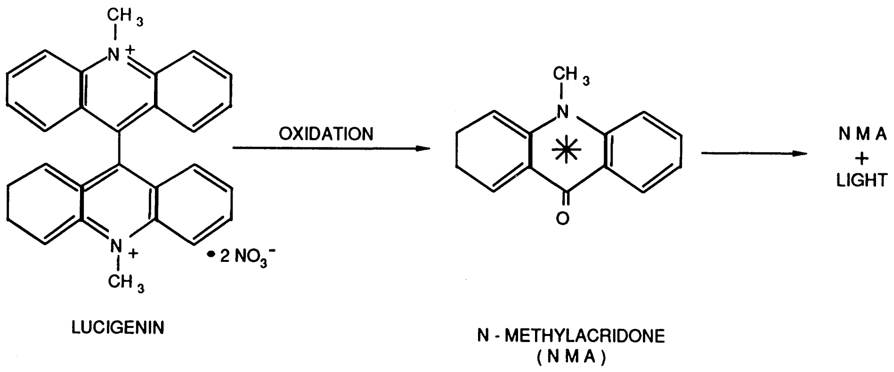

FIG. 6. Chemiluminescence reaction for lucigenin (asterisk indicates luminescent excited state).

high-energy intermediate. This intermediate and a fluorophore (fluorescent product) then form a charge-transfer complex which dissociates to produce an excited-state fluorophore. The fluorophore subsequently emits CL. Peroxyoxalate CL has useful applications in the quantification of hydrogen peroxide or fluorophores such as polycyclic aromatic hydrocarbons. Two of the most commonly used oxalate esters are bis-(2,4,6-trichlorophenyl)oxalate (TCPO) or bis-(2,4-dinitrophenyl)oxalate (DNPO). Peroxyoxalate CL can be used over a wide *p*H range. TCPO can be used from *p*H 5 to 9, with the maximum CL intensity occurring at approximately *p*H 7. Measurements at more acidic *p*H can use DNPO. A weak base such as triethylamine, tris(hydroxymethyl)aminomethane, or imidazole is usually included in the reaction mixture in order to catalyze the reaction and increase CL intensity (Birks, 1989).

1.3.3 Lucigenin. Lucigenin (N,N'-dimethyl-9,9'-diacridinium nitrate) is another commonly used system that undergoes CL reaction in alkaline solution to produce N-methylacridone with emission of CL light. Figure 6 shows a schematic diagram for the lucigenin CL reaction. The CL emission originates from an excited singlet state of N-methylacridone, which exhibits a CL spectrum from 420 to 500 nm with a maximum at about 440 nm (Totter, 1975). The chemical reactions are complicated and probably involve both oxidation and reduction steps, although the overall reaction is an oxidation. Lucigenin can react either with hydrogen peroxide or with a reductant plus oxygen. The presence of catalysts like Co(II), Fe(III), Fe(II), Cu(II), Cr(III), and Ni(II) can considerably increase the CL emission.

Acridinium esters and acridans (Fig. 7) react similarly to lucigenin to also yield N-methylacridone- and CL light.

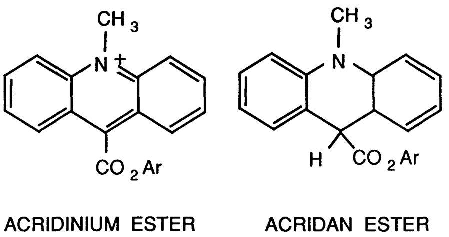

FIG. 7. Structure of acridinium and acridan phenyl esters. Ar, aromatic system.

1.3.4 Singlet-Oxygen Sensitization Systems. Various CL reactions involve singlet oxygen which can be formed by the folowing reactions:

$$S + h\nu \rightarrow {}^1S^* \rightarrow {}^3S^*, \tag{10}$$

$${}^3S^* + {}^3O_2 \rightarrow S + {}^1O_2, \tag{11}$$

where S denotes the ground state of a sensitizer for singlet oxygen; ${}^1S^*$, an excited singlet state of the sensitizer; ${}^3S^*$, an excited triplet state of the sensitizer; ${}^1O_2$, the singlet state of molecular oxygen; and ${}^3O_2$, the triplet state of molecular oxygen.

In the presence of a singlet-oxygen acceptor, A, the following reaction, which involves direct energy transfer from singlet-oxygen dimers to a dye capable of fluorescence, may occur:

$$2\ {}^1O_2 + A \rightarrow 2\ {}^3O_2 + {}^1A^* \rightarrow A + h\nu, \tag{12}$$

where A denotes the state of acceptor A, and ${}^1A^*$, an excited singlet state of A. The formation of singlet-oxygen dimers in Eq. (12) is well studied and many investigators have reported CL by this process. Acceptors have included violanthrene, methylene blue, and chlorophyll (Birks, 1989). Another reaction that can produce CL involves formation of a fluorescent product:

$$^1O_2 + A \rightarrow (AO_2) \rightarrow \text{Product}^* \rightarrow \text{Product} + h\nu. \tag{13}$$

In this reaction the acceptors may form dioxetane intermediates that can decompose to yield CL. Although most dioxetanes decompose in solution to yield predominantly excited triplet states producing little CL, there are acceptors that form dioxetanes exhibiting good excited singlet yields. These include lophine (2,4,5-triphenylimidazole) and some of its derivatives (White and Harding, 1964).

1.3.5 Tris(2,2′-bipyridine)ruthenium(II). Another CL system is noteworthy because the reagent is regenerated and thus can be recycled. This system, ruthenium tris-bipyridine(bpy), involves reaction of $Ru(bpy)_3^{3+}$ and $Ru(bpy)_3^{+}$ to produce an excited state of $Ru(bpy)_3^{2+}$, a stable species which decays to the ground state by emitting an orange emission. $Ru(bpy)_3^{3+}$ and $Ru(bpy)_3^{+}$ can be electrogenerated from $Ru(bpy)_3^{2+}$ by reduction at approximately -1.3 V, and oxidation at approximately $+1.3$ V.

2. INSTRUMENTATION

2.1 Photometric Detection Systems

Chemiluminescence can be very sensitive because it involves an emission technique. The basis of this sensitivity in emission spectrometry is well known. Absorption spectrometry involves the detection of small changes in a large signal (light beam passing through the sample into the detector) that is always present and produces an intrinsic photon noise which determines the detection limit. On the other hand, emission spectrometry is not limited by the high level of the excitation radiation since most of this radiation is eliminated by excitation monochromators or optical filters, and appropriate excitation/detection geometry. In CL, there is no excitation light source, and thus no scattered excitation light problem. The background noise of the sample is the limiting factor.

The instrumentation commonly used to detect CL is relatively simple and is essentially similar to that used for luminescence. Most of the discussion on detection instrumentation in this section also applies to conventional luminescence.

A typical CL detection system may have the following basic components:

(a) a dispersive element, such as an optical filter, a monochromator, or a polychromator; and
(b) an appropriate detector.

No excitation light source is required since the chemical reactions provide the necessary excitation energy. Because the luminescence signals of commonly used CL systems usually have broadband features, the monochromators and related instrumentation for CL do not need to be sophisticated and costly. The CL emission from the sample is collected through appropriate optics and focused onto the entrance slit of a dispersive element. There are two basic classes of luminescence spectrometers: single-channel instruments and multichannel instruments. The first type of instrument generally uses a monochromator coupled to a photomultiplier, whereas the latter uses a polychromator interfaced to a multichannel detector, such as a vidicon, a photodiode array, or a charge-coupled device (CCD).

A wide variety of manufacturers of luminescence spectrometers are available, each offering a variety of models with different performance characteristics and each offering different options. Basic instrument components are also commercially available and easily assembled. An investigator may assemble off-the-shelf components for his or her particular applications.

The most commonly used luminescence spectrometer is a photomultiplier coupled with a double-grating monochromator. The spectral resolution and the sensitivity of the spectrometer are strongly dependent on the characteristics of the monochromator and the photomultiplier tube. Modern holographic gratings generally offer excellent stray-light rejection. The single-photon counting method can be used for detection. Unlike the more conventional analog detection method, the single-photon counting signal output is digital in nature, producing discrete pulses of charge. The digital technique has proven to have several advantages over the analog method, especially for low-level signal detection (Malmstadt *et al.*, 1972; Vo-Dinh and Wild, 1973, 1974).

Photomultipliers are widely used as CL detectors for their high spectral sensitivity, wide operating range, low cost, and relatively simple electronics. Whenever low-intensity signals are observed in CL measurements, it is desirable to improve the sensitivity of detection by recording the entire spectrum simultaneously. Interferometric methods, e.g., Fourier-transform techniques, can enhance the detection sensitivity only if the noise of the measured signal is detector limited.

With monochromators, only one spectral resolution element, or channel, can be monitored at a time. Detectors that permit the recording of the entire spectrum simultaneously, thus providing the multiplex advantage, are known as multichannel detectors. A well-known example of a multichannel detector is the photographic plate. More modern multichannel detectors include the vidicon, the diode array, and the charge-coupled device (Talmi, 1975; Campion and Woodruff, 1987). In multichannel spectrometers, the detector is placed at the focal plane of a polychromator, which is a monochromator with the exit slit removed. As a result, the entire emission, dispersed at all wavelengths within the polychromator, is detected simultaneously. The simultaneous detection of all the dispersed emission using n spectral resolution elements reduces the measurement time by a factor of n in the case of an S/N (signal-to-noise)–limited measurement, or improves the S/N ratio by a factor of n in the case of a time-limited measurement.

There are several types of multichannel detectors commercially available. One device used in the 1970s is the vidicon, which is essentially a television-type device comprised of an array of microscopic photosensitive diode junctions that are grown upon a single silicon crystal wafer. These diode junctions provide individual microelements that are used to detect simultaneously the radiation dispersed by the polychromator. Prior to detection, each diode is charged to a preset reversed-bias potential by a fast-scanning electron beam. The electromagnetic radiation that strikes the diode causes depletion of the charge in each diode. A current proportional to the incident radiation recharges the diode to the preset potential when the electron beam scans again, thus providing information on the intensity of the incident light that has struck the diode. Consequently, an almost instantaneous recording of the spectral intensity at each diode is generated in the computer memory of the vidicon detector. Vidicons are capable of integrating radiation intensity over multiple scanning cycles through their charge-storage capabilities. Sensitivity can be further enhanced by incorporating an image-intensification section in front of the vidicon to yield a silicon-intensified target (SIT) vidicon.

Another multichannel detector is the diode array, which also utilizes photodiodes as detection elements. Recording of the signal is performed with direct on-chip circuitry rather than with a scanning electron beam. Signal amplification is achieved by a microchannel-plate image intensifier. Gated detection down to 5-ns time resolution can be performed with the intensified diode array. Intensified diode arrays are currently the most widely used multichannel detectors.

Recently, other types of devices, such as charge-coupled devices (CCDs), have received increasing use because of their high quantum yields, two-dimensional imaging capabilities, and very low dark currents (see CHARGE-COUPLED DEVICES). Charged-coupled devices have several advantages, including

1. high quantum yields and wide spectral response compared to those for photomultipliers,
2. low dark current when cooled to less than 140 K (permitting integration of the luminescence emission over extended periods of time), and
3. immunity from light shock or intense bursts of radiation.

This immunity is an important feature in CL because of the wide range in reaction rates (over 15 orders of magnitude), resulting in a very wide range of photon fluxes. An important advantage of CCDs is that the read noise is much lower than that of photodiode arrays. With CCDs a process involving on-chip charge combining, often referred to as "binning," can reduce the effect of read noise. The advent of CCD detectors allows the investigation and applications of weakly CL systems that could not be detected otherwise. Jalkian and Denton (1988) have developed CCD instruments for wavelength-dispersive and nondispersive CL measurements. Figure 8 shows a wavelength-nondispersive luminometer employing a (512 ×320)-element CCD detector (Jalkien and Denton, 1988). The wavelength-dispersive instrument was used to record the spectrum of luminol, whereas the nondispersive instrument, which is simple in design and offers improved sensitivity, was mainly used to perform quantitative measurements.

2.2 CL-Based Detectors for Chromatography and Flow-Injection Systems

Chemiluminescent reactions in the gas phase and in solution have been successfully used to develop an extremely wide variety of detectors in gas and liquid chromatographs. In general, CL-based detectors are very sensitive and selective to the specific species that undergo CL reactions. For example, the measurement of NO by its CL reaction with O_3 provides the basis for gas chromatography (GC) detectors. The limit of detection of NO is in the part-per-trillion (ppt) range. The dynamic range of the analytical curve for the CL method is over 6 orders of magnitude. Figure 9 shows a schematic diagram of a CL-based detection system for GC. In general, GC detectors include active-nitrogen detectors, ozone-induced detectors, sulfur-based detectors, fluorine-based detectors, and chlorine-dioxide-based detectors (Birks, 1989).

A variety of CL reaction schemes in solution have been used to develop detectors for liquid chromatography (LC). The CL systems include luminol, lucigenin, peroxyoxalates, Ru(bpy), electrochemiluminescence, and the luciferin/luciferase (bioluminescence) reactions. Another example described in a previous section involves the use of CL reactions of hydrogen peroxide for liquid chromatography detection. For details, the reader is referred to a recent book dealing specifically with chemiluminescence and photochemical reaction detection in chromatography (Birks, 1989).

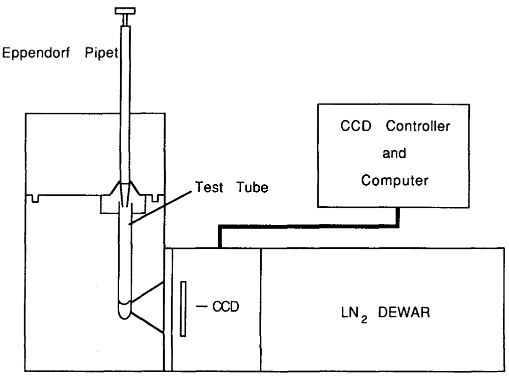

FIG. 8. Wavelength-nondispersive luminometer (from Jalkian and Denton, 1988).

A variety of CL-based detection systems can also be operated as post-column reactions for flow injection as well as chromatographic systems (Birks, 1989) (see CHROMATOGRAPHY). The instrumental device involves a method to deliver and mix the CL reagents with the column effluent and an appropriate detection flow cell that permits monitoring the CL signal. A typical instrumental setup for CL application in flow injection and chromatography is shown in Fig. 10.

Because of the reactions kinetics involved in the CL process, the CL emission intensity is usually a transient signal rather than a constant signal. The CL emission intensity I_{CL} (photons/s) is directly proportional to the rate of chemical reaction dM/dt [(molecules reacting)/s]:

$$I_{CL} = \Omega_{CL}(dM/dt). \qquad (14)$$

Since the rate of the CL reaction varies with time due to consumption of reagents, the CL intensity also varies with time. In order to optimize the sensitivity of detection, one needs to measure the CL signal at its maximum level which occurs after a specific time delay following reagent mixing. In general, the CL signal reaches the maximum level in a second or less after reagent mixing and decays to the background level in a few seconds. The nature of the solvents used in flow-injection analysis (FIA) or LC is an important parameter affecting the CL intensity. Table 1 illustrates the effect of various solvents on the CL intensity of luminol (Birks, 1989).

3. APPLICATIONS

The use of CL is gaining increasing popularity due to its simplicity and sensitivity. The description of various CL applications in this section is not aimed to give an extensive list of all possible applications but rather to provide an overview of selected examples of CL studies in order to illustrate their usefulness in a wide variety of fields.

3.1 Monitoring Atmospheric Pollutants

There is an extremely wide variety of analytical instruments for monitoring gaseous species using CL reactions. These devices are based on various schemes (e.g., $NO+O_3$, CH_2+N, $CH+N$, etc.). Van Zoonen *et al.* have developed a solid-state CL detector for hydrogen peroxide for potential application to acid rain analysis (Van Zoonen *et al.*, 1985). The acidity of rain and cloudwater is affected by the levels of sulfur oxides and nitrogen oxides released into the atmosphere and subsequently dissolved in the water. One of the main reactants in the decomposition cycle of sulfur oxides is believed to be hydrogen peroxide. An important problem related to monitoring hydrogen peroxide is the low concentrations of these species, which are unstable in aqueous samples. The normal hydrogen peroxide concentrations in rain water may vary from less than 1 μg/L (3×10^{-8} *M*) in polluted areas to more than 1 mg/L (3×10^{-5} *M*) in clean areas. The CL monitor used peroxylate CL and consisted of a two-bed reactor packed with solid trichlorophenyloxalate (TCPO) and 3-aminofluoranthene immobilized on controlled-pore glass beads. The detection limit was 1.5×10^{-8} *M* and the dynamic range of the analytical curve was 6 orders of magnitude. The quenching of peroxyoxalate CL was used as a new detection principle in FIA and high-performance liquid chromatography (HPLC) (Van Zoonen *et al.*, 1986). Figure 11 shows a block diagram of the CL-based detector for FIA and HPLC.

3.2 Measurement of Trace Metals

The CL detection method in liquid chromatography has used the luminol reaction for trace metals separated by ion-exchange chromatography (Birks, 1989). Mixtures of Cu^{2+} and Co^{2+} and of Cu^{2+}, Co^{2+}, and Ni^{2+} were separated on an anion-exchange column as their chloride complexes. Manganese(II) has been determined at part-per-billion (ppb) levels by detection of the CL emission produced

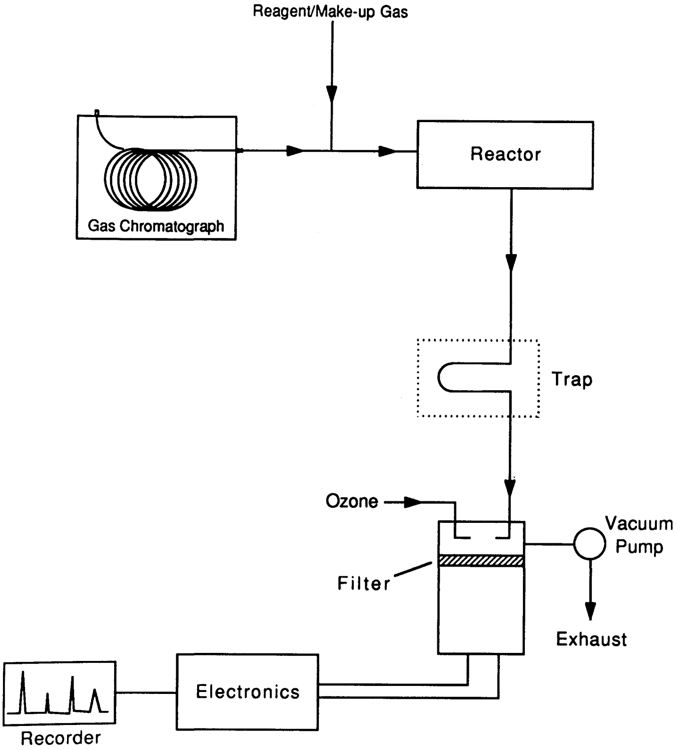

FIG. 9. Schematic diagram of a CL-based detector using the $NO+O_3$ reaction for gas chromatography (from Birks, 1989). A cold trap is used to trap nonvolatile species before they pass into the CL reaction chamber where the effluent is mixed with an excess of O_3. Light produced from the $NO+O_3$ reaction is detected by a photomultiplier tube.

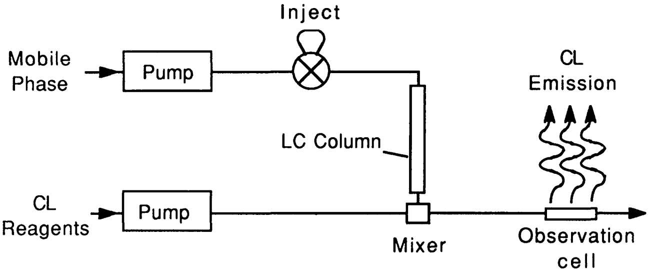

FIG. 10. Experimental setup for CL applications in liquid chromatography (from Birks, 1989).

by oxidation of luminol with hydrogen peroxide (Burguera, 1980).

3.3 Determination of Alcohols, Ethers, Aldehydes, and Saccharides

The approach involving peroxide has been used to detect a variety of aliphatic oxygen-containing compounds, such as alcohols, ethers, aldehydes, and saccharides. This general method is based on the principle that if an analyte of interest can be converted into a specific amount of hydrogen peroxide, then addition of a luminol-catalyst reagent mixture will permit quantitation of the peroxide produced and thus the original analyte. Gendelman and Birks have described a photooxygenation CL system that used anthraquinone-sensitized photooxygenation (Gandelman and Birks, 1982). Various alcohols, ethers, aldehydes, and saccharides were separated on a reverse-phase column using a mobile phase containing anthraquinone-2,6-disulfonate. The column effluent passed through a photochemical reactor where H_2O_2 was produced and subsequently detected via Co^{2+}-catalyzed luminol CL.

Table 1. Solvent effects on luminol chemiluminescence.[a]

	CL intensity[b]		
	Catalyst		
Organic solvent	Co^{2+}	Cu^{2+}	Cr^{3+}
Methanol	0.22	0.95	0.08
Ethanol	0.19	0.93	0.23
Acetone	0.94	0.85	0.80
Acetonitrile	0.09	0.98	1.33

[a] Taken from Birks, 1989.

[b] The CL relative intensities are given for a 10% organic–90% aqueous solvent mixture divided by the intensity for a 100% aqueous solution.

3.4 Determination of Polycyclic Aromatic Hydrocarbons

Chemiluminescence of polycyclic aromatic hydrocarbon (PAH) compounds, emitted at a platinum electrode, can be utilized to determine these compounds in aprotic (i.e., containing no protons) solvents (Cruser and Bard, 1969). This CL method has been applied for detection in liquid chromatography (Hill *et al.*, 1986). Electrogenerated CL of PAHs was observed in micellar solution (Haapakka *et al.*, 1988). When polarized during a cathodic potential pulse in the presence of peroxodisulfate ions in aqueous acetate solution (*p*H =7.0), a micelle-forming surfactant (Brij-35), and a PAH compound, an oxide-covered aluminum electrode produced an intense electrochemiluminescence where the emitting species was the micelle-encapsulated PAH. The limit of detection was $10^{-8}M$ for 9,10-diphenylanthracene.

3.5 Analysis of Proteins, Amino Acids, and Other Biological Systems

Species that do not participate directly in CL reactions can still be detected by their interactions with other species which are catalysts for the reaction. This indirect approach has been used in several variations to detect a wide range of analytes. For example, amino acids have been separated via ion exchange and detected on the basis of their complexation with catalysts such as Co^{2+} or Cu^{2+}. Several amino acids including arginine, glycine, histidine, hydroxyproline, proline, and valine have been analyzed with limits of detection from 1 pmol for histidine to 2 nmol for most of the other amino acids (Koerner and Nieman, 1987). It is noteworthy that this method permits detection of both primary and secondary amino acids without derivatization. This general approach allows detection of substances that complex with a transition-metal ion catalyst. Catecholamines, with Cu^{2+} as the catalyst, can also be analyzed by reverse-phase chromatography and detected at 1 pmol levels by the CL method (Koerner and Nieman, 1987). Thyroglobulin, gamma-globulin, and ovalbumin have been determined via size-exclusion chromatography using CL detection (Hara *et al.,* 1985).

Clinical methods for protein analysis have been developed using changes in either absorption or fluorescence characteristics induced by the formation of complexes with the probe molecule. One of the major advantages of such methods is that chemical modification of the analyte is not required. Woolf and Crayeski have developed a method using CL to quantitate protein-probe complexes (Woolf and Grayeski, 1988). The method was based on chemical excitation of a complex formed by the binding of a fluorescent molecule to the hydrophobic portion of the protein. The fluorescent molecule was excited with an aqueous peroxyoxalate CL reaction. The resulting CL intensity was enhanced by the hydrophobic environment of the protein. This CL method was developed for human albumin and has a detection limit of 21.6 ng/mL.

3.6 Analysis of Drugs and Food Components

Aminoglycoside antibiotics are good Cu^{2+} ligands, and the three components of gentamicin-C in commercial gentamicin sulfate have been determined via ion-pair chromatography using CL detection (Koerner and Nieman, 1987). Many organic compounds such as drugs and food components are slowly oxidized in air and produce an extremely weak CL emission. This phenomenon has been used to investigate the stability of organic compounds (Edo *et al.,* 1985). Chemical change of food components during processing and storage involves the amino-carbonyl reaction. Investigations of the amino-carbonyl reaction have dealt with melanoidines, the main reaction products, and with the effects of amino-carbonyl reactions on the aging of the human body and diseases of adulthood (Edo *et al.,* 1985). Kurosaki *et al.* (1989) have reported a weak CL emission from amino-carbonyl reactions of *L*-lysine with various sugars and aldehydes in aqueous solution. Among the aldehydes and sugars investigated, glycolaldehyde and *D*-arabinose exhibited the most intense CL signal (Table 2). The browning reaction monitored from the UV absorption at 420 nm was used as an index of the amino-carbonyl reaction. The results in Table 2 shows a gradual increase during the course of the reaction and a similar trend was observed for the CL emission intensity. The studies indicated that the CL signal of the amino-carbonyl reaction reached a maximum after approximately 1 h. The CL emission also depended on the *p*H, and a linear relationship between the CL intensity and hydrogen-ion concentration was reported. In nitrogen-purged solutions, no CL was observed, thus supporting the hypothesis that the CL of the amino-carbonyl reaction is produced by an oxidation reaction. The study indicated that CL may be useful in evaluating the stability of

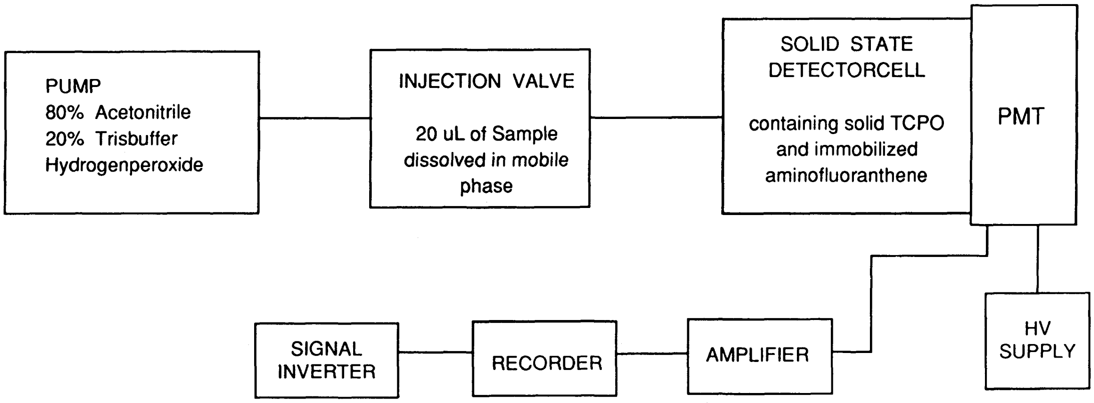

FIG. 11. A CL detector for flow-injection analysis and high-performance liquid chromatography (from Van Zoonen *et al.*, 1986).

Table 2. Chemiluminescence in the amino-carbonyl reactions of sugars and other carbonyl compounds with *L*-lysine.[a] (Taken from Kurosaki *et al.*, 1989.)

	Absorbance at 420 nm (counts/s)	
Sample	Maximum CL	Browning[b]
Hydroxy aldehyde		
Glycoaldehyde	46 370	206.0
Polyhydroxy aldehydes and ketones		
Aldotriose		
Glyceraldehyde	30 450	12.9
Aldopentoses		
D-arabinose	42 130	3.3
D-Ribose	30 530	3.6
D-xylose	37 890	3.0
Aldohexoses		
D-glucose	31 030	0.8
D-galactose	23 450	1.6
Ketohexoses		
D-fructose	27 980	1.5

[a] Aqueous solutions of *L*-lysine and sugars (each 50 nmol/L) were heated at 100 °C.

[b] The browning absorbance at 420 nm was determined after 25 min.

crude drugs extracted from natural resources that contain many amino acid derivatives including proteins and sugars.

3.7 Determination of Sulfides

Several oxidizing systems have been used to determine sulfides by monitoring their CL emission (Klockow and Teckentrup, 1976). These CL systems involved sodium hypochlorite with and without a sensitizer, and hydrogen peroxide with osmium tetroxide, peroxidase, or catalase as catalyst. Sulfides could be detected over a large concentration range from 10^{-4} to 100 ppm.

3.8 Chemiluminescence Immunoassays

Chemiluminescence immunoassays can be performed by labeling either antibodies or antigens with a CL compound of interest. CL immunoassays offer several advantages, including high sensitivity, excellent stability of the label, simplicity of the instrumentation, and flexibility of the measurement. Several types of CL immunoassays can be performed. The simplest method involves direct replacement of the radioactive label, e.g., ^{125}I, by a CL label. Such applications have used dioxetanes (Wynberg *et al.*, 1981), acridium phenyl esters (Weeks *et al.*, 1983), and isoluminol (Schroeder *et al.*, 1978) to label haptens (parts of antigens that induce an immune response) or small peptides. A variety of assays using CL have been developed for the quantification of protein and peptide hormones such as hCG, human chorionic gonadotrophin (Kohen *et al.*, 1984), and *alpha*-fetoprotein (Weeks *et al.*).

3.9 Nucleic Acid Detection, Hybridization, and Sequencing

One of the most widely used techniques in molecular biology deals with nucleic acid hybridization to detect specific DNA sequences immobilized on membranes. In addition, the increasing interest in human genome mapping and sequencing has induced the rapid development of many DNA cloning and sequencing techniques. The usual procedure for detection and quantification of specific DNA or RNA sequences is mainly based on the procedure originally described by Southern (1975). This method, often referred to as Southern blotting, involves transferring electrophoretically separated DNA fragments from a gel to a membrane support followed by hybridization with a labeled probe. The blot is washed and the DNA of interest is detected by autoradiography or other detection techniques. Conventional methods use radioactive labeled probes which give high sensitivity for detection. Separated DNA fragments are most often detected with radioisotopic labels such as ^{125}I, ^{32}P, and ^{35}S. Radiometric techniques generally suffer from several disadvantages: radioisotopes have limited shelf-life (e.g., about 60 days or ^{125}I); instruments for detection and reagents are relatively expensive; and special precautions are required for the shipping, handling, and waste disposal of radioactive materials. Consequently, a number of techniques have been developed for nonradiative probe labeling and detection. Various nonradioactive labels include fluorophors (e.g., fluorescein and tetramethylrhodamine), metal atoms (e.g., colloidal gold), enzymes (e.g., alkaline phosphatase, acid phosphatase, microperoxidase, and horseradish peroxidase), and antigen:antibody or biotin:avidin enzyme-conjugated systems (Wilchek and Bayer, 1988).

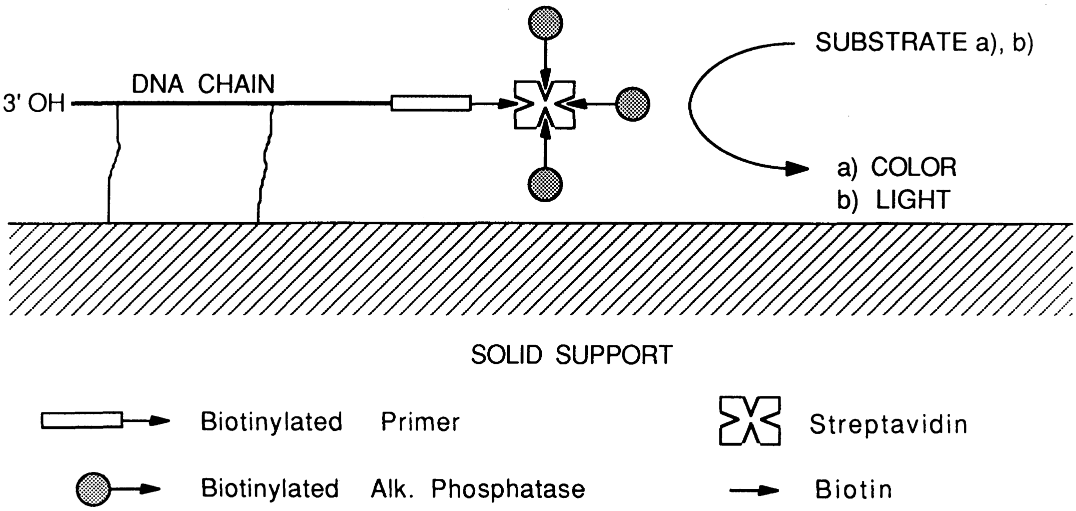

FIG. 12. Chemiluminescence detection of immobilized DNA using an enzyme-catalyzed reaction (from Beck *et al.*, 1989). The curved arrow indicates reaction of the substrate with biotinylated alkaline phosphatase to form a luminescent or colored product.

Because the luminol moiety can be quantitated conveniently at trace levels, there is current interest in the use of luminol or related derivatives as labels in immunoassays (Kricka and Carter, 1982).

Recently, enzyme-based chemiluminescence and bioluminescence assays have been developed for detecting DNA. Enzyme-based labels offer a nonradioactive technique that is very sensitive because of their catalytic amplification process. Alkaline phosphatase (AP) is an enzyme system that has been used recently for CL assays. Alkaline phosphatase exhibits a high degree of heat stability. The crude enzyme, extracted from *E. coli,* shows no loss of activity when heated at 85 °C for 30 min, or at 95 °C for 8 min in the presence of magnesium (Schlesinger and Barret, 1965). Alkaline phosphatase is also stable in low-*p*H environments. These properties of remarkable thermal stability and excellent resistance to environmental conditions makes alkaline phosphatase a commonly used label for DNA detection. Bronstein *et al.* reported recently the development of a direct CL dioxetane-based enzyme substrate which provides improved sensitivity (Bronstein *et al.*, 1990). Dioxetanes are four-membered ring peroxides incorporating a weak oxygen-oxygen bond which easily decomposes to form strong carbonyl products. This chemical reaction is accompanied by a release of up to 100 kcal/mol of energy capable of producing a strong CL emission. The luminescence signal is produced from a direct CL substrate, disodium 3-(4-methoxyspiro [1,2-dioxetane-3-2'-tricyclo$[3.3.1.1.^{3,7}]$decan]-4-yl) phenyl phosphate (AMPPD), which decomposes upon dephosphorylation with alkaline phosphatase. The CL signal obtained from alkaline-phosphatase cleaved AMPPD on a Southern blot may be detected on instant film or x-ray film.

Beck *et al.* (1989) reported a nonradiative detection technique for DNA sequencing based on CL using biotinylated alkaline phosphatase. The CL detection methodology was similar to

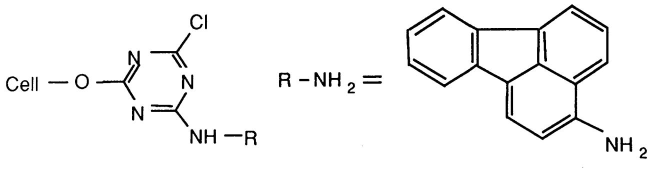

FIG. 13. Example of reactant immobilized on solid substrate: 3-aminofluoranthene immobilized on cellulose for CL detection of hydrogen peroxide (from Gubitz *et al.*, 1985).

colorimetric staining and involved a biotin/streptavidin interaction. A 5′-biotinylated oligonucleotide was used as a primer extension reaction for DNA sequencing or as a probe for hybridization to a target DNA. Biotinylated alkaline phosphatase was bound to the biotinylated 5′-end of the oligonucleotide via a streptavidin bridge and catalyzed the light reaction by cleaving off a phosphatase group from an added CL substrate. The CL emission was detected by a Polaroid or x-ray film. The method, capable of detecting DNA in the hundred-attomol range, has been developed for DNA sequencing. Figure 12 shows a schematic diagram for the CL detection of DNA using an enzyme-catalyzed reaction. The results currently reported by many researchers have indicated that luminescence detection technology using CL systems immobilized on solid substrates or membranes (Fig. 13) has permitted the development of a new generation of simple, rapid, and ultrasensitive detection assays for environmental and biochemical applications (Beck *et al.*, 1989, Gubitz *et al.*, 1985).

ACRONYMS

ABEI: aminobutylethylisoluminol
CCD: charge-coupled device
CL: chemiluminescence
DNA: deoxyribonucleic acid
DNPO: bis-(2,4-dinitrophenyl)oxalate
FIA: flow-injection analysis
GC: gas chromatography
HPLC: high-performance liquid chromatography
IC: internal conversion
ISC: intersystem crossing
LC: liquid chromatography
RNA: ribonucleic acid
SIT: silicon-intensified target
SVL: single vibronic level
TCPO: bis-(2,4,6-trichlorophenyl) oxalate
VR: vibrational relaxation

GLOSSARY

Aprotic Solvent: Solvent containing no proton.

Fluorophore: A species that emits fluorescence.

Luminescence: An emission process that involves transitions between electronic states of an atom or a molecule.

Singlet State: Electronic state having a spin equal to 0.

Triplet state: Electronic state having a spin equal to 1.

30.1
Introduction

Chromatography is the most widely used separation method for chemical analysis. While it is not a spectroscopic method, it is often combined with or used with spectroscopic methods such as ultraviolet/visible (UV/Vis) absorption spectroscopy or mass spectroscopy (MS). A spectrometer can be an integral part of some chromatographs; for example, a UV/Vis spectrometer is most commonly used as a detector for high-performance liquid chromatography (HPLC). Alternatively, chromatographs are coupled to, or used with, spectrometers such as MS, and the combined technique, gas chromatography–mass spectrometry (GC–MS or GC/MS), is an example of so-called hyphenated methods.

This chapter focuses on chromatography, but it includes relevant information about spectroscopic detection systems, including, in some cases, the interface between the chromatograph and the spectrometer. The outline of the remainder of the article is as follows. The first section is devoted to a description of basic concepts that apply to all forms of chromatography. This is followed by sections devoted to the two most common types of chromatography, GC and LC, followed by a shorter section on the third type, supercritical fluid chromatography (SFC). The final sections elaborate on spectroscopic detection, mainly mass spectrometry (MS), and a few special topics.

For each type of chromatography, a description of the general uses of the technique is followed by sections on instrumentation and modes of separation. In Section 30.4.1, the four essential components of a chromatograph, namely, the mobile-phase (MP) delivery system, the sample injector, the separation column (i.e., the stationary phase (SP)), and the detector, are described. In Section 30.4.2, a discussion of separation principles (i.e., the physical/chemical mechanism of resolving a mixture into its individual components) is combined with examples of a few applications that illustrate the usefulness and limitations of the techniques.

30.1.1
Historical Summary

In 1903, the Russian botanist Tswett devised a separation method that is now called *liquid-column chromatography* (*LC*). He separated structurally similar yellow and green chloroplast pigments

Encyclopedia of Applied Spectroscopy. Edited by David L. Andrews.

ISBN: 978-3-527-40773-6

by placing a leaf extract onto the top of a column of calcium carbonate particles and then washing the column with carbon disulfide (by gravity flow of the liquid). The colored pigments formed visible bands that became separated as they moved down the column. Tswett coined the term *chromatography* (from Greek, meaning "color writing"), although he also realized that the method was applicable to colorless compounds. Significant achievements in biochemistry and the chemistry of complex natural organic compounds were made possible by this method. However, the technique was time consuming and tedious, thereby restricting more widespread use in chemical separations and analysis. Faster and more efficient separations would only come years later, as a result of the theoretical and instrumental advances.

In a classic, Nobel-prize-winning paper, Martin and Synge (1941) advanced the theory of chromatography and predicted that high-speed LC would require very small column particles and high pressure. The technology for doing this was not available for many years, but, in the interim, James and Martin (1952) published the first paper on GC as had been suggested by Martin and Synge 10 years before. The potential of the technique was quickly recognized by other workers, who provided engineering advances that made gas chromatographs practical and useful, and GC became a major separation tool, providing additional advances in the theory of chromatography. It took about 10 more years until it was suggested that the principles of GC should be applied to LC. Giddings, among others, published important papers (Giddings, 1963) that gave rise to high-pressure liquid chromatography (HPLC), resulting in improved or higher performance LC, also known by the label *HPLC*. As a result of advances in instrumentation, HPLC methods have gradually approached the quality of GC methods in terms of speed and resolution. Further information about the history of chromatography can be found in the many publications by Ettre and Zlatkis (1979), Ettre (2002) and Ettre (2003).

Unfortunately, GC has some inherent limitations; it requires samples to be in the vapor phase, which limits its usefulness to compounds that can be volatilized. Current estimates are that only about 20% of known organic compounds can be satisfactorily separated by GC without some chemical modification (such as esterification of organic acids, which produces more volatile analytes). Modern LC, (HPLC), is suitable for analyzing most of the remaining 80% of known organic compounds, as well as many inorganic compounds.

Chromatography, primarily GC and HPLC, is used for rapid, efficient separation and analysis of complex mixtures of organic and inorganic compounds in the pharmaceutical, chemical, biomedical, biochemical, food, energy, cosmetics, and environmental industries, to name a few. With over 160 000 chromatographers around the world, chromatography forms one of the largest fields in the physical sciences. Clearly, it is not possible to do justice to all areas of such a large field in this short chapter. Therefore, in the sections that follow, the emphasis is on the most important theoretical, chemical, and procedural aspects of chromatography, along with an emphasis on spectroscopic detection.

30.2
Basic Concepts

30.2.1
Definition of Chromatography

Chromatography is a separation method in which the components of a sample partition between two phases: one phase is a stationary bed with a large surface area, and the other is a gas or liquid (MP), which percolates through the stationary bed. The sample is carried by the MP through the column. Samples partition (equilibrate) between the MP and the SP based on their solubilities or their relative tendencies to sorb on/in each of the respective phases. For this generalized introduction, we refer to the phases using these general terms and the symbol S for stationary and M for mobile. The components of the sample (called *solutes* or *analytes*) separate from one another based on their *relative* affinities for the two phases. This type of chromatographic process is called *elution*.

The "official" definition of the International Union of Pure and Applied Chemistry (IUPAC) is "Chromatography is a physical method of separation in which the components to be separated are distributed between two phases, one of which is stationary (SP) while the other (the MP) moves in a definite direction. Elution chromatography is a procedure in which the MP is continuously passed through or along the chromatographic bed and the sample is fed into the system as a finite slug" (Ettre, 1993).

30.2.2
Classification

Chromatography is classified according to the physical state of the MP. Thus, if the MP is a *gas*, the technique is called *GC*, and if it is a *liquid*, it is called *LC*. A subclassification can be made according to the state of the SP. If the SP is a solid, the GC technique is called *gas–solid chromatography* (*GSC*), and if it is a liquid, *gas–liquid chromatography* (*GLC*). The names used in liquid chromatography are more diverse and do not usually follow this simple pattern. A complete classification scheme is shown in Figure 30.1.

30.2.3
Mechanism of Operation

The objective in any chromatographic separation is to move individual materials through a column at different velocities so that they exit from the column at different times. In a typical experiment, a mixture of materials is injected into a flowing stream of a carrier medium (the MP) at the top of a chromatographic column, containing the SP. The MP is either a gas, a liquid, or a supercritical fluid. Common SPs are either solids or liquids. Liquids are kept stationary in the column by coating them on the inner wall of the column or by coating them on solid supports that are then packed (like solids) in the column. An alternative way to classify columns is to differentiate between packed columns and nonpacked, or open tubular (OT) columns.

A component in a sample mixture can interact with the mobile and SPs in a number of given ways. Operative partition mechanisms in chromatography are often discussed in terms of the nonpolar or polar nature of the sample, MP, and SP. A material is said to have nonpolar character if the electronic charge is uniformly distributed in the individual

molecules that compose the material. An example of a nonpolar molecule is methane (CH_4), which has a zero dipole moment because of the symmetrical arrangement of the individual dipoles constituted by the carbon–hydrogen bonds. In contrast, a material is said to have polar character if any region of the individual molecules that compose the material possesses an excess or deficiency of electronic charge relative to the rest of the molecule. Many electrically neutral molecules have polar character that can be exploited in chromatographic separations. As an illustration, consider the polar nature of the molecules benzene, butanol, 2-pentanone, nitropropane, and pyridine (Miller, 2005). The π-electron cloud of the benzene molecule can interact with the mobile and SPs through an electron donation mechanism. Butanol can interact via hydrogen bond formation with proton-accepting sites on the liquid or SP. The 2-pentanone molecule can interact through interactions of its dipoles with those of the mobile or SP. The nitro group on nitropropane is an electron-accepting group, which will be retained by SPs that possess electron-donating character. Finally, the unpaired electrons on the pyridine molecule can participate in the formation of hydrogen bonds with mobile or SPs that possess proton-donating character.

A final example demonstrates the concept of relative polarity. Consider a family of aliphatic, straight-chain alcohol molecules, each member of which is classified as polar. As the length of the carbon chain is increased, the polarity of the molecule decreases (relative polarity index: methanol > ethanol > propanol > butanol, etc.). In the examples provided in this chapter, we observe that polar sample molecules have a strong tendency to partition into polar mobile and/or SPs through one or more of the mechanisms described above. Conversely, nonpolar molecules will tend to partition into nonpolar phases. Ionic species are separated using familiar ion-exchange reactions as well as other methods that exploit their ionic nature.

30.2.4
Other Definitions and Symbols

The hypothetical chromatogram shown in Figure 30.2 displays the response of a detector as a function of time, t. The sample (composed of species 1 and 2) is applied to the top of the column as a narrow band. If a species has no interaction with the SP, it elutes from the end of the column when the total volume of MP introduced at the top of the column equals the void volume of the column. The time for elution of unretained species is t_M. The molecules of species 1 and 2 are swept along at the velocity of the MP, and they would all exit from the column at the same time were it not for the differences in their interactions with the SP. The time that each species actually spends in the SP, the adjusted retention time $t_R{}'$, determines when it will exit from the column. In practice, retention is often defined in terms of the retention time t_R:

$$t_R = t'_R + t_M \tag{30.1}$$

With reference to Figure 30.2, species 1 spends less time in the SP and therefore has a shorter retention time than species 2. Thus, the retention time serves to characterize a given analyte in a given chromatographic system. The x-axis in Figure 30.2 can also represent the

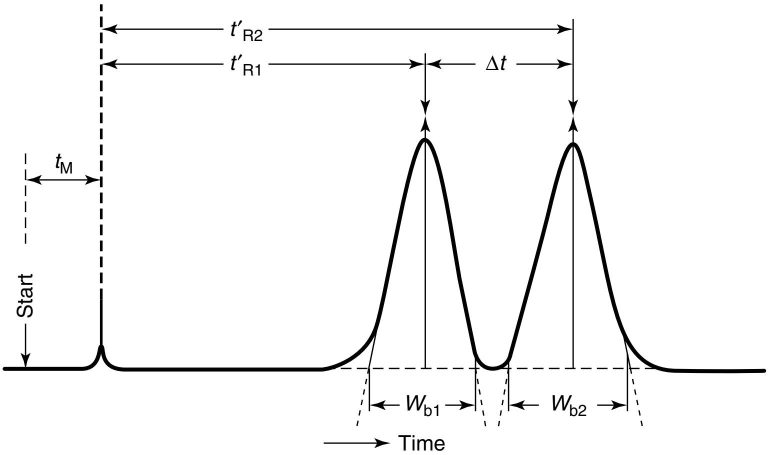

Fig. 30.2 Hypothetical chromatogram showing the separation of two analytes. The adjusted retention time is shown for each analyte as t'_R, and the retention time for a nonretained species as t_M. Chromatographic peak widths at base are labeled w_b. (Yost *et al.*, 1980); reprinted with permission.

volume V of MP that has flowed in a given time t, because, at a constant MP flow rate, F, the following relationship holds

$$V_R = t_R \times F \tag{30.2}$$

Consequently, volume and time are often used interchangeably on chromatograms and chromatographic data.

Another parameter elated to retention time is the retention factor, k:

$$k = \frac{V'_R}{V_M} \tag{30.3}$$

It too can be used for qualitative analysis for a specified chromatographic system.

While the components in the sample are being separated and eluted, the once-narrow bands broaden. This is primarily the result of three effects: (i) the differences in the path that each component travels through the column; (ii) the longitudinal diffusion effects; and (iii) slow equilibration of the components between the mobile and SPs. As a result of this band spreading, the components elute as Gaussian-like peaks like the one shown in Figure 30.3. They are broadened in proportion to the square root of the retention time, so the latter peaks are the broadest. It is this square root relationship that makes it possible to separate peaks even though the peaks are themselves being broadened, because the peaks are being separated from each other on a linear basis.

As shown in Figure 30.3, the peak width is denoted as w_b when measured at the baseline. For a Gaussian peak, that width is four times the standard deviation of the curve, 4σ. To get an estimate of the efficiency of a given separation, one can compare the retention time with the peak width. The parameter that has been defined for that purpose is the plate height, N.

$$N = \left(\frac{V_R}{\sigma}\right)^2 = 16\left(\frac{V_R}{w_b}\right)^2 \tag{30.4}$$

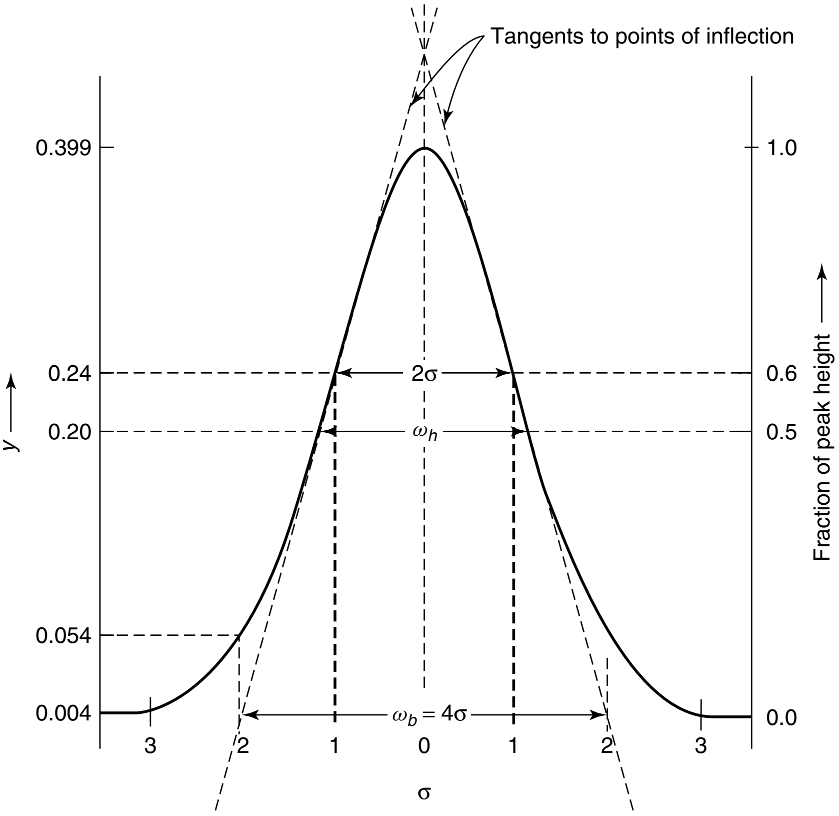

Fig. 30.3 Idealized Gaussian or normal distribution (Miller, 2005); reprinted with permission.

The name plate height came from the concept of theoretical plates that was in use in distillation processes when GC was first applied to petroleum separations. Briefly, the term *theoretical plate* referred to an imaginary unit in the chromatographic column wherein one complete equilibration of an analyte between the stationary and MPs occurred, as was visualized in distillation columns. In the entire column, there would be N of these units, but of course they do not exist in reality. For a given set of chromatographic conditions, N is approximately constant for all the peaks, and it is used in the industry to specify the quality of a column. It is a useful measure of column efficiency because it conveys the ability of the column to provide narrow peaks and good separations, and it can be easily calculated from chromatograms. This measure of column efficiency is frequently normalized to the column length L to give the plate height, H:

$$H = \frac{L}{N} \tag{30.5}$$

Other fundamental parameters are used not only to measure the quality of a separation scheme but also in the design of a separation. The separation factor α is a measure of the ability of a particular separation scheme to separate two components, and it can be defined in terms of the quantities represented in Figure 30.2:

$$\alpha = \frac{k_2}{k_1} = \frac{V_{R2}'}{V_{R1}'} \tag{30.6}$$

If the separation factor α is 1.0, the peaks coincide and there is no separation.

The efficiency of separation depends on the difference in retention times and the sharpness of the peaks, and is commonly described in terms of the resolution (R_s) of a particular method:

$$R_s = \frac{2(t'_{R2} - t'_{R1})}{(W_{b1} + W_{b2})} \tag{30.7}$$

Narrow peaks with very different retention times are said to be separated with high resolution. A well-resolved peak arising from a pure substance is very desirable from both an analytical and a preparative viewpoint. R_s can also be expressed in terms of N, k, and α (Purnell, 1960).

$$R_s = \frac{1}{4}(N)^{\frac{1}{2}}\left[\frac{(\alpha - 1)}{\alpha}\right]\left[\frac{k_2}{(1 + k_2)}\right] \tag{30.8}$$

A fundamental knowledge of the physical and chemical processes occurring on the column is critical to the successful design and performance of a separation. The experimental variables that control N, k, and α (and consequently R_s) are different for GC, LC, and SFC, and are briefly discussed in the sections that follow. Chromatographers experienced in these techniques know how to adjust the experimental conditions to maximize the resolution of a given separation.

30.2.5
Qualitative and Quantitative Analysis

Since most chromatographs are equipped with detectors, it is possible to use the chromatographic data (the chromatogram) for both qualitative and quantitative analysis. The chromatographic retention parameters such as retention time or retention factor do serve to characterize a given solute and can be used for making qualitative identification when compared with standards. Correct peak assignments can be made by comparison with a literature chromatogram or by comparison with a chromatogram from injection of a known standard. However, for positive confirmations of the identities of unknown components in a mixture, spectral measurements are required, most commonly by MS. Chromatographic data alone are not sufficient for identifying a true unknown chemical. Alternatively, identification can be done by collection of effluent fractions (corresponding to individual components) followed by off-line spectroscopic analysis.

Quantitative analysis is usually based on measurements of the heights or areas of the chromatographic peaks and comparison with heights or areas resulting from known standards in accordance with normal analytical practice. Especially in GC, it is common to use the internal standard method or the method of standard addition. When standards are not available, or when peaks have not been identified, it is common practice to calculate an area percentage by dividing the peak area of the desired peak by the sum of the areas of all the peaks. Such a calculation provides only an approximate quantitative analysis because the detection sensitivity of various compounds varies and only true calibration with standards can account for these differences. Also, it is often the case that some compounds may not have been detected by the particular detector being used (a nonuniversal detector) so the true sum of the peak areas cannot be found. Modern chromatographs do have good data acquisition and processing equipment (e.g., computers with integration and calibration software) for fast and accurate quantitation.

30.3
Gas Chromatography (GC)

GC was introduced as an analytical and separation technique in the 1940s and 1950s, in large part because of the work of Martin and Synge, referred to earlier. The first commercial chromatographs became available in 1955. The first ones were made to use packed columns, so all of the early literature uses them. When OT capillary columns were invented, the proponents attempted to show that they were superior, but these columns were patent-protected and not too widely used. Also, they required some modifications of the early instruments, resulting in two types of GC instruments. Today, the instruments designed to accept capillary or OT columns are the more popular ones and they are featured in this discussion.

GC is used for analysis of mixtures containing inorganic or organic compounds that have vapor pressures greater than about 0.1 Torr (10 Pa) at instrument operating temperatures. GC can be used to analyze solids, liquids, and gases. Amounts ranging from 10^{-2} to 10^{-12} g can be introduced and analyzed.

30.3.1
Instrumentation

A schematic of a capillary GC instrument is shown in Figure 30.4. Each of the individual parts is briefly described.

30.3.1.1 Carrier Gas Supply

The most popular carrier gases used as GC MPs are helium, and hydrogen, followed by nitrogen and argon. Where available, helium is preferred over hydrogen because of the latter's explosive characteristic. Carrier gases must be very pure, and gas scrubbing techniques for removal of oxygen, hydrocarbons, and water are used to assure purity at the point of use. Flow rates are accurately controlled and, for those cases where the pressure may vary, modern instruments are equipped with automatic pressure regulation to achieve constant flow rates. Typical flow rates are 20–100 ml min^{-1} for packed columns and 0.1–10 ml min^{-1} for capillary columns.

30.3.1.2 Sample Introduction

Microliter syringes are most commonly used for the introduction of liquid samples and solutions. Automated systems using microsyringes are highly desirable and readily available. For gases, gas-tight milliliter syringes or valves are used. Injector temperatures are regulated so as to be high enough to vaporize the injected sample, but not so high as to decompose it. Injectors usually have a rubber septum over the top of the column, which is pierced by the syringe during sample introduction. Direct introduction of the sample onto the column is possible and is known as *on-column injection.*

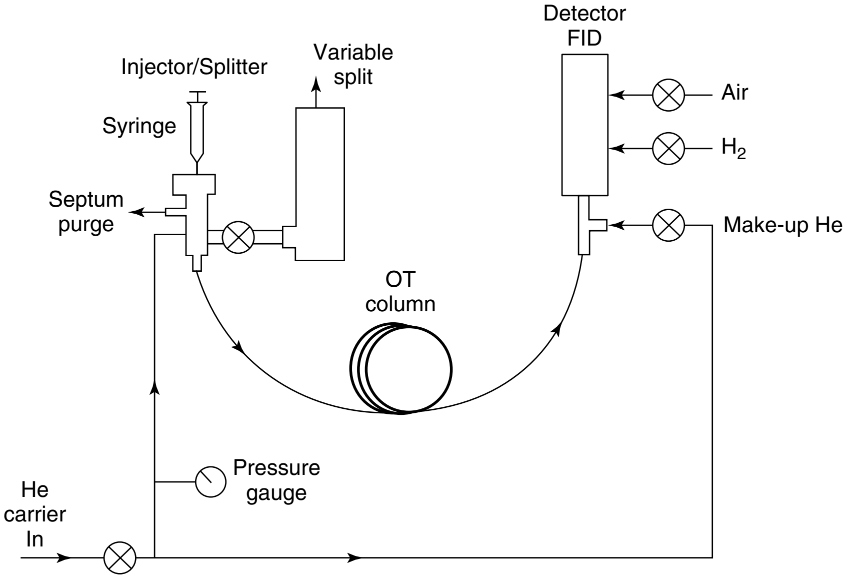

Fig. 30.4 Schematic of a typical gas chromatograph (McNair and Miller, 1998); reprinted with permission.

Because of the difficulty in injecting very small volumes of samples as required for capillary column GC, a sample inlet splitter is usually used. Small samples from split injection maintain separation efficiency and resolution. Sample splitters have a mixing chamber in which the injected sample and carrier gas are thoroughly mixed prior to being split. Typical splitting involves sending 50–99.9% of the mixture to waste through a vent tube, with the remainder being introduced onto the column. It is also possible to make a so-called splitless injection, whereby the entire mixture is directed to the column using the same apparatus, but a more involved procedure is required. A stated earlier, on-column injection is a third alternative.

The introduction of gas samples is most often accomplished with a gas sampling valve. In one valve position, a sample loop of known volume is filled with the sample gas at a known pressure. When the valve is activated, a precise amount of sample is swept out of the sample loop and onto the column by the carrier gas. This is the same type of valve that finds use in HPLC.

Other techniques can be used to introduce samples from unusual matrices. Injection of volatile components present in a relatively nonvolatile liquid can be performed by the headspace (HS) method. In one form of HS, called *purge-and-trap technique*, the liquid is sparged with an inert gas, and the volatile components are trapped by adsorption on a solid support or by condensation in a cold trap below the boiling point of the most volatile component. The trapped species are then volatilized and directed into the carrier gas stream.

Pyrolysis GC is useful for nonvolatile samples such as organic polymers. In this method, the sample is thermally pyrolyzed under controlled conditions, and the decomposition products are then analyzed by GC.

30.3.1.3 Columns

There are two types of GC columns: packed and capillary. Typical packed columns are constructed from 2–4-m lengths of stainless-steel or glass tubing with inside diameters (i.d.) of 2–4 mm. Columns are packed with 100–1000-μm-diameter porous particles. The particles are left untreated for separation by GSC and are coated with a liquid phase for GLC. Typical loading levels of liquid phases on the solid supports are about 0.5–10.0% by weight.

Typical capillary columns are 10–100-m lengths of 0.1–1.0-mm-i.d. metal or glass tubing. These columns have no packing material, and are often referred to as *OT columns*. The inner wall of the tubing has a coating that functions as the SP. GSC capillary columns have a porous layer deposited on the inner wall (porous-layer open tubular, (PLOT)). In GLC, the liquid phase may be directly applied to the inner wall (wall-coated open tubular, (WCOT)) or to a support material coating the inner wall (support-coated open tubular, (SCOT)). The thickness of a typical liquid SP film in a capillary column ranges from 0.2 to 0.5 μm. The tremendous popularity of capillary columns is due to the extremely high resolution separations that can be obtained. SPs with a variety of chemical and physical properties are available. As is seen in Section 30.3.2, the choice of an SP is dictated by the separation problem at hand.

Accurate control of column temperature is essential for reproducible GC. Column ovens that regulate temperatures within 0.2 °C between 25 and 450 °C are adequate for this purpose. Cryogenic equipment is used for temperature regulation down to about −100 °C for those applications requiring lower temperatures.

Temperature Programming (PTGC) Isothermal GC, the maintenance of a constant temperature on the column, can result in poor resolution of early-eluting peaks and significant band spreading of late-eluting peaks. Consequently, it is often desirable to use temperature programming whereby the column temperature is raised from a low initial temperature to a high final temperature during the GC run. Most GC ovens have the capability to provide one or more temperature gradients for this purpose.

A comparison of the effect of temperature programming can be seen by comparing Figure 30.5, an isothermal separation and the corresponding programmed temperature separation of the same sample. In the latter case, the early peaks are much better separated, the late peaks are eluted earlier, the peak shapes are nearly the same and are symmetrical, the total time required is decreased, and six additional compounds are eluted after the C_{15} peak. Good quantitation is obtained using temperature programming gas chromatography (PTGC) and it is also ideal for initial screening of new samples. There are a few disadvantages, the major one being the requirement that the SP have a wide temperature range of stability. In some cases, the SP may show increased bleeding during the run, since its vapor pressure increases with the temperature increase, causing the baseline to drift upward. However, in most cases, the advantages outweigh the disadvantages, and PTGC is very popular.

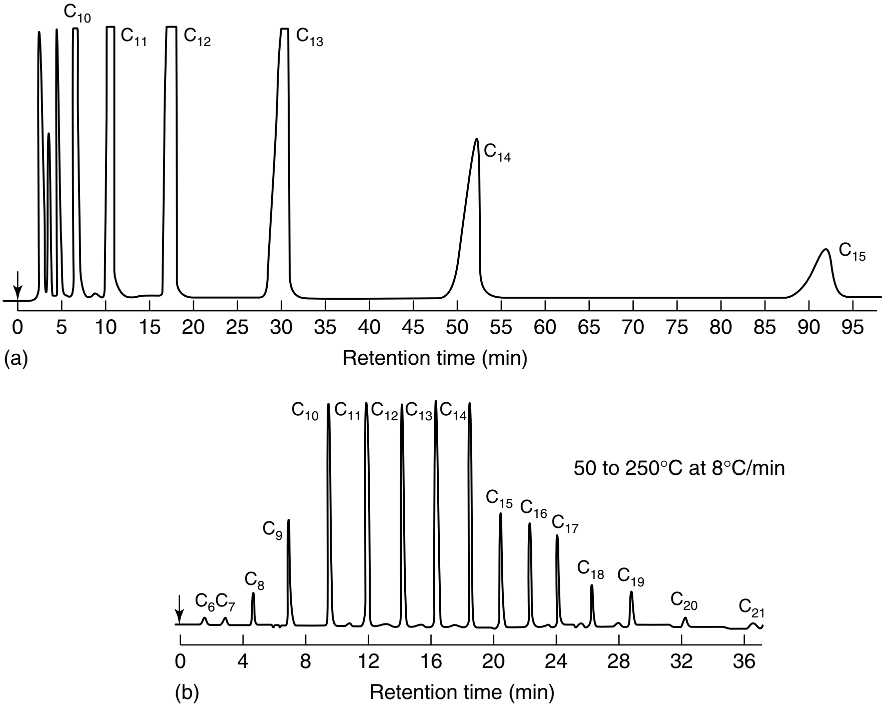

Fig. 30.5 A comparison of (a) isothermal and (b) temperature-programmed separation of *n*-paraffins (McNair and Miller, 1998); reprinted with permission.

30.3.1.4 **Detectors**

Most of the detectors used in GC were invented for this use, and many of them are based on ionization phenomena. The main exception is the thermal conductivity detector (TCD), which was already in use to measure the thermal conductivity of gases and, with minor modifications, became an ideal GC detector in the early days. For optimal use, a carrier gas of high thermal conductivity, like helium or hydrogen, is required; of course, safety precautions must be taken if hydrogen is used. It is a universal, nondestructive detector, but one with only a modest detectivity (about 10^{-8} g). The most popular one at present is the flame ionization detector (FID), which uses an oxy-hydrogen flame to burn the eluents from the GC column, thereby producing ions and electrons to form a current.

Only a few of the detectors are spectroscopic, but MS is a detector that is ideally suited to provide data for both qualitative and quantitative analysis. It is discussed later along with its use for HPLC. Infrared (IR) detection is similarly useful and it is also discussed later. The only other spectroscopic detector that finds use is the flame photometric detector (FPD). It employs a photomultiplier tube in combination with optical filters to monitor light emission generated in a flame similar to that used in the FID. Bandpass filters that transmit 394- and 526-nm radiation make this detector specific for luminescence

Tab. 30.1 Gas chromatography detectors.

Detector	Detection limit (g)	Selectivity
Thermal conductivity (TCD)	10^{-8}	Universal
Flame ionization (FID)	10^{-11}	Organics
Electron capture (ECD)	10^{-13}	Halogens, nitro-groups
Flame photometric (FPD)	10^{-10}–10^{-11}	Sulfur, phosphorus
Mass spectrometric (MS)	10^{-12}	Organics, others
Infrared spectrometric (FTIR)	10^{-8}	Most organics, others
Photoionization (PID)	10^{-10}	Aromatic organics, arsenic, sulfur, phosphorus
Hall electrolytic conductivity (HECD)	10^{-7}	Sulfur, nitrogen, phosphorus, halogens
Nitrogen phosphorus (NPD)	10^{-9}	Sulfur, nitrogen, phosphorus, arsenic
Discharge ionization (DID)	10^{-9}	Universal for liquids and gases
Gas density (GADE)	10^{-5}	High molecular weight
Helium ionization (HID)	10^{-9}	Universal for gases
Ultrasonic	10^{-7}	Universal for gases

from sulfur- and phosphorus-containing species, respectively. The detection limit of the FPD is about 10^{-11} g for phosphorus-containing and 10^{-10} g for sulfur-containing analytes. A few characteristics of GC detectors are given in Table 30.1.

30.3.2
Modes of Separation

30.3.2.1 Gas–Liquid Chromatography (GLC)

In GLC, the important parameters are the nature of the liquid SP and the temperature. The MP is inert and relatively unimportant in determining the mode of separation. Historically, GLC is also referred to as *partition chromatography* since the separation mechanism is based on partition equilibration of the analyte between the liquid and gas phase.

Hundreds of high boiling liquids and some solids have been used as SPs, providing a wide variety of available chemical properties (e.g., polarity, chemical functionality) and physical properties (e.g., particle size, film thickness). In fact, there are too many to enable one to select the very best one for a given analysis. However, with the current emphasis on the very efficient capillary columns, the need for high selectivity has decreased and only a few carefully chosen SPs are necessary to handle most analyses. A family of silicone polymers that differ in the functional groups they contain has become the most popular SPs. The least polar one is a polydimethylsiloxane polymer abbreviated as PDMS. Replacement of the methyl groups with more polar ones like phenyl, cyano, or fluoro results in more polar phases. Another common polar SP is a polyethyleneglycol like Carbowax 20M. Interest in using the class of compounds known as *room temperature ionic liquids* (*RTILs*) is increasing. Often, phases are chemically bonded to the inside wall of a silica capillary tube to make WCOT columns. For a more complete description of the range of available choices and the criteria used in their selection, the reader is referred to works by Grob and Barry (2004) and McNair and Miller (1998) which cover this subject in detail. In this section, some examples are provided to illustrate the capabilities of GLC.

The gas chromatograms in 30.5, which were used to illustrate PTGC, show the separation of a mixture of aliphatic hydrocarbon standards as described earlier. The hydrocarbons are typical of those found in gasoline-range petroleum products. The subscript *i* in the designation C_i refers to the number of carbon atoms found on the straight-chain backbone of the molecule. These chromatograms were obtained on a capillary column (coated with a nonpolar liquid phase) using column temperature programming and an FID. The nonpolar hydrocarbons have a high affinity for the nonpolar SP. A given hydrocarbon will reside in the SP until the temperature is raised high enough to generate a partial vapor pressure sufficient to increase its equilibrium concentration in the carrier gas, relative to its concentration in the SP. Therefore, the separation mechanism is primarily based on the differences in boiling points among the different hydrocarbons. The PTGC analysis begins with the column at a low temperature, below the boiling point of all the hydrocarbons. As the temperature of the column is gradually increased, hydrocarbons with successively higher boiling points are successively eluted. This type of analysis is a standard test method for determining the boiling range distribution of petroleum products, a so-called simulated distillation.

Columns are often developed and optimized for specific applications. For example, a polar SP, consisting of methyl phenyl cyanopropyl silicone bonded to a fused-silica open tubular (FSOT) column, was developed specifically for the trace analysis of tetrachlorodibenzo-p-dioxins. Analysis of these compounds is very important because of their extreme toxicity, particularly 2,3,7,8-tetra-chlorodibenzo-p-dioxin, which is classified as a supertoxic material. The chromatogram shown in Figure 30.6 is for nine isomers of tetra-chlorodibenzo-*p*-dioxin that differ only in the position of the chlorine atoms on the aromatic ring structure. The GC effluent is monitored with mass spectrometric detection, using selective monitoring of ions with mass-to-charge ratios of 320 and 322. These values correspond to the molecular weights of ions formed by ionization of the tetra-chlorodibenzo-*p*-dioxin molecule (i.e., no fragmentation), taking into account the natural relative abundance of the chlorine isotopes, ^{35}Cl and ^{37}Cl. The location of the chlorine atoms influences the relative polarities and boiling points of the individual isomers. Both properties are exploited in the separation shown in Figure 30.6.

The effect of column polarity on retention in GC is further illustrated by the example shown in Figure 30.7. Here, the injected sample, containing 25 different organic solvents, is split and chromatographed simultaneously on two capillary columns. The upper trace is the chromatogram obtained on a nonpolar column, while the lower trace is the chromatogram obtained on a polar column. Detection is achieved by the use of flame ionization detectors for effluent from each column. Notice that polar compounds such as ethanol, isopropanol, *n*-butanol, and 3-methyl-1-butanol elute more quickly from the nonpolar column than they do from the polar column, where their affinity

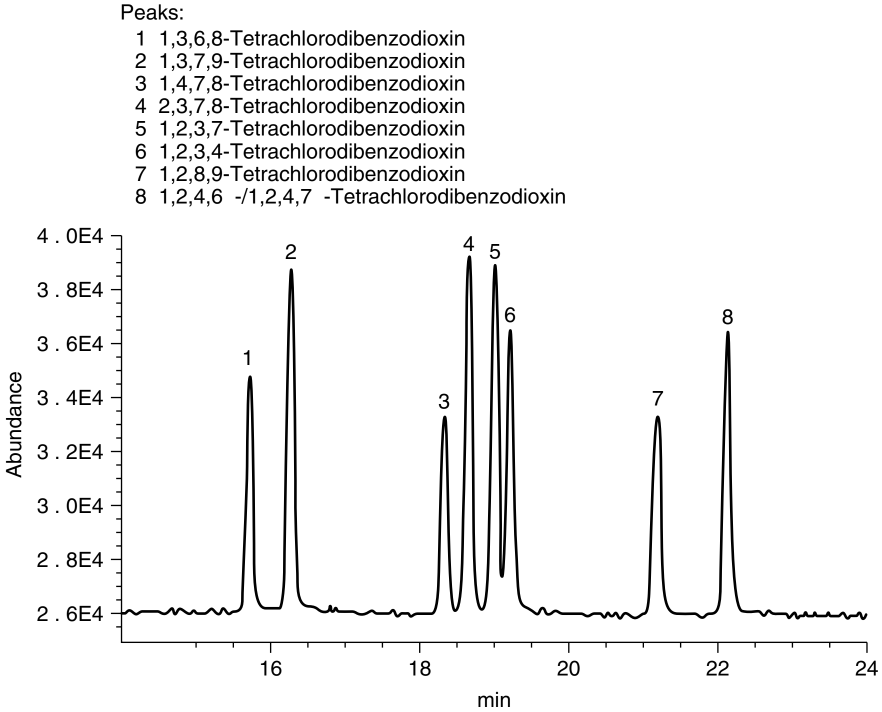

Fig. 30.6 Gas chromatogram of nanogram mixture of dioxins. Column: 35-m-long × 0.32-mm-i.d. fused-silica column, coated with 0.25-µm film of methyl phenyl cyanopropyl silicone. Column temperature: held for 0.5 min at 70 °C, then at 30 °C min^{-1} to 200 °C, then at 5 °C min^{-1} to 270 °C. Carrier gas: helium. Sample introduction: splitless injection. Detector: mass spectrometer, selected ion monitoring at m/z 320 and m/z 322. Peak assignments as noted in legend. (Quadrex Corp., 1990); reprinted with permission.

for the SP results in longer retention times. Also notice that within a series of like compounds (e.g., methyl, ethyl, isopropyl, and butyl acetate), elution is in the order of increasing boiling point on both columns, similar to the effect observed in Figure 30.5.

30.3.2.2 Gas–Solid (GSC)

GSC refers to GC performed on solid SPs. Whereas in GLC every attempt is made to minimize adsorption of solutes on active sites on the support (so that partition is based solely on liquid–liquid interactions), adsorption is the principal separation mechanism in GSC. Typical materials used as SPs include porous polymers, silica gel, diatomaceous earth (a natural form of silica), crushed firebrick, porous carbon, and zeolites (also commonly referred to as *molecular sieves*). One unique GSC separation using a molecular sieve can separate oxygen and nitrogen, as well as the other permanent gases (e.g., hydrogen, nitrogen, oxygen, argon, carbon monoxide, and carbon dioxide) and low-boiling compounds (e.g., methane, ethane, ethylene, and acetylene).

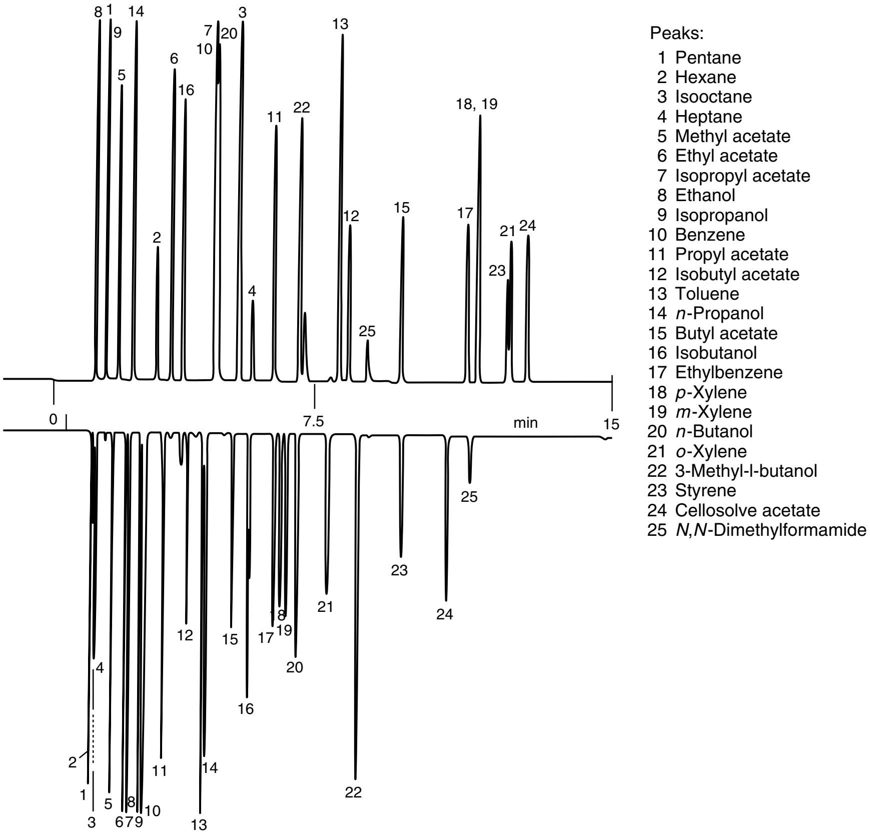

Fig. 30.7 Gas chromatograms of a mixture of organic solvents. Upper chromatogram column: 25-m-long × 0.32-mm-i.d. fused-silica column, coated with 1.0-μm phenyl vinyl methyl silicone film. Lower chromatogram column: 25-m-long × 0.32-mm-i.d. fused-silica column, coated with 0.50-μm polyethylene glycol film. Column temperature: held for 3 min at 35 °C, then at 5 °C min^{-1} to 100 °C. Carrier gas: helium, 1.5 mL min^{-1}. Sample introduction: split injection. Detectors: dual flame ionization (FID). Peak assignments as noted in legend. (HNU/Nordion Systems, 1990); reprinted with permission.

30.4
Liquid Chromatography

Modern LC, also referred to as HPLC, was introduced as an analytical separation technique in the early 1970s, and it has become the most widely used chromatographic technique. HPLC complements GC in that it provides rapid analysis of thermally labile, nonvolatile compounds that would be difficult or impossible to do by GC. Some typical examples of applications of HPLC are separation and quantitation of individual components in complex mixtures, analysis of nominally pure compounds for trace impurities, and isolation of pure compounds for synthetic and/or identification purposes. It can be used to analyze solids or liquids. A typical sample is 10 μl of a 0.1–100-mg/ml solution of the sample in a suitable solvent, although quantities as small as 10^{-6} g can be analyzed.

30.4.1
Instrumentation

A typical HPLC instrument is shown schematically in Figure 30.8. A basic, simple instrument is depicted; additional solvents, mixing valves, precolumns, and filters are often necessary, in addition. The following discussion is limited to the components shown in the figure.

30.4.1.1 Solvent Delivery Systems

Unlike GC where the MP is inert, the HPLC MP actively competes with the SP for analytes. A partitioning takes place between the two phases, so the composition of the MP is very important and may require mixtures of liquids. In one type of solvent delivery system, proportioning valves deliver precisely controlled volumes of solvent from reservoirs to the mixing chamber. A liquid chromatograph may have as many as four reservoirs, enabling solvent mixtures to be used as the MP. The liquid MP is delivered from the mixing chamber to the top of the chromatographic column by a high-pressure pumping system with output capabilities as high as 40 MPa and flow rates in the range of 0.1–10 ml min^{-1}. Gradient elution techniques (*see* Section 30.4.2.5), where the composition of a two-, three-, or four-component MP is changed in a stepwise or continuous manner, are achieved by microprocessor control of the solvent proportioning valves. Gradient elution techniques in LC are used in much the same way that temperature programming is used in GC to enhance resolution. MPs commonly used in LC include water, dilute aqueous pH buffer solutions, acetonitrile, tetrahydrofuran, methanol, chloroform, hexane, and methylene chloride, as well as miscible mixtures composed of one or more of these solvents.

30.4.1.2 Injection Valves

Injector valves are designed to accommodate sample introduction of microliter or milliliter sizes. Sample loops are completely filled with sample while the MP

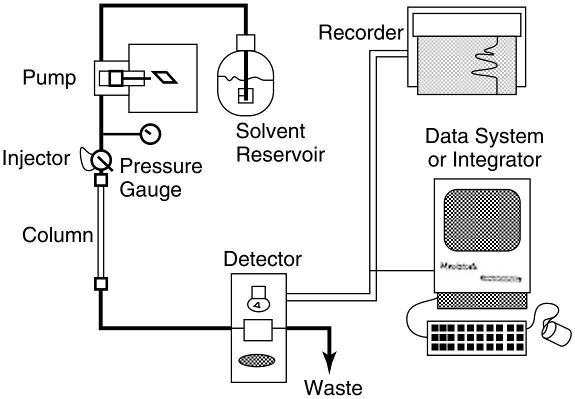

Fig. 30.8 HPLC schematic (Miller and Crowther, 2000); reprinted with permission.

is pumped through a different port on the valve. When the port to the sample loop is opened, the sample is flushed out of the loop by the MP and a precise amount of sample is delivered to the top of the chromatographic column. A typical injection volume is 1–100 µl. Automated systems based on these injection valves are commercially available.

30.4.1.3 **Columns**

The heart of the liquid chromatograph is the high-performance column on which the separation takes place. Typical columns are constructed from 3- to 25-cm lengths of 2–5-mm-i.d. stainless-steel tubing, although larger diameter columns (e.g., 60 cm) are used for preparative work and smaller diameter "microbore" columns (1 mm) for applications requiring advanced detectors (such as MS or Fourier-transform infrared (FTIR) spectroscopy). Columns are packed with small (3–50 µm) particles that constitute the SP. SPs with a variety of chemical and physical properties are available. As seen in Section 30.4.2, the choice of a SP/MP combination is dictated by the separation problem at hand.

Since chromatographic theory indicates that packed column performance will improve as the size of the SP particles is decreased, there has been a trend in column development toward smaller and smaller particles. There is a limit beyond which it is too difficult to pack these tiny particles and it is reached around 2- or 3-µm diameter. The smaller diameters that produce better performance also require higher pressures for fast analysis, and this situation has produced the latest version of HPLC commonly known as (*UHPLC*), *ultrahigh performance liquid chromatography*. UHPLC columns work at the limits of current technology, but they are the most efficient packed columns in use.

Another, alternative, commercial column introduced in 2001 is the monolithic column. Manufactured by a sol–gel process into a single stable rod, the monolithic columns so produced are enclosed in a plastic PEEK sheath. Compared to conventional microparticulate columns, the monolithic columns usually exhibit a lower pressure drop and can be operated with high efficiencies at higher flow rates.

30.4.1.4 **Detectors**

Most HPLC detectors are adapted from existing detection systems, many of which are spectroscopic. By far, the most common is based on the classic UV/Vis absorption spectrophotometer. As is the case with GC, MS is one of the most powerful and useful detectors to be used with HPLC, and it is discussed together with GC/MS. Table 30.2 summarizes some of the characteristics of the most common

Tab. 30.2 Common HPLC Detectors.

Spectroscopic
Ultraviolet absorption (UV/Vis)
Fixed wavelength UV
Variable wavelength UV
Photodiode array (PDA), also called *diode array detector* (*DAD*)
Fluorescence
Mass spectrometer (MS)

Refractive index (RI)
Evaporative light scattering detector (ELSD)

detectors and a brief discussion of some of them follows.

The refractive index (RI) detector functions as a nearly universal detector, that is, a detector that responds to nearly all analytes. This results from the fact that with the large number of available LC solvents, it is usually possible to design an experiment so that the analytes have refractive indices different from the MP. RI detectors are nondestructive and typical detection limits are about 10^{-6} g for a component in the injected sample.

UV/Vis absorbance detectors are among the most popular LC detectors because most organic compounds absorb 190–700-nm radiation, while many other compounds that do not absorb can be chemically reacted to form absorbing species. UV/Vis detectors are of three types: (i) fixed-wavelength detectors, which operate at only one wavelength (usually 254 or 280 nm, where a large percentage of organic compounds exhibit at least some absorbance); (ii) variable-wavelength detectors, which operate at any selected wavelength between 190 and 700 nm; and (iii) photodiode array (PDA) detectors, which can monitor the entire wavelength region between 190 and 700 nm.

PDA detectors have found increasing use in the past several years because of their utility in qualitative identification of unknowns by their characteristic UV/Vis absorbance spectra. UV/Vis detectors are nondestructive, and for a strongly absorbing compound, the lower limit of detection is about 10^{-9} g. Further details on UV/Vis absorbance can be found elsewhere in the Encyclopedia.

Fluorescence detectors are more specific than UV/Vis detectors because not all compounds that absorb light subsequently fluoresce. The use of a fluorescence detector restricts the choice of a MP to one that does not fluoresce, and minute traces of fluorescent materials commonly present in solvents can cause problems. Fluorescence detectors are nondestructive and have detection limits of about 10^{-10} g. Further details on molecular fluorescence can be found elsewhere in the Encyclopedia.

There are several electrochemical detectors (ECDs). One measures the electrical conductivity of the LC eluent by applying an alternating voltage between two electrodes and measuring the resulting current. Conductivity is related to the current–voltage ratio and represents the contribution of the individual equivalent conductivities of all ions in solution. Another is amperometric in principle and causes a chemical transformation of the analyte. The effluent from the column passes a working electrode (one of three electrodes in the detector cell) set at a specific potential with respect to the reference electrode. If a species in the effluent can be oxidized or reduced at this potential, the transfer of electrons at the electrode–effluent interface serves as the detection signal. The main advantages of the amperometric detector are sensitivity (10^{-12} g) and selectivity (by prudent choice of the potential).

In the light-scattering detector (LSD), also known as the *evaporative light-scattering detector* (*ELSD*), the effluent from the column is nebulized and the resulting fine mist is introduced into a stream of preheated gas. The mist is passed through a high-temperature drift tube where the volatile solvent is vaporized, leaving very fine particles of solute in the carrier gas stream. Laser light scattered by these particles is detected by a PDA. These detectors are meeting the need for a universal detector, which has lower detection limits than the RI detector and is compatible with gradient elution techniques, unlike RI.

Other detectors are based on specific characteristics of the analyte (radioactivity, rotation of plane of polarized light). It should also be noted that the effluent leaving a nondestructive detector (RI, UV/Vis, fluorescence, FTIR) can be collected (in effluent fractions corresponding to separated components) and analyzed off-line by other analytical techniques, such as MS, FTIR spectroscopy, or nuclear magnetic resonance (NMR) spectroscopy. This very common approach for combining powerful separation and identification tools can allow unambiguous identification of unknown components in a complex mixture.

30.4.2
Modes of Separation

As was shown in Figure 30.1, the classification of HPLC methods is not primarily according to the states of the two phases, as was the case with GC, but is more extensive. The exception is liquid–solid chromatography (LSC). Other modes, as shown in Figure 30.9, usually carry the name of the mechanism by which the separation is achieved. Also note in Figure 30.9, that another difference in the classifications, compared with GC, is the identification of those methods performed on plane surfaces, not in columns. The major one of this type is thin-layer chromatography (TLC), which is discussed separately from the column methods in Section 30.4.4.

30.4.2.1 Liquid–Solid Chromatography (LSC)

LSC is also called *adsorption chromatography* since the mechanism of the separation is mainly adsorption. It is the oldest of the various LC modes and was the one used by Tsweet. It combines a polar SP (silica or alumina) with a nonpolar or slightly polar MP (e.g., heptane, hexane, or pentane, possibly mixed with a more polar solvent like methylene chloride, chloroform, or isopropanol). Variable amounts of trace

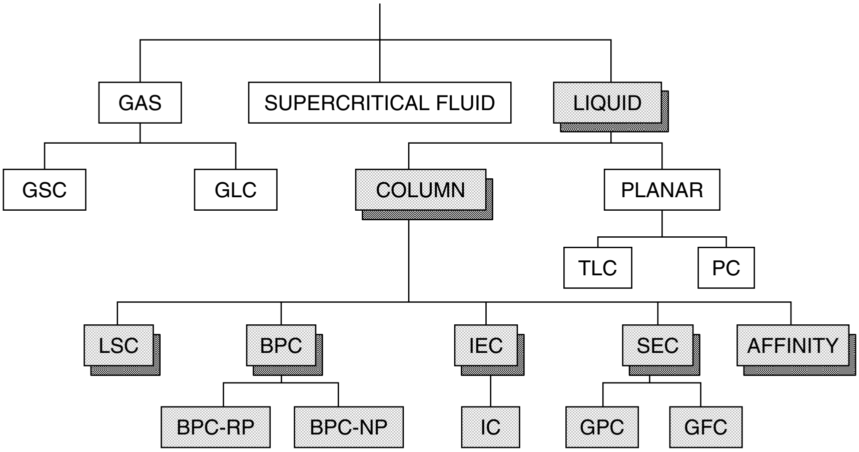

Fig. 30.9 Classification of liquid chromatographic techniques (Miller and Crowther, 2000); reprinted with permission.

water in these commonly used solvents presented a major problem with stability and reproducibility, which led to its loss of popularity. Since this system was originally the major one in use, it is also referred to as *normal phase* (*NP*) HPLC. Ironically, that name is still used even though LSC is currently not the normal mode of operation.

In general, polar molecules are strongly adsorbed on these SPs; therefore, they are the last to elute from the column. The opposite is true for nonpolar molecules. In Figure 30.10, a NP

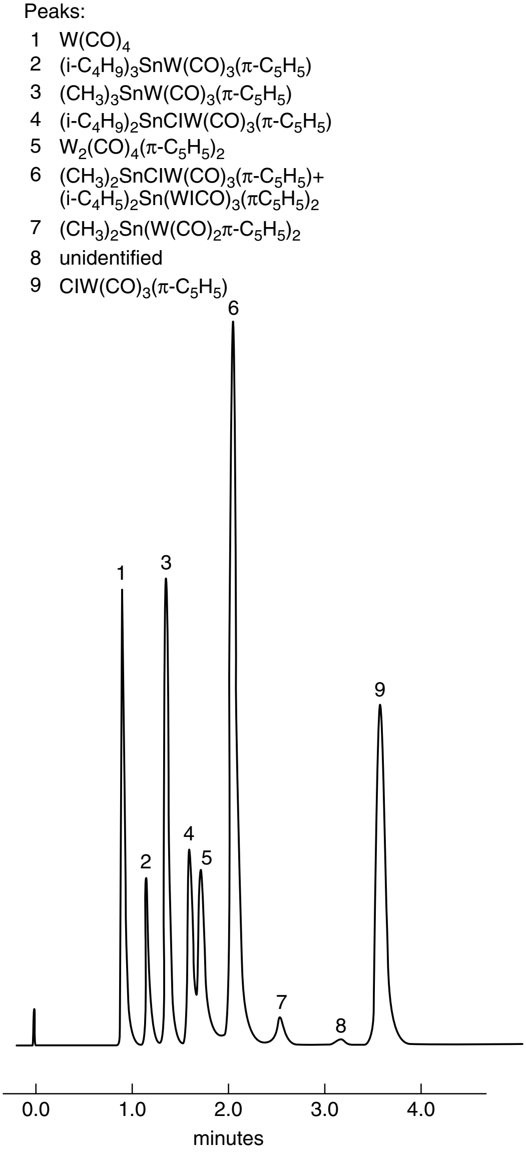

Fig. 30.10 Normal-phase liquid chromatogram of a mixture of tungsten carbonyl and tungsten tin carbonyl complexes. Column: 15-cm long × 4.6-mm i.d., 3-µm particles, cyano. Mobile phase: 10 : 90 mixture of tetrahydrofuran:hexane, 2 mL min^{-1}. Detector: UV absorbance at 220 nm. Peak assignments as noted in legend (Dewaele, 1990); reprinted with permission.

chromatogram of a mixture of tungsten carbonyl complexes and tungsten tin carbonyl complexes is shown (Dewaele, 1990). This chromatogram was obtained on a cyano column with detection based on UV absorbance at 220 nm. While LC is most commonly used for separation of organic materials, this example demonstrates its utility in resolving a complex synthetic mixture of organometallic compounds. While normal-phase chromatography (NPC) is particularly suited to nonpolar or moderately polar compounds that are not water soluble, it is not restricted to these cases.

30.4.2.2 Bonded-Phase Chromatography (BPC)

LSC and LLC have been replaced for the most part by bonded-phase chromatography (BPC) in which a liquid phase is chemically bonded to a solid support to become the SP. The main advantage of BPC compared with LLC is that the SP is stable and not susceptible to physical or chemical removal by action of the MP. The most common SPs are those bonded to siloxanes (see Table 30.3), although organic resins are returning to use after a decline in popularity in the 1970s and 1980s. Siloxane-based packing materials are prepared by silanization of the surface hydroxyl groups on the silica particles with alkylchlorosilane compounds. For example, an octadecyl column would be prepared by reaction of the silica particles with a solution of dimethyloctadecylchlorosilane to produce a chemically modified surface. It will be seen that the functional group bonded to the SP critically affects the types of separations that can be performed; some are for NPC, and others are for phases of opposite polarity, called *reversed phase* (*RP*).

30.4.2.3 Reversed Phase Chromatography (RPC)

The production and use of BPC in which the SP is nonpolar has become very popular. Since the polarity of such columns is the opposite or reverse of those used in LSC, their use has been designated as reversed-phase chromatography (RPC). This definition applies to nonpolar columns, whether or not they are the bonded type. The MP used with them is polar, making RPC complementary to NPC.

Typically in RPC, a hydrocarbon-bonded support, such as methyl-, octyl-, or octadecyl-siloxane (ODS), is used with an MP composed of water, methanol, acetonitrile (ACN), tetrahydrofuran, or a mixture of some or all of these solvents.

Tab. 30.3 Bonded-phase chromatography stationary phases.

Designation	Surface chemical formula
Silica (Si)	Si-OH
Amino (NH_2)	$Si\text{-}O\text{-}Si(OH)_2\text{-}(CH_2)_3\text{-}NH_2$
Cyano (CN)	$Si\text{-}O\text{-}Si(CH_3)_2\text{-}(CH_2)_n\text{-}CN$
Methyl (C_1)	$Si\text{-}O\text{-}Si\text{-}(CH_3)_3$
Phenyl (C_6)	$Si\text{-}O\text{-}Si\text{-}(CH_3)_2\text{-}C_6H_5$
Octyl (C_8)	$Si\text{-}O\text{-}Si\text{-}(CH_3)_2\text{-}(CH_2)_7\text{-}CH_3$
Octadecyl (C_{18})	$Si\text{-}O\text{-}Si\text{-}(CH_3)_2\text{-}(CH_2)_{17}\text{-}CH_3$

In RPC, the more polar materials have greater affinities for the MP and so elute first.

Consider, for example, the RP chromatogram of a mixture of sugars shown in Figure 30.11. This chromatogram was obtained on an amino column with gradient elution using an acetonitrile/water MP and detection based on laser light scattering (Letter, 1991). The individual sugars elute in three groups, with the low molecular weight (MW = 180) fructose and glucose molecules first, the higher molecular weight (MW = 342) sucrose, maltose, and lactose molecules next, and the highest molecular weight (MW = 504) raffinose molecule last. For these sugar molecules, polarity (and order of elution) is a function not only of the molecular weight but also of the relative position of the polar hydroxyl and hydroxymethyl groups on the molecule. The latter accounts for the excellent separation even among molecules with the same molecular weight.

30.4.2.4 **Ion-Pair Chromatography (IPC)**

When ions are present in samples run by RPC, they typically elute very quickly (with little or no retention) because they do not interact appreciably with the nonpolar SP. As a consequence, they are not separated from one another. One way to remedy this situation is to add a counterion to the MP and form ion pairs that are uncharged. Reversed-phase ion-pair chromatography (RPIPC) is performed with conventional RP LC columns and with polystyrene-divinylbenzene resins that have no ion-exchange sites. The MP contains ions that combine with the sample ions to create neutral ion pairs.

For example, the separation of a mixture of carboxylic acids by RP could be done using a MP that has a low pH, so that the acids would be present

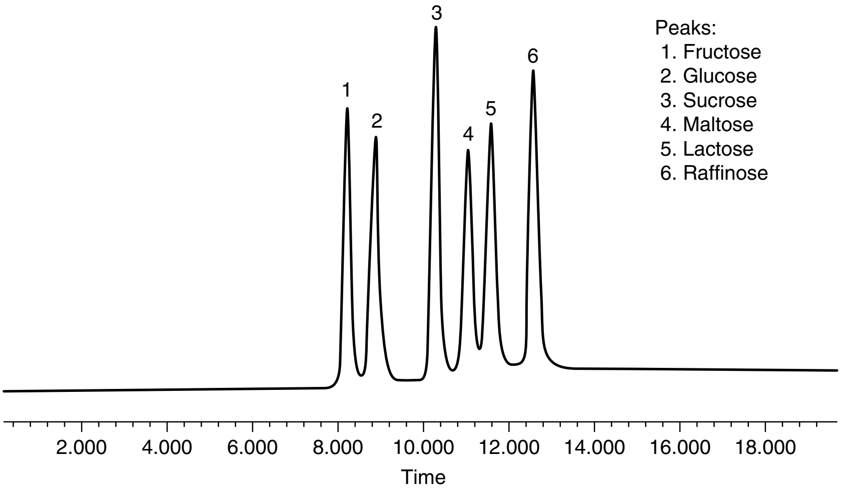

Fig. 30.11 Reversed-phase liquid chromatogram of a mixture of sugars. Column: 25-cm long × 4.6-mm i.d., 10-μm particles, amino. Mobile phase: initially 85 : 15 acetonitrile:water, then linear gradient to 60 : 40 acetonitrile:water over 10 min; 1.5 mL min^{-1}. Detector: laser light scattering. Injection size: 20 μL. Peak assignments as noted in legend (Letter, 1991); reprinted with permission.

as neutral carboxylic acids. However, if it were necessary to run the sample at a pH above that of the pK_a of the acids, the acids would be present as the carboxylate anions. To make them neutral, the addition of a cationic tetraalkylammonium ion would form neutral ion pairs with the carboxylate anions and they would likely be separated by this methodology, RPIPC.

30.4.2.5 **Gradient Elution**

Isocratic separations, where the MP is unchanged throughout the chromatographic process, often give poor resolution of early-eluting peaks, significant band spreading of late-eluting peaks, and unnecessarily long separation times. The solution to these problems is gradient elution, where the MP composition is continuously changed during the separation. It is used to speed the elution of strongly retained compounds or to retard the elution of early-eluting compounds. For optimum resolution and speed of analysis time, it is necessary to begin with a MP just strong enough to dissolve the most soluble species in the sample, and finish with a MP strong enough to remove the most insoluble species from the column. The resulting separation is optimized similar to the way GC separations are optimized by programmed temperature operation.

30.4.2.6 **Ion-Exchange Chromatography (IEC) and Ion Chromatography (IC)**

IC and ion-exchange chromatography (IEC) are used for the separation of ionic compounds, inorganic and organic. IEC is performed on SPs that possess ionic sites on the surface, using aqueous, ion-containing MPs. Columns are packed with small (5–25 μm) particles of polystyrene-divinylbenzene resin or (less commonly) silica whose surfaces are chemically modified for specific applications. For anion analysis, the SP particles have surface cationic sites such as amines ($NR_3{}^+$). For cation analysis, the SP has surface anionic sites such as sulfonates ($SO_3{}^-$).

In classical IEC, separation is based on ion exchange of sample ions (X) and MP ions (Y) with the charged groups (S) of the SP. If anions are to be separated (anion exchange), the SP contains cationic groups and the reaction in the column follows Eq. (30.9).

$$X^- + S^+Y^- \longrightarrow Y^- + S^+X^- \quad \text{(anion exchange)} \tag{30.9}$$

Conversely, to separate cations (cation exchange), the stationary contains anionic groups as shown in Eq. (30.10).

$$X^+ + S^-Y^+ \longrightarrow Y^+ + S^-X^+ \quad \text{(cation exchange)} \tag{30.10}$$

Sample ions are in competition with MP ions for sites on the ion-exchange resin that serves as the SP. Sample ions that do not bind as strongly to the resin as MP ions will elute early in the chromatogram, while sample ions that interact more strongly will be retained and elute later in the chromatogram.

A significant advance in the practice of IEC resulted from the work of Small, Stevens and Bauman (1975) who modified IE methods so that universal detection of ions at very low concentrations became possible. The method, called *IC*, uses a conductivity detector and a second column that permits the reduction of the background conductivity of the MP to reduce the magnitude of the baseline signal. The sample must be in aqueous form for introduction into the chromatograph. A typical sample is 50 μL of a 0.1–100-mg/L solution of the sample in a suitable solvent.

MPs commonly used in IC are dilute (approximately 10^{-3}–10^{-5} molar) aqueous solutions of ionizable materials such as sodium hydroxide, hydrochloric acid, mixtures of sodium carbonate and sodium bicarbonate, and mixtures of organic acids such as oxalic acid, citric acid, and tartaric acid. In RP IC, water-soluble organic solvents such as methanol and acetonitrile can be added to the MP. Quantities as small as 10^{-6} g can be analyzed.

30.4.2.7 **IC Instrumentation**

Measuring the small conductivity due to an eluting ion in the presence of the high background conductivity of the MP is difficult. Suppression of the conductivity of the MP, or eluent, dramatically improves the sensitivity (Small, Stevens and Bauman, 1975). Consider the example where a sodium hydroxide MP is used to separate anions. A low concentration of sample anions exits from the column containing the SP along with a high concentration of sodium and hydroxide ions. The column effluent is then passed through a second cation-exchange column (suppressor column), with hydrogen ions attached to the ion-exchange sites on the resin. Sodium ions displace hydrogen ions from these sites, with two beneficial results. First, water is formed by the reaction

$$\mathrm{Na^+OH^-} + S^-\mathrm{H^+} \longrightarrow \mathrm{H_2O} + S^-\mathrm{Na^+} \qquad (30.11)$$

Therefore, the effluent from the suppressor column has the very low conductivity of deionized water (as opposed to the high conductivity of a sodium hydroxide solution) and provides an excellent background for sensitive conductivity measurements on the anions. Second, the sample anions are paired with hydrogen ions instead of sodium ions as a consequence of the reaction

$$\mathrm{Na^+}X^- + S^-\mathrm{H^+} \longrightarrow \mathrm{H^+}X^- + S^-\mathrm{Na^+} \qquad (30.12)$$

As a result, detector sensitivity to the analyte anion is maximized because the equivalent conductivity of the hydrogen ion is approximately seven times as large as that of the sodium ion. The situation for cation analysis is completely analogous. Here, an anion-exchange suppressor column loaded with hydroxide ions is used to suppress the conductivity of the MP. The development of fiber suppressors and membrane-type suppressors simplified the procedures for this type of detection and provided improvements in resolution and sensitivity compared to the use of column suppressors.

Nonsuppressed conductivity uses the same conductivity detector just described, but without suppression of the MP conductivity. This technique for ion analysis is sometimes referred to as *single-column IC*. Low background conductivity is achieved by use of low concentrations (10^{-3}–10^{-5} molar) of MPs composed of ions that have a high affinity for the SP. UV/Vis absorbance detectors can be used to detect ions that absorb radiation in the 190–700-nm range. Alternatively, light-absorbing species produced by post-column reaction of a nonabsorbing ion with a complexing reagent can be detected. An example of this is absorbance detection at 520 nm of the complexes formed between 4-(2-pyridylazo)-resorcinol (PAR) and transition-metal ions such as Fe(II), Fe(III), Cu(II), Ni(II), Zn(II), Co(II), and Pb(II). Finally, absorbance detection can be accomplished using a UV/Vis-absorbing MP (e.g., phthalate buffers) to detect nonabsorbing ions. Here, eluting ions decrease the measured absorbance and are observed as negative peaks in the chromatogram. Limits of detection for electrochemical and UV/Vis detectors are approximately the same as for LC.

In Figure 30.12, the ion chromatogram of an aqueous mixture of 34 anions, both inorganic and organic, is shown. This chromatogram was obtained with suppressed conductivity using a ternary solvent system of sodium hydroxide.

In Figure 30.13, the separation of alkali-metal cations, as well as of the ammonium ion, is achieved using a cation-exchange resin. This chromatogram was obtained on a surface-sulfonated cation-exchange resin using dilute hydrochloric acid as the MP and eluent-suppressed conductivity detection. The observed retention behavior results from the increasing affinity of the cations for the SP as the ionic radius is increased.

30.4.2.8 **Size-Exclusion Chromatography (SEC)**

Size-exclusion chromatography (SEC) is used to separate molecules on the basis of their physical size. SEC with aqueous MPs is sometimes referred to as *gel filtration chromatography* (*GFC*), while SEC with nonaqueous MPs is sometimes called *gel permeation chromatography* (*GPC*). SPs are porous silica microspheres (e.g., 5-µm particles) or polymer

beads that have porous microstructures with very well controlled pore size distributions. Typical pore sizes in these particles range from 6 to 100 nm. Molecules that are too large to permeate the pores in the particle travel around the particles and appear first in the chromatogram. Small molecules that can permeate the pores travel a long and tortuous path through the particles; therefore, they have longer retention times. MPs are chosen on the basis of their solvating power for the sample. In order to restrict the retention behavior to size-exclusion effects, it is essential that the components in the sample have a very high solubility in the MP. In the size-exclusion chromatogram shown in Figure 30.14, the components elute in the order of decreasing molecular weight (Yost, Ettre and Conlon, 1980). An important application of SEC is the analysis of molecular weight distributions of polymeric materials.

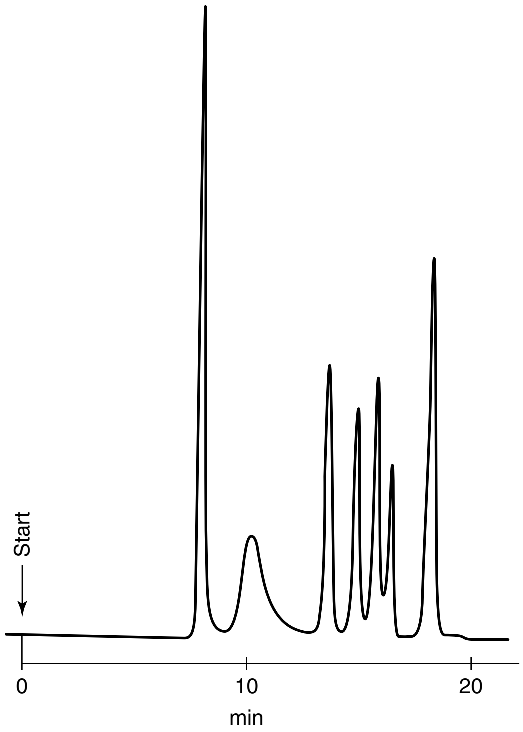

Fig. 30.14 Size-exclusion chromatogram of a mixture of organic molecules and polystyrene molecular weight standards. 30.4.3
Preparative Liquid Chromatography

The objective in preparative LC is to isolate significant quantities of chemical compounds in a high-purity form. The amount of material can be very large (grams), as might be required for synthetic applications, or quite small (milligrams) for the purpose of chemical identification and analysis by other instrumental methods. For small-scale preparative LC, a standard liquid chromatograph can be used, with the addition of high-sample-capacity columns (diameters of 0.7–2.5 cm) if necessary. Large-scale industrial preparative liquid chromatographs have large MP reservoirs, large flow-rate capabilities, large-capacity columns (some as high as 60 cm in diameter), and automated fraction collection systems. In preparative LC, the capacity of the column is frequently exceeded, so that resolution is much poorer than would be realized in a normal analytical separation. A common strategy is to load as much sample onto the column as possible without degrading the resolution to the point where it is not possible to isolate a pure fraction. This strategy minimizes the number of repeated injections and fraction collections necessary to obtain the required quantity of purified material. Prep LC continues to develop and some recent papers can be found in the *Journal of Chromatography A* (2003, Vol. 1006. Seidel-Morgenstern, A.).

Preparative separations are especially useful in chiral separations whereby production quantities of chiral drugs can be produced. For more information about chiral separations, see Section 30.7.2.

30.4.4
Thin-Layer Chromatography

Most of the techniques shown in the chromatographic classification schemes in Figures 30.1 and 30.9 are carried out in columns. The exception is the one-labeled planar, consisting of two techniques, paper chromatography (PC) and TLC. PC was the older technique and it has been largely replaced by TLC. In classical TLC, the SP is dispersed on the surface of a planar surface like a square glass plate, and the samples are applied as spots on one edge of the plate using a pipet or an eye-dropper. The plate is then dipped in a solvent reservoir and MP-flow through the SP occurs as a result of capillary forces. The components in the sample are spatially separated on the plate and are detected by charring, chemical staining, UV/Vis reflectance, radiographic, or fluorescence techniques. The physical and chemical mechanisms for separation in TLC are the same as those in modern column LC, but there are some small differences due to the fact that the MP is moving on a dry bed and the flow is not controlled. The most common SP is silica gel, which means that the separation mode is most often NP. However, RP TLC plates are also available, and most of them are available in a small particle size, giving rise to higher performance, so-called high-performance thin-layer chromatography (HPTLC).

Instrumental and automated methods for TLC have been developed. New techniques for applying the sample to the plate have also dramatically improved the resolutions that can be achieved. Instrumental methods for recording chromatograms such as densitometry, UV/Vis absorbance, and fluorescence have reduced the time required for analysis, while providing detection limits as low as 10^{-12} g (using fluorescence detection). Most dramatic are instrumental methods for forced flow of the MP, which can reduce separation times and improve separation efficiencies, because smaller SP particles and larger plate sizes can be used. The most popular of these methods is called *overpressurized layer chromatography* (*OPLC*) the instrumentation for which has been available for about 25 years. Excellent details are given in the chapter on OPLC in Sherma and Fried's, 2003 *Handbook*, a useful reference for all of TLC. Instrumental methods are more popular in Europe than in the United States, where most TLC is still performed manually. The determination of acrylamide in drinking water by HPTLC combined with MS is a typical example of instrumental TLC (Alpmann and Morlock, 2008); the authors show that their results are comparable to those obtained by HPLC/MS.

30.5
Supercritical Fluid Chromatography (SFC)

SFC is not as popular as GC or HPLC. The name implies that the MP is a supercritical fluid and has properties between a gas and a liquid. The classification system shown earlier in Figure 30.1 appropriately shows SFC placed between GC and LC. It was introduced in the early 1960s by Klesper, Corwin and Turner (1962) at a time when HPLC was being developed and some chromatographers used sufficiently high pressures to create supercritical fluids. Advocates of SFC claim that it has the best attributes of GC and HPLC, and that it has the performance characteristics of a *unified* chromatographic system. Carbon dioxide is the most commonly used MP, and therefore SFC more closely resembles normal-phase HPLC.

In an age of concern about the environment, its use is highly desirable and has caused SFC to be labeled as a green process (Anon, 2007). This characteristic is especially important for preparative work.

Numerous separations and analyses of high-molecular-weight, thermally unstable, relatively nonvolatile compounds not suitable for analysis by GC were pursued during the remainder of the decade. However, with the advent of the more convenient method of HPLC in the 1970s, interest in SFC subsided rapidly. There was renewed interest with the introduction of the first commercial SFC instrument in 1982, and since then there have been technological advances in SFC instrumentation that have further popularized the technique. Applications that would be difficult or impossible to do by either GC or HPLC have been shown to be amenable to analysis by SFC (Griffiths, 1988). Examples include the separation of lipids and phospholipids, pharmaceutical products, as well as fuel oil distillates that can be separated into fractions corresponding to particular chemical families (e.g., paraffins, olefins, naphthelenes, and aromatic compounds). SFC can be used to analyze solids and liquids in amounts ranging from 10^{-2} to 10^{-12} g.

30.5.1
Operating Characteristics

A supercritical fluid is a substance that is above its critical temperature and pressure. By far the most common supercritical fluid used as a chromatographic MP is carbon dioxide, which has a critical point of 31 °C and 7.4 MPa. At the critical point, carbon dioxide has a density of 0.448 g/mL. Since carbon dioxide is relatively nonpolar, modifiers such as methanol, ethanol, acetonitrile, propylene carbonate, and water are sometimes added to increase MP polarity and therefore the solvating power for some samples. Other less commonly used MPs in SFC include ammonia, nitrous oxide, and sulfur dioxide.

SFC requires well-regulated control of both temperature and pressure. The high pressures are usually achieved by compression of a gas (e.g., carbon dioxide) with a high-pressure syringe pump. The condensed MP is then heated to supercritical temperatures. Some properties of supercritical fluids, such as solvating power, diffusion, and viscosity, are functions of density (Smith, Wright and Yonker, 1988). Density programming (also called *pressure programming*, since MP density is a function of pressure) is therefore used to improve resolution in SFC separations in an analogous way to that in which temperature programming and gradient elution are used in GC and LC, respectively. Pressure programming is achieved by microprocessor control of the pressure in the fluid delivery system.

SFC instrumentation can be modeled after either GC or LC instrumentation and both types are available commercially; the columns used can be packed or OT. Packed-column instruments resemble HPLC instruments and OT column instruments resemble GCs. In either case, a restrictor is required at or near the exit to keep the pressure high enough to keep the fluid above its critical pressure. The simplest restrictor is a 10-μm-i.d. capillary tube joined to the column outlet by a zero-dead-volume union fitting. Instruments using packed columns have become more popular, and, like HPLC, the most popular detector is UV. SFC is flexible: preparative separations are possible as well as hyphenated SFC/MS instrumentation.

30.5.2
Modes of Separation

30.5.2.1 Isobaric SFC

The simplest form of SFC is performed at constant pressure, isobaric. As in GC and LC, the selection of a MP/SP combination is based on the requirements of the separation. Among the more important factors are sample polarity and solubility of the sample in the supercritical fluid. In Figure 30.15, the supercritical fluid chromatogram of a mixture of hydroxybenzoic acids is shown (Berger and Deye, 1990). This chromatogram was obtained on a NP (cyano) LC column with a carbon-dioxide-based MP. Methanol and citric acid are added to the supercritical carbon dioxide to increase the solubility of the polar hydroxybenzoic acids in the MP. In the absence of these additives, the elution of the more polar, strongly retained components would occur with poorer resolution and only after much longer times.

30.5.2.2 Pressure Programming

Isobaric separations often suffer from the same problems that occur in isothermal GC and isocratic LC. The solution to these problems is pressure programming, where the density of the MP (and therefore the solubility of a given solute in the MP) is continuously increased during the separation by increasing the pressure. In Figure 30.16, three supercritical fluid chromatograms of a solution of the surfactant Triton X-114 are shown (Giorgetti *et al.*, 1989). These chromatograms were obtained on an RP (C18) LC column with a carbon-dioxide-based MP. The designator *n* in the figure denotes the number of monomer units in each polymeric surfactant molecule. Methanol was added to the supercritical carbon dioxide to increase the solubility of the surfactants in the MP. Comparison of Figure 30.16(a) and (c) clearly illustrates the beneficial effect that pressure programming can have on resolution. In addition, comparison of Figure 30.16(a) and (b) demonstrates the improvement in resolution that can be realized by increasing the methanol content in the MP in a linear fashion, much like gradient elution in LC.

30.6
Spectrochemical Detection

In prior sections, several spectroscopic detectors have been described, but one of them is of special importance: MS. The combination of a chromatographic instrument interfaced to MS is often referred to as a *hyphenated method* and designated as GC–MS or GC/MS, HPLC/MS, and so on. Multiple hyphenation, as in GC/MS/MS, is also common and sometimes called *hypernation*. These combinations can be considered to be multidimensional as well, and that topic is covered in Section 30.7.1.

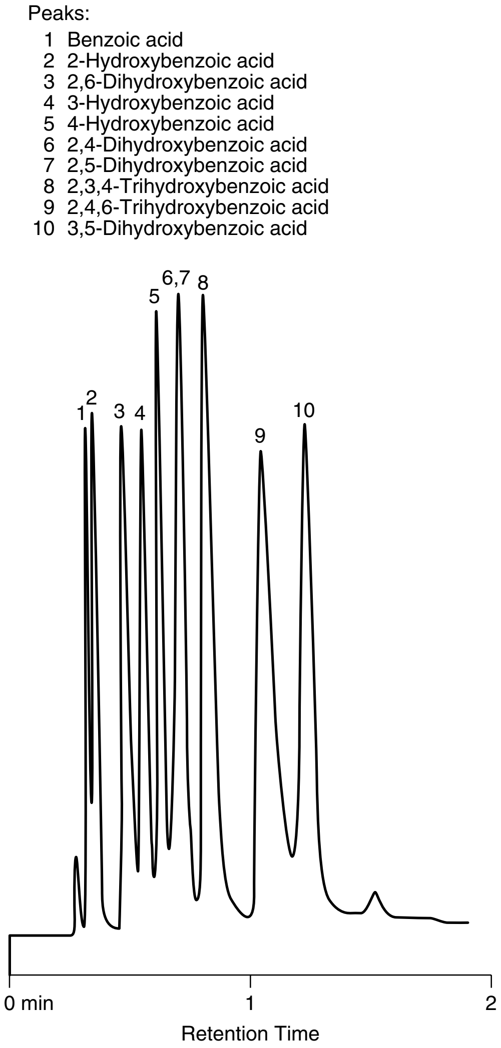

Fig. 30.15 Supercritical fluid chromatogram of a mixture of hydroxybenzoic acids. Column: 10-cm long × 2-mm i.d., normal phase, 7-µm particles, cyano. Column temperature: 60 °C. Mobile phase: carbon dioxide, containing 7.4% added methanol and 0.04% added citric acid. Pressure: 20 MPa. Flow rate 1.0 mL min^{-1}. Sample introduction: 0.2 µL on-column injection. Detector: UV/Vis absorbance at 230 and 430 nm. (Berger and Deye, 1990); reprinted with permission.

An alternative way of describing these combinations is simply to consider the mass spectrometer to be the detector attached to the chromatographic system. Thus, it is sometimes called the *MSD*, or the *mass selective detector*. Mass spectroscopists could also consider the chromatograph to be a special inlet system for MS. No significance is attached to either concept in this section, which is mainly concerned with GC/MS and LC/MS. Later, some discussion is included on the other hyphenated MS methods and other chromatographic combinations such as those with FTIR and NMR spectrometry.

With MS, it is possible to determine the molecular weight and molecular formula of an unknown compound.

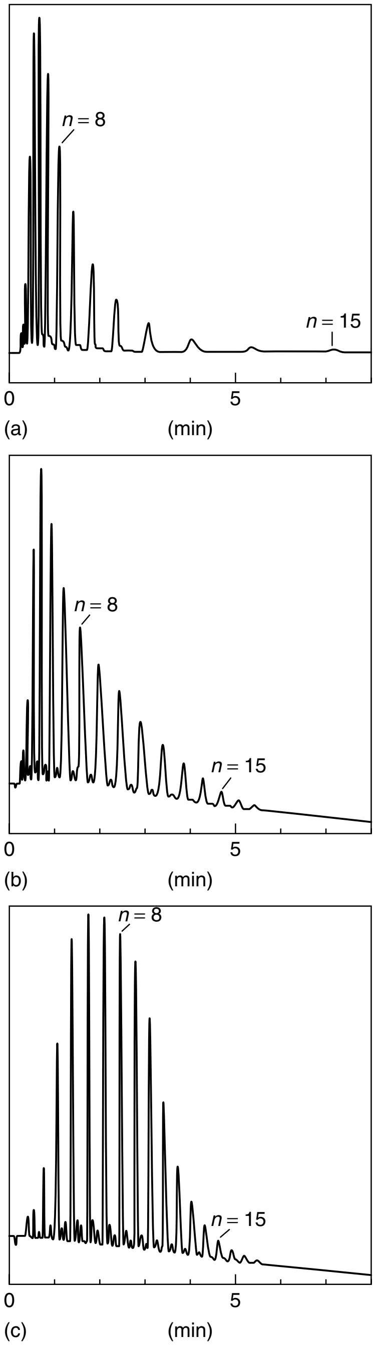

Fig. 30.16 Supercritical fluid chromatograms of the surfactant Triton X-114. Column: 10-cm long × 2-mm i.d. reversed-phase, 3-µm particles, C_{18}. Column temperature: 170 °C. Mobile phase: carbon dioxide with methanol modifier. Flow rate: 2 mL min^{-1}. Sample injection loop. Detector: UV absorbance at 278 nm. (a) Isobaric at 21.0 MPa, constant modifier flow (0.125 mL min^{-1}). (b) Isobaric at 21.0 MPa, modifier gradient (0.025–0.4 mL min^{-1} over 8 min, linear). (c) Pressure program (13.0–37.5 MPa in 8 min), constant modifier flow (0.125 mL min^{-1}) (Giorgetti *et al.*, 1989); reprinted with permission.

In addition, characteristic fragmentation patterns (produced by sample ionization) can be used to deduce molecular structure. Spectrometers in common use with chromatographic systems include quadrupole analyzers, quadrupole ion-trap mass spectrometers, and magnetic/electrostatic dual-focusing instruments. Time-of-flight (TOF) mass spectrometers are becoming increasingly popular. Typical detection limits of about 10^{-12} g can be realized with MS.

Data from a conventional mass spectrometer can be collected in two ways, total ion chromatogram (TIC) and single ion, called *single ion monitoring* (*SIM*). In TIC (also called *scan mode*), all ions detected are displayed as one signal, so the output looks just like a chromatogram from any other chromatographic detector. Any peak in this TIC can be examined to see what ions it contains, and this information is used primarily to identify unknowns as just described. By comparison, the SIM output is set to display only those ions (of a given mass-to-charge ratio) that have been chosen for collection. So, for example, if the mass of a particular analyte or analyte fragment is chosen as the single ion, the only peaks in the chromatogram will be for peaks that contain that ion. If a characteristic fragment ion is chosen, all analytes that fragment to give that ion, and only that ion, will appear in the chromatogram. Up to six ions can be acquired using conventional MS software. SIM is more selective and sensitive than TIC. Consider the difference between the acquisition of data over a range, which covers all possible ions (say 43–500), for a TIC, compared to one that collects data for only six ions, for a SIM. The former collects data for 76 times as many ions (457/6), so much more time is spent on each ion in SIM, increasing its sensitivity. Consequently, SIM is used primarily for quantitative analyses, often at trace levels.

Conventional chromatographic columns are normally operated so that the column exits are at atmospheric pressure, although it is possible to run a GC with a vacuum outlet. By comparison, mass spectrometers must be run under high vacuum. Thus, the process of joining the two involves an interface that can take a chromatographic effluent at atmospheric pressure and reduce it to a vacuum condition (about 10^{-6} torr). As will be seen, this process is different in GC and HPLC, but has been ideally achieved in both cases. It is much easier to couple a GC effluent to an MS than an HPLC effluent, which contains a liquid MP and often a buffer both of which have to be removed or enriched or exploited (solvent-assisted ionization).

Consequently, GC/MS was the first hyphenated technique to be successfully produced (1959) and it has become a relatively simple and cost-effective instrumental method. Bench-top instruments have become smaller and mass production has allowed the costs of instruments to decrease. Both parts of the instrument as well as all data are handled by computer, and these too have improved and become less expensive.

The actual identification of an unknown analyte can be accomplished by matching its mass spectrum from the TIC with reference spectra available in the MS software. The largest MS data base, containing over 130 000 spectra, is available from NIST.

30.6.1
GC/MS

The basic incompatibility between a gas chromatograph and a mass spectrometer is the pressure difference. The chromatograph separates components at column pressures of about 10^5 Pa with carrier gas flow rates of 0.1–100 ml min^{-1}, while the ion source of the mass spectrometer operates at pressures of about 10^{-4} Pa (10^{-6} torr). OT columns up to 0.32 mm i.d. are well suited for use in a GC coupled to an MS because of their low flow rates, typically 1–2 ml min^{-1}. The type of interface, called *direct*, is used with OT (capillary) columns. The end of the OT column is extended from the GC directly into the ion source of the MS. The GC flows are low enough, and the vacuum pumping high enough, that the necessary vacuum required by the mass spectrometer can be easily maintained. In this arrangement, the outlet of the GC column is operated at vacuum. This is not common, but it has been shown that vacuum operation can, in fact, be advantageous (Cramers, Scherpenzeel and Leclercq, 1981).

Further details on mass spectrometers can be found elsewhere in the Encyclopedia as well as in books by Oehme (1999) and McMaster (2008).

Today, GC/MS has become almost as routine as GC itself, and a GC/MS system is an essential part of most GC research labs. For the analysis of volatile samples, there is no better instrument.

30.6.2
LC/MS

MS can also be interfaced with a liquid chromatograph for perhaps the ultimate in identification capabilities. The past few years have seen major changes and improvements in LC/MS. Interfacing was initially more difficult, but a major innovation was the realization that interfaces could also serve as the ionization devices. This field is now in a growth spurt and has been adapted to handle biological samples that were previously considered impossible to be run by MS. Currently, LC/MS plays a major role in biotechnology due to its capability to perform rapid, high-resolution separations and identifications of large biomolecules. While LC/MS itself is not new, books covering the new advances and applications continue to be written (Ardrey, 2003; Niessen, 1999).

The key advances in instrumentation that made LC/MS possible were the development of narrow-bore (1-mm-i.d.) LC columns that can be operated at very low MP flow rates (as low as 0.1 mL min^{-1}), and interfaces for introducing liquids into the ion source of the mass spectrometer. In HPLC/MS, the ion sources also serve as the interfaces; thermospray ionization (TSI), electrospray ionization (ESI), and atmospheric pressure ionization (API) are the most popular. The latter two can be carried out at atmospheric pressure, a method of sampling that seemed impossible only a few years ago.

In adapting a HPLC method to LC/MS operation, several changes in MP composition need to be considered. These include

- increasing the volatility of the buffer;
- changing the pH;
- adding adducts, such as Na.$^+$

The MP needs to be volatile. Reversed-phase methods are usually ideal because the major components, water and methanol or ACN, meet this requirement. However, when buffers are used in RPLC, they also need to be volatile. Ammonium acetate is one example, and trifluoroacetate (TFA) can be used to form ion pairs with basic analytes, thereby making them neutral and decreasing their interference with MS detection.

30.6.3
Other Hyphenated Methods

Other spectroscopic instruments that have been interfaced to chromatographs are FTIR and NMR. Like the mass spectrum, an IR spectrum is a highly characteristic property of an organic compound. The complementary nature of IR and MS data makes the combination of them in series the most powerful method for analysis of unknowns by GC. In the case of GC/FTIR, large samples are desired because they facilitate detection by IR, but the vapor-state analytes are not easily sampled by IR. A light pipe has been designed that can be heated to keep the analytes in the vapor state and also meet the following requirements of a good IR cell for use with GC: small volume, long path length, and high transmission. A typical light pipe is 50 cm × 1 mm in size and has a reflecting gold coating. Its description and details of its use including the data handling requirements have been discussed (Griffiths, de Haseth and Azarraga, 1983). The other interface is a type of matrix isolation in which the analytes are frozen on a rotating band, which moves into the IR beam. A comparison of these two types has been published (Schreider, Demirian and Stickler, 1986).

The liquid from a HPLC is compatible with normal IR sampling and is less of a problem. However, LC MPs may not be transparent in the IR, and water is a particularly difficult solvent to handle. For volatile organic solvents, evaporation is possible, and the remaining nonvolatile analytes can be deposited into KBr and pressed into pellets. Further discussion can be found in reference (McDonald, 1986).

Mixed tandem combinations like GC/FTIR/MS are also possible since IR is nondestructive; it is possible to combine the three instruments into one. The special requirements and some applications have been described (Wilkins, 1983). Other tandem combinations are also possible. A common one is HPLC/UV/MS.

NMR does not have the low detectability limits of the other spectroscopies used in tandem with chromatography, so it has not been used as extensively. Also, the high magnetic field of current NMR instruments requires that the chromatograph be located at a considerable distance from the NMR probe. There are only a few reports of its use with GC, and, for HPLC, special glass flow cells are needed. For proton studies, the MP should ideally have no protons, so for RP work, deuterium oxide is used. Other deuterated solvents are quite expensive. LC/NMR is finding use in the pharmaceutical industry for impurity analysis (Lindon, Nicholson and Wilson, 2000). At least one commercial instrument offers LC/MS/NMR.

Other chromatographic methods that have been coupled with MS include TLC, SFC, capillary electrochromatography CEC) and capillary zone electrophoresis (CZE). SFC is handled much like GC, and CEC much like HPLC. TLC is quite different and requires special techniques. Details can be found in Poole's book (Poole, 2003).

30.7 Selected Other Topics

30.7.1 Multidimensional Separations

When a conventional one-dimensional separation is not adequate to resolve all the components of a sample, it may be possible to devise a multidimensional process that will yield better resolution. The concept is to spread out the separation in two dimensions rather than just one. The basic theory of two-dimensional separations was presented by Giddings, first in a paper (Giddings, 1984) and then in Cortes' book (Giddings, 1990) on the subject. Although the latter covers multiple dimensions, most of the actual applications are only two-dimensional. These two dimensions need to be orthogonal (at right angles) in order to maximize the two-dimensional space created. Indeed, Giddings' definition is based on that premise (Giddings, 1984). Orthogonal methods are those that use different mechanisms or modes of action in the separation. For multidimensional column methods, each column should provide a very different type of separation. For example, in GC/GC, one column could be very polar and the other nonpolar. The combination of LC and GC would be considered two-dimensional by virtue of the large difference in their separating mechanisms. A two-dimensional LC separation might combine RP in one column with SEC in the second, thereby attaining true orthogonality. A second requirement for true orthogonality is that components separated in the first dimension must not be recombined in the second dimension. The number of peaks that can be resolved in a two-dimensional separation is the product of the peak capacities of the two operations, thus showing the advantage of two-dimensional methods. As opposed to planar methods, in which the components are distributed in two-dimensional *space*, two-dimensional column separations give components distributed in two-dimensional *time*. Column separations have the added advantage of on-line detection.

A two-dimensional separation can be run off-line or on-line, the latter being preferred for convenience, ease of automation, and improved data handling. The disadvantage to the on-line mode is that the MPs may be incompatible, especially in LC, as in a combination of RP with NP HPLC; the former MP is usually aqueous and the latter nonaqueous. This problem seldom occurs in GC, where the MP can be helium for either polar or nonpolar column separations, and GC/GC is a very common two-dimensional method.

Optimization of the separation is usually called *tuning*, which can be achieved in several ways, including

- using one column of normal length and one of very short length;
- adjusting column variables such as temperature and flow rate;
- using innovative valving or modulation between the columns;
- using cryogenic trapping; and
- using original software to make optimal use of complex data such as that obtained by MS detection.

Descriptions of the different methods and combinations of multidimensional separations and some applications can be found in the volume edited by Mondello, Lewis and Bartle (2002).

30.7.1.1 GC/GC

Much of the early GC/GC work involved heart cutting, which refers to the process of isolating a poorly separated portion (a cut) of the molecules from the first dimensional process and running it on the second dimension. Heart cutting is not a true two-dimensional process since the whole sample is not run in the second dimension. It is still a valuable procedure and one that provided the first GC examples of improved resolution by the use of two dissimilar columns.

For a true two-dimensional GC separation, a cryotrap or modulator is usually required (Ledford, TerMaat and Billesbach, 2007; Hinshaw, 2004). A fraction from the first column is isolated with the modulator and transferred to the second column. Since only a single detector is used, the separation in the second column has to occur in less time than it takes to elute a single peak from the first column. Usually it is desirable to take three or four samples from each peak from the first column, so the run time for the second column can be only a few seconds at most. Since the second separation must be very fast, the second column is short and is operated at a high temperature and fast flow rate. One of the most impressive applications has been the analysis of cigarette smoke; in one case, over 30 000 peaks were isolated using GC/GC/TOFMS (Dalluge, Beens and Brinkman, 2003). In effect, the use of an MS detector to give a GC/GC/MS system results in a separation that is indeed three dimensional.

The interface/modulator between the two columns can take several forms; the two most common ones are a thermal sweeper and a cryogenic trap. At least two commercial instruments are available, including a retrofit for an existing GC and a complete GC/GC/TOFMS instrument. Papers from the First International Symposium on Comprehensive Multidimensional GC, which include reports of modulation devices and many applications have been published (Brinkman, Th., U.A. and Vreuls, R.J.J. 2003).

30.7.1.2 LC/GC

The combination of LC and GC is usually performed in the order indicated – LC being the first dimension. The interface between the systems must be capable of transferring the relatively large amount of MP from the LC into the GC. The popular transfer techniques are (i) retention gap, also called *on-column*; (ii) concurrent eluent evaporation, employing a loop type interface; and (iii) hot injectors, most often with programmed temperature vaporization (PTV). To divert the large volume of gas generated by vaporizing the LC solvent, types 1 and 2 are usually operated with a solvent vapor exit (SVE) placed between the precolumn and the analytical column. The relatively volatile solvents often used in NP LC can be handled, but the aqueous phases used in RP, which may also contain nonvolatile salts, are more difficult, and as a consequence there has not been much development of RPLC/GC.

30.7.1.3 LC/LC

A variety of two-dimensional LC methods have been described, many of which show similarities to the two-dimensional GC methods, including heart cutting. In designing an LC/LC procedure, however, one has to deal with the fact that the MPs differ between modes. In LC, unlike in GC, the MP, as well as the SP, participates in the process of defining the retention characteristics of the system. Thus, the combination of two LC columns of differing separating characteristics is likely to require the use of two different MPs. Consequently, a truly orthogonal LC/LC system is often limited by the necessity to have compatible MPs. For example, NP followed by RP might present difficulties with immiscibility of the NP fraction injected on the RP column. Some LC combinations that do work are

IEC and RPLC;
SEC and RPLC;
SEC and NPLC; and
combinations of RPLC with electrophoretic methods.

30.7.1.4 Other Combinations

These GC and LC examples of multidimensional chromatography serve as a fitting introduction to many other combinations. The major ones are with SFC and capillary electrophoresis (CE). Since SFC is intermediate in characteristics between GC and LC (*see* Section 30.5), and some consider it to be the ideal unified technique, it is a natural to combine with GC or LC or both. Also, the CE methods (CZE and CEC) are very similar to capillary RPLC and IEC and make ideal combinations with HPLC.

30.7.2
Chiral Separations

Chromatography is even capable of separating optical isomers, a process that is becoming increasingly important, especially in the pharmaceutical industry. For many drugs, only one optical isomer is pharmacologically active, and a total analysis that does not separate and quantitate the enantiomers is unsatisfactory. Enantiomers have identical physical properties and can rarely be separated by conventional chromatographic systems. Thus, new approaches to the separation of chiral compounds have been developed.

This separation challenge has been addressed by various methods, the oldest being the formation of diastereomers. A racemic mixture of optical isomers (designated *R* and *S*) cannot be separated chromatographically unless a chiral element is introduced into the procedure. One way is to react the mixture with a chiral reagent (designated, e.g., R'), to form reaction products that will have two chiral centers: one isomer will generate an RR' reaction product, and the other the SR' combination. These two diastereomers will have different physical properties and can be separated chromatographically with nonchiral phases. This approach was the major one used in GC when the field began to develop over 30 years ago. However, it has some disadvantages, and since not all analytes are amenable to analysis by GC, other approaches to chiral separations have been developed. These can be divided into two groups: those using chiral stationary phases (CSPs), and those using chiral mobile phases (CMPs). The use of CSPs is the most popular method for achieving chiral separations because chiral groups can be bonded to the surface of a stationary support. For GC, CSPs are the only option, since it has not been found possible to operate GC with CMPs. Considerable development work on CSPs has been done for HPLC phases. Pirkle (1986) has discussed the early work on CSPs for HPLC, giving examples and describing the way they work. Much less use has been made of CMPs in chiral HPLC separations, where it is assumed that the analytes form strong associations with a chiral component in the MP and that these complexes interact differently with the achiral SP. Although the mechanisms are not all clear, intermolecular associations that seem to form the basis of chiral separations are hydrogen bonding, metal chelation, ligand exchange, and ion-pair formation.

It should also be noted that SFC is of great utility in chiral separations, a major advantage being its relatively low pressure drop over the analytical column, which allows the use of multiple columns in series to achieve higher efficiencies. These SFC columns do not have to contain identical packing materials; use of different column trains can provide unique selectivities. In addition, SFC is ideal for preparative chiral separations since the MP is volatile, easily removed, and nontoxic. A single reference for more information about chiral separations is the book by Beesley and Scott (1998).

30.7.3
Capillary Electrochromatography (CEC)

Electrophoresis is not a chromatographic method, but a technique often used by chromatographers, and one that has been combined with HPLC to produce a technique called *CEC*. The common use of capillary columns brought electrophoresis and HPLC together. The first reported use of electrophoresis in OT capillary columns was published in 1967, but it was later, in 1979–1981, that a real impetus was given to the field by the use of fused-silica columns similar to those used in capillary GC. Later, when a pseudo-SP was introduced as a secondary phase, the technique took on some characteristics of LC and became known as *electrokinetic chromatography* (*EKC*) or, if the second phase was micellular, *micellar electrokinetic chromatography* (*MEKC*). Although scientists call MEKC a chromatographic process, others do not. Subsequently, however, the use of WCOT columns, and packed capillaries with SPs of the type used in RP HPLC, launched the operational mode now called *CEC*, a bona fide chromatographic method, one which has features of both RPLC and capillary zone electrophoresis, CZE (see Figure 30.1).

The CEC apparatus most closely resembles CZE, an illustration of which is shown in Figure 30.17. A packed column similar to one that could be used in HPLC, having a small (50–250 μm) i.d. is used along with a electrophoretic voltage gradient (up to 35 kV) and a flow electroosmotic flow (EOF) of the MP (or run buffer) caused by the resulting electroosmotic pressure. Since the highest electrophoretic mobilities are obtained with acetonitrile–aqueous buffer mixtures, this mixture has become the most popular; a good buffer concentration is about 1 mM. In the most common usage, the detector (usually a UV detector similar to one that would be used in HLC) is located near the cathode end and samples are introduced into the capillary at the anode end. Ionic analytes are driven by the electrostatic field, and, in addition, ions and molecules are transported by the electroosmotic flow, which performs the same function as the pump needed to move the solvent in HPLC. The SP in the column serves as a partitioning agent just as it does in HPLC, and the combination of these forces causes a separation of the analytes.

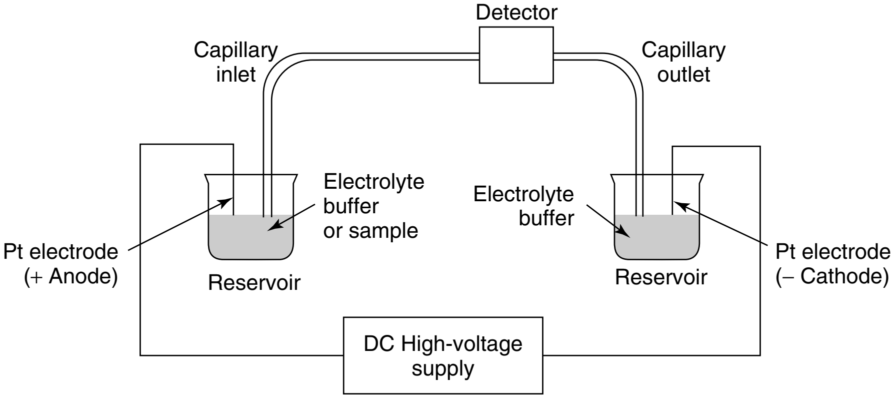

Fig. 30.17 Typical apparatus for capillary electrochromatography (CEC) and capillary electrophoresis. Reproduced with permission from Christian, G. D. *Analytical Chemistry*, 6th edition, John Wiley & Sons. Copyright 2004, John Wiley & Sons.

Tab. 30.4 Advantages and disadvantages of capillary electrochromatography (CEC). Reprinted from reference (McNair and Miller, 1998) with permission from John Wiley & Sons.

Advantages	**Disadvantages**
1. Greater efficiency	1. Poor detectivity
2. Wide range of applications	2. Poor quantitative precision
3. Faster	3. Poor migration time precision
4. No troublesome pumps	4. High-voltage hazard
5. Less expensive for chiral analyses	

The advantages and disadvantages of CEC listed in Table 30.4 are mainly comparisons with HPLC. The main advantage is the higher efficiency that results from the ideal flow pattern obtained in electrophoresis. The combination of HPLC and CZE provides CEC separations based on both effects for ionized materials and thus can effect separations not possible by HPLC alone. And, since the electrophoretic effects are predictable, the combined effects should be predictable if one has separate chromatographic data. Of the disadvantages, the poor detectivity and precision are sufficiently severe to discourage many chromatographers from the use of CEC, although CE is finding use for chiral separations.

The 1981 paper by Jorgenson and Lukacs (1981) is generally considered to mark the beginning of CEC, and the fundamentals have been summarized by Pyell (2001) who reported that efficiencies are about 10 times better for CEC than for HPLC. An entire volume of the *Journal of Chromatography A* is devoted to CEC (Horvath, 2000), and two books are available (Deyl and Svec, 2001; Krull *et al.*, 2000).

Glossary

Bonded-Phase Chromatography: Liquid chromatography performed with a stationary phase that is chemically bonded to a particulate supporting material such as silica powder. See also normal-phase chromatography, reversed-phase chromatography.

Capacity Factor: An old term that is no longer used. See Retention Factor.

Capillary Column: In gas or supercritical fluid chromatography, the small-diameter, open tubular column that contains the stationary phase. Inner wall of the tubing is coated with a solid or liquid film that functions as the stationary phase. The major type is a wall-coated open tubular (WCOT) column.

Carrier Gas: Mobile phase in gas chromatography.

Chromatogram: The output from a chromatographic separation that shows the response of the detector as a function of time.

Chromatograph: The instrumentation used in chromatography (noun). To separate and analyze components in a mixture by chromatography (verb).

Column: In chromatography, the glass, metal, or plastic tubing that contains the stationary phase.

Detector: In chromatography, the device used for dynamic monitoring of the chemical compounds leaving the column.

Gas Chromatography (GC): Chromatography with a gaseous mobile phase.

Gas–Liquid Chromatography (GLC): Gas chromatography with a liquid stationary phase that is dispersed on or bonded to a particulate packing material or to the inner wall of the column.

Gas–Solid Chromatography (GSC): Gas chromatography with a solid stationary phase.

Gel Filtration Chromatography: Size-exclusion chromatography with an aqueous mobile phase.

Gel Permeation Chromatography: Size-exclusion chromatography with a non-aqueous mobile phase.

Gradient Elution: In liquid chromatography, a technique for improving resolution, which consists of continuously changing the composition of the mobile phase during the separation.

Height Equivalent of a Theoretical Plate: Originally, a quantity used to describe the efficiency of a particular separation scheme, but no longer used. See plate height.

High-Performance Liquid Chromatography (HPLC): Modern liquid chromatography using mobile phases pumped at high pressures, stationary phases consisting of columns containing densely packed, small-diameter particles, and dynamic detection of the components eluting from the column.

Injector: In chromatography, the device used to introduce a sample onto the top of the column.

Ion Chromatography (IC): A group of liquid chromatography techniques used for the separation and analysis of ions.

Ion-Exchange Chromatography (IEC): Ion chromatography with an ion-exchange resin as the stationary phase.

Ion-Pair Chromatography: Ion chromatography with a reversed-phase or polymeric stationary phase, and a mobile phase containing chemical reagents that form neutral ion pairs with the sample ions.

Liquid Chromatography (LC): Chromatography with a liquid mobile phase. See also high-performance liquid chromatography.

Liquid–Solid Chromatography (LSC): Liquid chromatography with a solid stationary phase.

Mobile Phase (MP): In chromatography, the flowing gas, liquid, or supercritical fluid that carries the individual components of a mixture through the stationary phase.

Nonpolar: A property of a material resulting from the distribution of electronic charge in the individual molecules. A material is said to have nonpolar character if the electronic charge on each molecule is uniformly distributed through the molecule. See also polar.

Normal-Phase Chromatography (NPC): Liquid–solid chromatography or bonded-phase chromatography with a polar stationary phase and a nonpolar mobile phase.

Number of Theoretical Plates: A measure of the efficiency of a particular separation scheme, now called *plate number*.

Open Tubular Columns (OT): See capillary column.

Packed Column: A column that contains the stationary phase as a packed powder or resin.

Plate Height (H): A measure of column efficiency equal to the column length (L) divided by the plate number (N).

Plate Number (N): A measure of column efficiency that is based on a comparison of an analyte's retention volume and its peak width.

Polar: A property of a material resulting from the distribution of electronic charge in the individual molecules. A material is said to have polar character if any region of the individual molecules that compose the material possesses an excess or deficiency of electronic charge relative to the rest of the molecule. See also nonpolar.

Resolution (R_S): In chromatography, a quantity which describes the efficiency and degree of separation achieved in the chromatographic separation of two chemical compounds.

Retardation Factor for Column Chromatography (R): A measure of chromatographic retention behavior, equal to the average speed of a given analyte through the column divided by the average mobile phase velocity. Also equal to V_M/V_R.

Retardation Factor for Thin-Layer Chromatography (R_F): A measure of chromatographic retention behavior, equal to the distance traveled on a TLC plate by a given analyte divided by the distance traveled by the solvent (MP) front.

Retention Factor (k): A measure of chromatographic retention behavior equal to V'_R/V_M. Formerly called *capacity factor*, *capacity ratio*, and *partition ratio*, none of which should now be used.

Retention Time (t_R): In chromatography, the length of time a chemical compound spends in the column.

Reversed-Phase Chromatography (RPC): Bonded-phase chromatography using a nonpolar stationary phase and polar mobile phase.

Separation Factor (α): In chromatography, a measure of the ability of a separation scheme to separate two components. Also referred to as the *selectivity*.

Size-Exclusion Chromatography (SEC): Liquid chromatography technique that separates chemical compounds on the basis of their physical size. See also gel filtration chromatography, gel permeation chromatography.

Stationary Phase (SP): In chromatography, the solid or liquid phase that resides in the column. The stationary phase is a powder or resin packed into the column or a film deposited on or bonded to the inner wall of the column.

Supercritical Fluid: A material that is above its critical temperature and pressure.

Supercritical Fluid Chromatography (SFC): Chromatography with a supercritical fluid as the mobile phase.

Temperature Programming (PTGC): In gas chromatography, a technique for improving resolution, which consists of continuously changing the column temperature during the separation.

Thin-Layer Chromatography (TLC): Liquid chromatography with a stationary phase dispersed on a solid planar surface. Mobile-phase flow through the stationary phase occurs as a result of capillary forces.

INTRODUCTION

This article dwells on the common, discrete circuit elements, including semiconductors, found in electronic circuitry. Some attention is given electric power elements as well. The emphasis is placed on the basic applications of various circuit elements with a number of circuit diagrams to illustrate these. Integrated circuits are not discussed as such but in some applications their inclusion is a necessary part of a functional relationship, e.g., the operational amplifier.

The arrangement of the article is in nine sections each devoted to a particular circuit element. Each section is composed of a short

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

introduction describing the element followed by a discussion of various applications of the element as it is commonly, and sometimes not so commonly, used.

The writing is in terms that can be understood by a scientist or technician who has some basic knowledge of electricity but is not experienced in electronic or electrical circuits. A list of references for further reading is included at the end of the article which provide details of specialized topics and in some cases include more general tutorial chapters for electronics tyros.

1. CONDUCTORS

1.1 Introduction

The elements that are the best conductors of electricity at ordinary temperatures are the metals. The best conductor is silver, followed closely by copper, gold, and aluminum in that order. The most widely used material for conductors is copper because of its abundance and low cost relative to silver. Aluminum conductors are sometimes used to minimize weight and cost, but aluminum's ability to conduct electricity is only 60% of that of copper.

1.2 Applications

1.2.1 Power Transmission. Long-distance electric power transmission lines often span distances up to several hundred miles. Because the resistance of a conductor increases with length, it is important to minimize the conductor resistance when a large amount of power is to be transmitted over long distances. Otherwise an unduly large amount of energy loss will occur. Decreasing the resistance can be accomplished by using a large-diameter conductor. However, there are practical limits of excessive weight and cost resulting from too large a diameter.

The energy loss in a conductor is proportional to the square of the current. The power transmitted is proportional to the voltage–current product, VI. Consequently, for a given VI product, if the voltage is doubled and the current halved, the power can be transmitted at one-quarter the loss in the transmission line. The result is that long-distance power transmission lines deliver power at voltages up to a practical limit of a few hundred-thousand volts. This requires a current of only a few amperes to transmit power at megawatt rates on reasonably sized conductors.

1.2.2 Signal Transmission. Signal currents are encountered in communications and computer networks, and generally in all electronic systems. The currents are usually quite small. Consequently, conductors for signal currents are usually selected for properties other than low resistance.

Two important properties of signal conductors are characteristic impedance and shielding from noise. Conductors are usually not used for transmitting signals over distances longer than a few kilometers. For longer distances, microwave links or fiber-optic systems provide larger bandwidths and signal-to-noise ratios.

The main consideration for selecting conductors for signals is protecting the information content of the signal from corruption. Just which type of conductor should be used in a particular application depends upon the frequency spectrum of the signal, the electrical noise environment, and the power level of the signal.

1.2.2.1 Coaxial Cable. High-frequency signals, ranging from 1 MHz to 1 GHz, usually require coaxial cables. Such cables consist of a conductor surrounded by insulation and covered by a tubular conducting shield as shown in Fig. 1. The shield prevents energy from being lost through outgoing radiation, and noise pickup from external sources of radiation. The coaxial cable should be terminated in its characteristic impedance to prevent signal energy from being reflected back to the source.

1.2.2.2 Low-Frequency Conductors. For frequencies ranging up to the end of the audio spectrum (about 20 kHz), no special consideration generally needs to be given for the

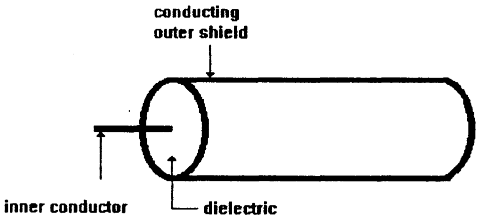

FIG. 1. Typical section of coaxial cable.

choice of conductors. However, when signal power levels are quite low, some shielding or twisted-pair configurations may be required to prevent noise pickup.

1.2.2.3 Instrumentation. Instrumentation and measurement systems often employ frequencies up to 100 kHz applied to balanced circuit transducers. Conductors employed with these circuits can cause serious unbalances and crosstalk errors because of their capacitance coupling to other conductors or system ground. These conductors should be shielded cables in matched pairs or terminated with adjustable capacitors to balance out their capacitance effects.

1.2.2.4 Digital Signal Conductors. For distances up to a few meters, digital signals can be transmitted in parallel mode over multiconductor cables without loss of information. Quite often these cables have their conductors molded into a flat ribbon. At the low impedances and relatively high power levels encountered in digital systems, noise pickup and capacitance coupling between conductors is not often significant as long as the frequency is kept low.

For distances up to a few kilometers, serial mode transmission of digital signals is more appropriate. Where bit transmission rates exceed 4000 bits per second, properly terminated coaxial cable is usually required to prevent loss of information. Bit rates less than 4000 can usually be safely handled by a twisted-pair cable configuration such as encountered in many telephone circuits.

1.3 Superconductors

Certain metals and alloys exhibit zero resistivity when their temperature is lowered to below 20 K. Conductors made from these materials are referred to as superconductors and indeed have zero resistance. Superconducting wires are very expensive compared to copper conductors, and so their use is limited to special applications where cost is a secondary consideration.

One application of superconducting wire is in the design of solenoids to produce very large magnetic fields. Such solenoids are only used in research laboratories and in special medical or industrial processes. See the articles SUPERCONDUCTING DEVICES and SUPERCONDUCTING MAGNETS for more details on superconductor applications.

In 1987, higher temperature (90 K) superconducting materials were discovered. Although these original materials were not suitable for most commercial uses, efforts are under way to develop high-temperature materials for commercial applications.

2. RESISTORS

2.1 Introduction

A resistor is a bilateral circuit element that obeys Ohm's law. Its purpose is either to limit the amount of current in a circuit for given applied voltage, or to produce a desired voltage for a given amount of current.

2.2 Physical Parameters

Resistors are configured in many sizes and shapes and usually employ carbon or metal as the active material. The physical size and materials of a resistor are determined by the amount of power it must dissipate without undue temperature rise. The electrical resistance is determined by the resistivity and geometry of the conducting material used. See the article RESISTORS for more information about the technology of resistor construction.

Resistance values may be indicated on the body of a resistor by alphanumeric coding, but most often by an industry standard color code given in Table 1.

Resistors are usually marked with colored bands. The color of the first band denotes the first significant figure of the resistor value, the color of the second band the second significant figure and the color of the third the power of ten by which the significant figures are multiplied. For example, the colors brown, red, and orange would denote a resistor value of 12 000 Ω. The industry also uses a set of standard values for resistors with a tolerance of 5% given in Table 2.

In addition to those with standard fixed values, resistors whose values are variable are

Table 1. Resistor color codes.

Black	0	Green	5
Brown	1	Blue	6
Red	2	Violet	7
Orange	3	Gray	8
Yellow	4	White	9

Table 2. Standard significant figures for 5% resistors.

12	22	39	68
13	24	43	75
15	27	47	82
16	30	51	91

also available. These are identified by various names such as potentiometers, photoresistors, thermistors and varistors.

2.3 Applications

2.3.1 Fixed Resistors. The principal application of resistors is in electronic circuits. In addition to their applications of current or voltage limiting, resistors are often used in conjunction with capacitors to produce time delays or to alter the frequency response of an electronic circuit as described in the section on capacitors. The termination of coaxial cables in their characteristic impedances is usually accomplished with an appropriately sized resistor.

2.3.2 Variable Resistors. Potentiometers are the most common form of variable resistors. An example of a potentiometer is shown schematically in Fig. 2. A potentiometer provides a way to divide a resistance of fixed value into two resistances in series whose ratio can be varied. The result is a variable voltage divider that finds wide application in electronic circuitry. For example, potentiometers are employed as volume controls or other adjustable controls in audio, radio, or video systems. Figure 3 is a typical example of a volume control circuit.

The potentiometer can be configured to provide a single variable resistance. This is accomplished by using the adjustable terminal and one fixed terminal as the terminals of a resistor leaving the other fixed terminal unconnected as shown in Fig. 4.

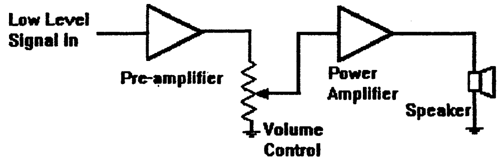

FIG. 3. Typical use of a potentiometer as a volume control.

Photoresistors are made from materials whose electrical resistance varies with the intensity of light incident on them (see PHOTODETECTOR DEVICES). These devices are used to produce voltage or current values that represent light intensity levels. Photoresistors are used to activate light-control circuitry and for photometric applications. Figures 5 and 6 are examples of photoresistor applications.

Thermistors are resistors whose resistance varies with temperature. They usually employ a semiconductor as the active material and therefore have a negative temperature coefficient, i.e., increasing resistance with decreasing temperature. Thermistors are used to produce circuit resistance that varies with temperature. An obvious thermistor application is in electronic thermometer circuits for the measurement and control of temperature.

Their negative temperature coefficient makes thermistors useful in compensating for the positive temperature coefficients of other resistors in a circuit. Figure 7 is an example of thermistor applications for temperature compensating fixed resistors.

Varistors are resistors whose resistances vary with the applied voltage. They are quite nonlinear. Characteristically, varistors have high resistance at low voltages and change rapidly to low resistance as the applied volt-

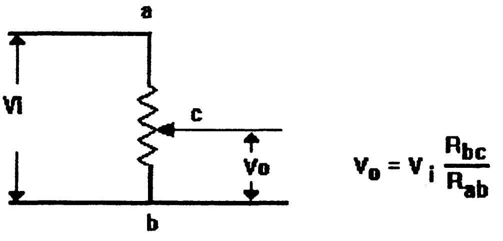

FIG. 2. A potentiometer used as a voltage divider.

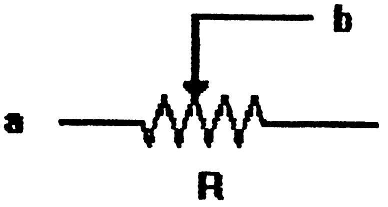

FIG. 4. Potentiometer used as a variable resistor. The resistance between *a* and *b* can be varied from 0 to *R* where *R* is the maximum resistance of the potentiometer.

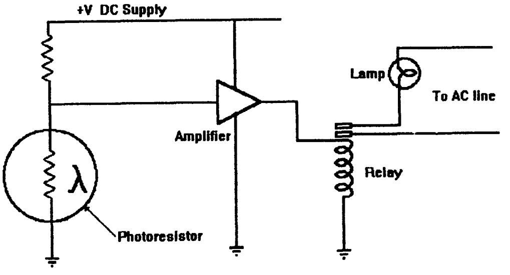

FIG. 5. Photoresistor on-off control. As the incident light on the photoresistor decreases the resistance increases until sufficient voltage is applied to the amplifier to energize the relay which turns the lamp on.

age increases beyond a certain threshold value. A widespread application of varistors is in overvoltage protection circuits for electrical equipment that is sensitive to power-line surges.

2.3.3 Chip Resistors. With the advent of surface mount technology in printed circuit-board electronics, a monolithic or chip resistor has been developed in recent years. A resistor of this type is formed into a rectangular parallelepiped with tinned surfaces for direct soldering to printed circuit-board conductors.

3. CAPACITORS

3.1 Introduction

A capacitor is a device that stores electrical charge. It is a two-terminal bilateral circuit element that obeys the relation $Q=CV$, where Q is the charge stored in the capacitor in coulombs, V is the voltage across its terminals in volts, and C is the capacitance in farads.

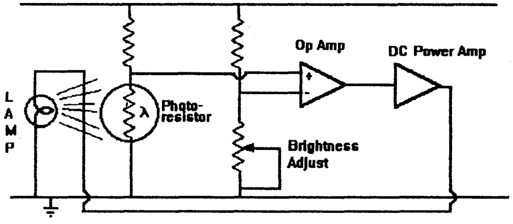

FIG. 6. Lamp intensity control circuit. If the lamp intensity changes, the photoresistance changes in such a way as to cause the amplifier to produce an opposite change in the lamp intensity.

3.2 Physical Parameters

Capacitors are manufactured in numerous shapes and sizes. Their basic construction consists of two parallel conducting surfaces insulated from each other by some dielectric material. Typical examples of dielectrics are air, paper, oil, and some form of plastic or metal oxide. Capacitance values range from picofarads to farads.

Most capacitors have a fixed value of capacitance. However, a few varieties of variable capacitances exist for use in circuits that require adjustment to a precise value of capacitance for best performance. Generally, the maximum capacitance values of variable capacitors range from a few to a few hundred picofarads.

3.3 Applications

3.3.1 *RC* Filter Circuits. Since the capacitive reactance varies inversely with the frequency, the zero-frequency, or dc, reactance of a capacitor is infinite. Conversely, the capacitive reactance at high frequencies can become very small compared to other elements in a circuit. Because of their frequency dependence, when capacitors are combined with resistors or other circuit elements, a class of circuits can be formed which are frequency selective, i.e., they may transmit or attenuate bands of frequencies. These circuits are generally referred to as filters.

Oscilloscope input circuits employ the infinite dc reactance of a capacitor to block dc

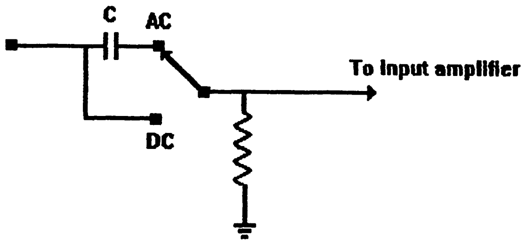

FIG. 8. Oscilloscope input circuit. When the switch is in the ac position a capacitor blocks dc voltage from the oscilloscope amplifier.

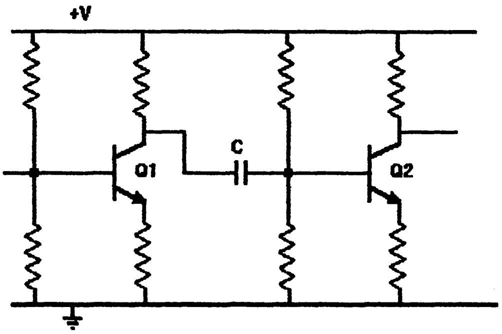

FIG. 9. Amplifier interstage coupling. The capacitor C prevents the dc output of first stage transistor Q_1 from reaching the input of the second stage transistor Q_2.

voltages that would preclude the effective display of small ac signals combined with the dc. Figure 8 is typical of an oscilloscope input circuit.

The dc blocking circuit is also used to interconnect stages of an amplifier to prevent the dc bias voltage of a preceding stage from upsetting the dc bias of a subsequent stage. An example of this circuitry is shown in Fig. 9.

The oscilloscope circuit is an example of an elementary filter circuit that is referred to as a high-pass filter. A high-pass filter generally transmits high frequencies while attenuating lower ones. If the roles of the capacitor and resistor are reversed, as shown in Fig. 10, a low-pass filter results, which passes dc and low frequencies while attenuating higher frequencies.

An altered version of the low-pass filter is shown in Fig. 11. Here, the resistor of Fig. 10 has been replaced by a rectifier diode. In this circuit the capacitor is charged to a dc voltage from current pulses passing through the diode. The capacitor discharges through the load connected across the capacitor. The result is a dc voltage across the load accompanied by a relatively much smaller ac voltage. This circuit is an elementary form of a rectifier and filter power supply circuit used to convert ac voltage into dc. See the section on diodes for more information about power supplies.

An example of a more elaborate filter circuit that attenuates a band of frequencies is the twin-T filter shown in Fig. 12. This is referred to as a band-stop or notch filter because of the shape of the response curve. In theory, zero transmission at the notch frequency is possible if the resistors and capacitors of the circuit are precisely matched. In practice, an attenuation of 60 dB is achievable.

A band-pass filter can be achieved if the twin-T filter is used as a feedback element in

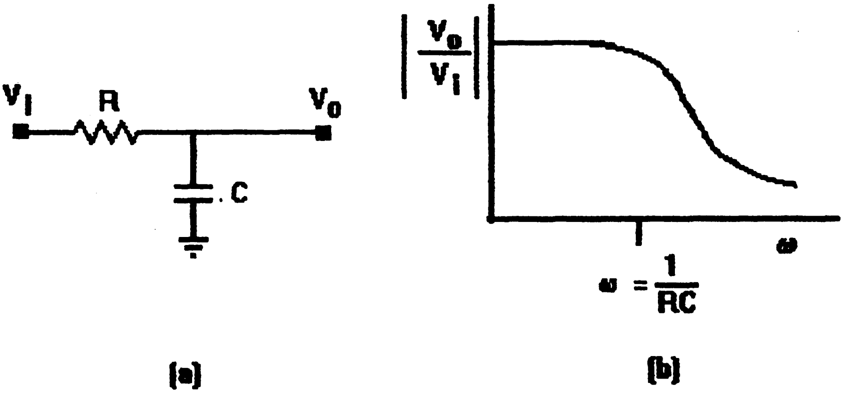

FIG. 10. Low pass filter. (a) A simple *RC* low-pass filter circuit. (b) Response of output voltage V_0 relative to the input as a function of the frequency.

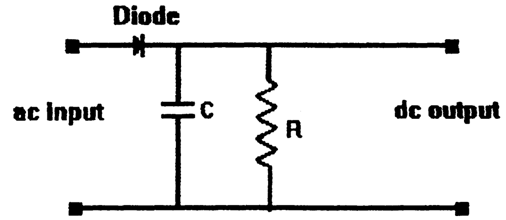

FIG. 11. Rectifier filter. The capacitor C and the diode form a low-pass filter to smooth out variations in the dc output produced by the ac. If the load resistor R is chosen so that the time constant *RC* is at least five times the period of the ac voltage, the dc variation will be approximately ±10% of the dc average. This assumes that no other load is connected in parallel with R.

an op amp circuit as shown in Fig. 13. In this case the high- and low-frequency parts of the response curve will be determined by the input resistor used. The sharpness of the band pass will also be affected by the value of this resistor.

3.3.2 *LC* Filter Circuits. Applications of capacitors in conjunction with inductors are discussed in Sec. 4.3.

3.3.3 Timing Circuits. The rate at which a capacitor charges or discharges through a resistor is determined in part by the product of the resistance and capacitance. This *RC* product is called the time constant of the circuit. Practical time constants can range from less than one microsecond to several minutes, depending on the values of resistance and capacitance chosen for the circuit.

Often the charging of a capacitor in an *RC* circuit is the basis for control applications that require on–off timing or timed intervals between events. One such application for the control of a photo enlarger lamp is described in Fig. 14.

Another important application of *RC* timing is in relaxation oscillator circuits. One such application is described in Fig. 15. Here, the period of the square wave generated by the oscillator is determined by the *RC* time constant which can easily be adjusted by varying *R*.

3.3.4 Energy Storage. As a capacitor is charged it accumulates energy proportional to the square of the charge accumulated. If the capacitor is charged slowly and then discharged quickly, the power obtained from the discharge can be many times the power of the charging source. This power amplification makes the capacitor useful in applications where large bursts of power are needed for short periods with relatively long intervals between bursts. Some typical applications are photo flash units, detonators, spot welders, and plasma pulse generators.

3.3.5 Power Factor Correction. Because most of the load on a power distribution system is large electric motors, the current and voltage on a power line may have a significant phase difference. This phase difference is measured by the power factor which is the cosine of the phase angle. A power factor significantly different from 1 results in excessive energy loss in the power system.

When capacitors are placed across the power line, they effectively tune out the inductive effects of the electric motor load, thereby reducing the phase difference to an acceptable level. These power-factor correction capaci-

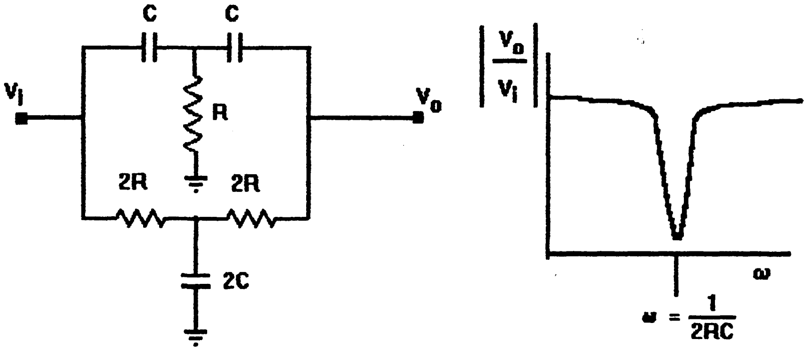

FIG. 12. Twin-T band-stop filter. When the capacitors and the resistors are carefully matched, the depth of the notch in the response curve can be as much as 60 dB.

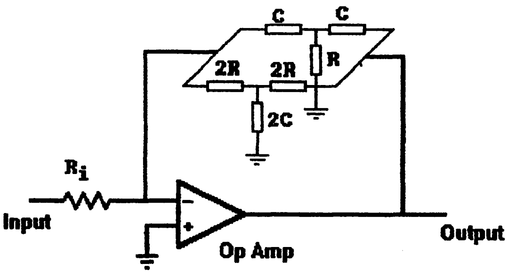

FIG. 13. Twin-T band-pass filter. When the circuit of Fig. 12 is used as the feedback network shown, a narrow band-pass filter is the result.

tors are usually very large compared to capacitors used in electronic circuits, since they must withstand thousands of volts across their terminals as well as severe weather and large variations in temperature.

4. INDUCTORS

4.1 Introduction

An inductor is a bilateral circuit element that obeys the circuit relation $V=L\,dI/dt$, where V is the voltage across the inductor terminals, dI/dt is the rate of change of current, and L is the inductance in henries. There is no voltage across the terminals of an ideal inductor if the current is not changing.

4.2 Physical Parameters

Inductors are usually formed by winding wire into a coil or coils. The inductor may be wound on a form containing ferromagnetic material to increase the value of inductance. Inductance values range from nanohenries to henries. Their physical sizes cover a wide range of volume and weight. For more information about their construction, see the article INDUCTORS.

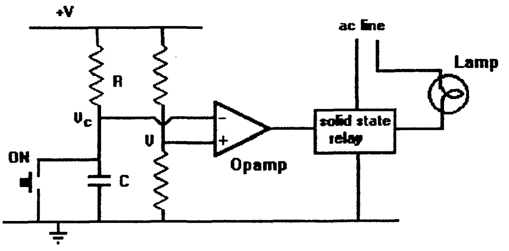

FIG. 14. Lamp timer circuit. When the on button is pushed, C discharges, which lowers V_c below V and turns the lamp on. When the button is released, C begins charging through R. When V_c exceeds V, the lamp turns off. The length of time the lamp is on depends on the time constant RC.

4.3 Applications

4.3.1 Filter Circuits. Since inductive reactance varies with frequency, inductors may be used in conjunction with resistors to form elementary filter circuits. This use of inductors is not common however, since resistor–capacitor filters are usually less expensive and bulky.

4.3.2 Low Frequency. Generally the physical size, weight, and cost of an inductance appropriate for low-frequency applications are very large compared to those characteristics required for high-frequency use. Consequently, circuit designers try to avoid using inductors for low-frequency applications wherever possible. However there are a few low-frequency applications that are commonly found.

An important low-frequency application of inductors is in the crossover networks used in stereo speaker systems. Here, inductors and capacitors form low-pass, band-pass, and high-pass filters that guide the audio signals to their respective speakers. Figure 16 is an example of a crossover network for a speaker system.

Another low-frequency application for inductors is the switching power supply for converting from one dc voltage to another. Here, the energy storage character of the

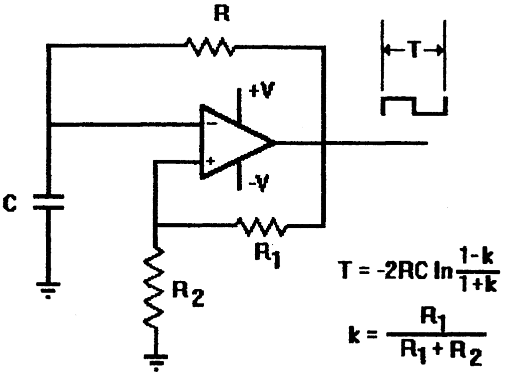

FIG. 15. Relaxation oscillator.The period of oscillation T depends on the RC time constant and the relative values of R_1 and R_2. When the resistors are all equal, the square-wave output is symmetrical.

inductor is used to provide for either a stepped-up or stepped-down voltage output from a primary dc source.

Elementary step-up and step-down circuits are shown in Fig. 17. Both of these circuits follow the same principle of operation. When the switch is closed, current builds up in the inductor. When the switch is opened, the inductor voltage adjusts to try to maintain the current flow and so maintains the capacitor voltage.

Usually the switches in the circuits of Fig. 17 are metal-oxide-semiconductor field-effect transistor (MOSFET) devices designed specifically for fast switching. The addition of sensing and processing circuitry allows for voltage regulation of these switching circuits as shown in Fig. 18. The output voltage of the switching regulator is controlled by controlling the duty cycle of the transistor switch.

Switching regulators offer improved efficiency over analog regulators that use pass transistors as the regulating elements. Switching frequencies may range from 20 kHz to 1 MHz or more.

4.3.3 High Frequency. When a capacitor is combined with an inductor, either in series or in parallel, a resonance phenomenon occurs. Over a narrow band of frequencies the impedances of the capacitor–inductor combinations vary drastically. For a capacitor and inductor in series, the impedance goes nearly to zero at the resonant frequency, while for a parallel combination the impedance becomes very large compared to the off-resonant values. These types of *LC* circuits are called resonant circuits and are most often used at high frequencies to produce very narrow-band filters. Figures 19 and 20 are examples of elementary resonant-circuit band-pass filters.

An elementary tuned amplifier that uses a resonant circuit is shown in Fig. 21. In practice, several of these amplifiers are cascaded and used as intermediate-frequency amplifiers in radio and television circuits. Usually each amplifier in the cascade is tuned to a slightly different frequency to amplify a band of frequencies sufficiently wide to pass the desired information.

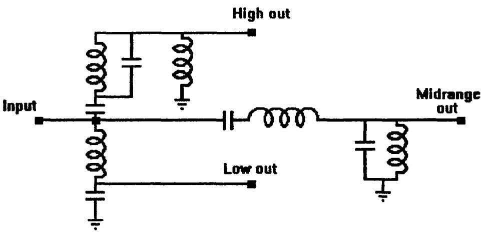

FIG. 16. Speaker system crossover network.

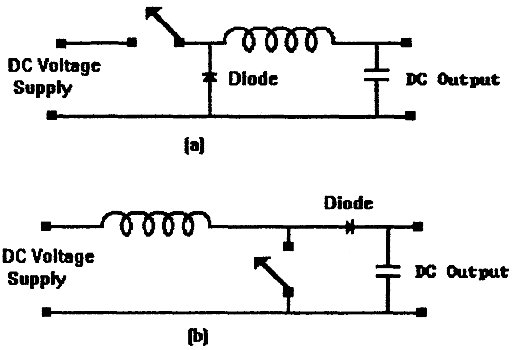

FIG. 17. Elementary switching power supply circuits. (a) This step-down circuit produces a voltage from zero to the supply voltage depending on the fraction of the time the switch is closed. (b) This step-up circuit produces an output voltage equal to or higher than the supply voltage again depending on the fraction of the time the switch is closed.

One inductor application that is used widely in radio-frequency circuits is the *LC* circuit shown in Fig. 22. The circuit is used to prevent high-frequency signals from reaching the power supply leads. The resonant frequency of the inductor–capacitor combination should be well below the effective range of the filter. Inductors used in this application are called radio-frequency chokes.

The electromagnetic interference (EMI) filter of Fig. 23 is an extension of the choke circuit. Here, inductor–capacitor combinations form a low-pass filter circuit, which is designed to prevent electromagnetic radiation

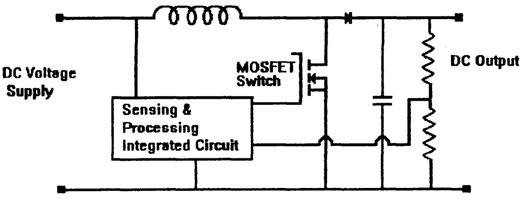

FIG. 18. Switching regulator circuit. The integrated circuit compares a fraction of the output voltage with an internal reference. If the output is too low the integrated circuit increases the "on" time of the MOSFET switch. If the output is too high the regulator decreases the "on" time.

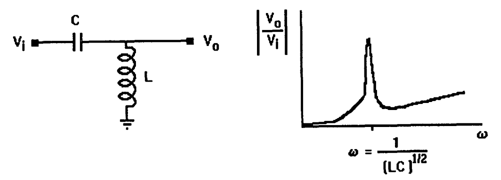

FIG. 19. Series resonant band-pass filter. This circuit has an input impedance of virtually zero at resonance and an output impedance that is very high.

from entering or leaving shielded enclosures containing high-frequency circuits.

Another form of an inductor can be made from a spiral trace etched in a printed circuit board. Such inductors range in value up to about 100 nanohenries and are useful at frequencies of several hundred megahertz. Also surface-mounting inductors for printed circuit-board applications are available. These inductors are contained in monolithic blocks that solder directly to a printed circuit board and range in value up to a few microhenries.

5. DIODES

5.1 Introduction

A diode is formed by a *p–n* semiconductor junction. It is a two-terminal unilateral device, allowing current to pass easily in one direction while virtually blocking current in the opposite direction. A typical diode volt–ampere curve and circuit symbol are shown in Fig. 24. For more details on the physics of diodes see the article SEMICONDUCTORS, ELEMENTAL—ELECTRONIC PROPERTIES.

5.2 Physical Parameters

The amount of current to be conducted, the reverse breakdown voltage, and the mechanical and thermal properties determine the physical size of a diode. Usual sizes range from cylinders 1 mm in diameter, 5 mm long to more than 3 cm in diameter, 7 cm long.

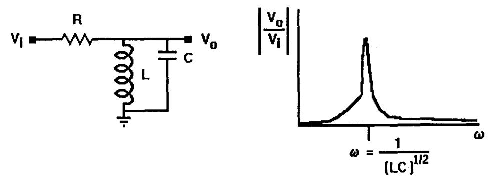

FIG. 20. Parallel resonant band–pass filter. This circuit has a very high input impedance at resonance and an output impedance that depends on the resistance of *R*.

5.3 Applications

5.3.1 Rectifier Circuits. The most universal application for diodes is the conversion of ac voltage into dc. In this application the diodes are called rectifiers. Circuits employing diodes for this purpose are called rectifier circuits.

Figure 25 is an example of an elementary, half-wave rectifier circuit. The output of this circuit is often called raw dc. For it to be useful in most applications the output must be filtered. An example of a capacitor filter is included in Fig. 25.

The half-wave rectifier circuit uses only half of the alternating voltage cycle to derive its output. A more efficient use of the ac source is the full-wave rectifier circuit, two versions of which are shown in Fig. 26. In this case the filtering needs only half as much capacitance as in the half-wave case because the fundamental ac component of the rectifier output is at twice the frequency.

Rectifier circuits usually are the primary source of dc power for electronic circuits. They are also used for less exacting applications such as battery charging and electroplating.

Automatic gain control circuits in radio and television receivers often employ the simple half-wave circuit of Fig. 25. In this application the voltage across the capacitor is a dc representation of the signal strength. This

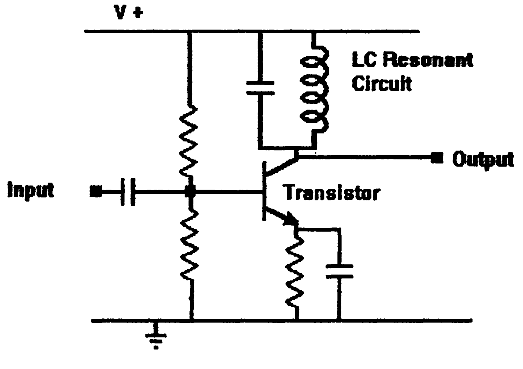

FIG. 21. Tuned amplifier. The action of the transistor supplies a current to the parallel resonant circuit proportional to the input voltage. When the input is at the resonant frequency of the *LC* combination, the output voltage becomes relatively large compared to nonresonant frequencies.

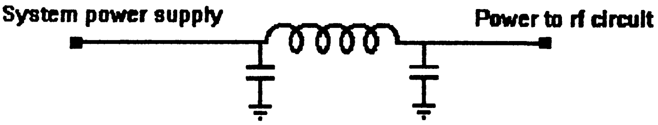

FIG. 22. Radio-frequency filter. High-frequency current is blocked from the power supply by the inductor. The current is shunted off to ground through the lower impedance paths of the capacitors.

voltage is used to control a gain determining element of the receiver to mitigate against fluctuations in the signal strength. Diodes for this application must operate at much higher frequencies than those used for power supply rectifiers; however, the power handling capability required of such diodes is insignificant compared with that of rectifiers. Consequently, these diodes are usually much smaller than rectifiers and have enhanced performance at high frequencies.

An interesting application of the ac-to-dc diode conversion is that of the clamp or dc restorer circuit shown in Fig. 27. This circuit adds a dc value to the ac output that is equal to the peak ac voltage less the forward voltage drop of the diode. The dc voltage added may be positive or negative depending on which direction the diode is installed. The circuit causes the output voltage to be clamped either above or below ground.

The dc restorer circuit suffers from error due to the diode forward voltage. For signals smaller than the forward voltage the circuit will not produce any significant dc restoration. This disadvantage is eliminated with the introduction of an operational amplifier, as shown in Fig. 28.

5.3.2 Overvoltage Protection. Circuits sometimes include diodes as protection devices to prevent over-voltage conditions that might cause damage or degradation of circuit performance. An example of such a circuit is shown in Fig. 29. Here, a relay coil is shown controlled by a transistor. When the transistor cuts off the current, the inductance of the relay coil could cause the collector voltage of the transistor to rise far above the supply voltage and permanently damage the transistor. The diode in the circuit prevents the collector voltage from rising more than a few tenths of a volt above the supply. At this voltage the diode begins to conduct, directing the inductive energy to the power supply without further voltage increase.

In automobile electrical systems, when current is cut off from the starter relay, the inductance of the relay coil can cause voltage spikes in the system that can damage the electronic control modules incorporated in modern vehicles. Diodes are used in a way similar to that of Fig. 29 to prevent damaging voltage spikes.

For logic gates, considerable damage can result from excessive input voltages. Figure 30 is an example of how diodes may be used to prevent excessive voltages from damaging gate inputs.

5.3.3 Zener Diodes. Normally, a diode reverse voltage that is sufficient to produce

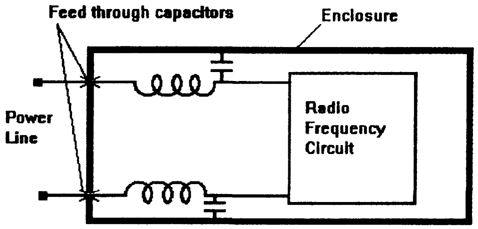

FIG. 23. Electromagnetic interference (EMI) filter. These circuits are identical to that of Fig. 22. They are used here to prevent high-frequency currents from escaping to the power line where they may cause interference in other devices attached to the line.

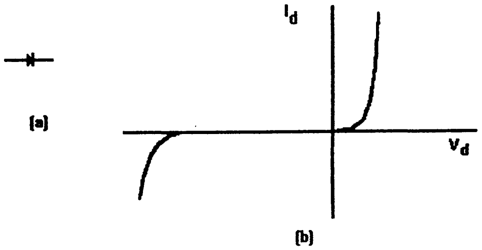

FIG. 24. The diode. (a) Circuit symbol. (b) Typical current–voltage characteristic curve.

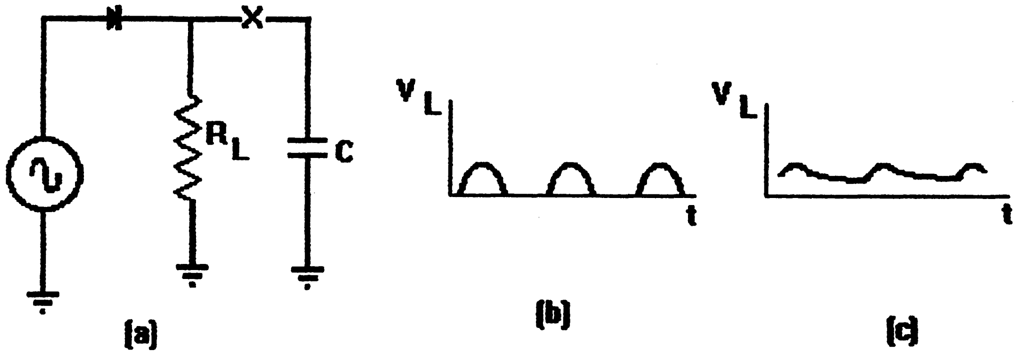

FIG. 25. (a) Half-wave rectifier circuit. (b) Variation in the voltage across the load resistor when *C* is not connected. (c) Load voltage variation when *C* is connected.

breakdown will permanently damage the diode. However, a class of diodes exist that are designed to accept reverse breakdown voltage and then recover to their original state when the voltage is removed. These diodes are called Zener diodes and the breakdown voltage is called the Zener voltage. Zener diodes are manufactured with a range of Zener voltages from 2.4 to 200 V.

One widely used application of Zener diodes is a voltage stabilizer or regulator circuit shown in Fig. 31. Here the output voltage will be at the Zener voltage of the diode as long as the input is above the Zener voltage.

The circuit of Fig. 31 has adequate regulation for some applications, but there will be some variation in output voltage as the load varies. If the current through the Zener diode can be held constant, the voltage will remain fixed except for some reaction to temperature variations. Figure 32 is an example of a regulated power supply that uses a Zener diode as a voltage reference which does not vary as the load varies. Zener diodes used for this purpose are usually temperature compensated units, which have a forward conducting diode incorporated in series with the reverse conducting Zener diode. Modern regulator inte-

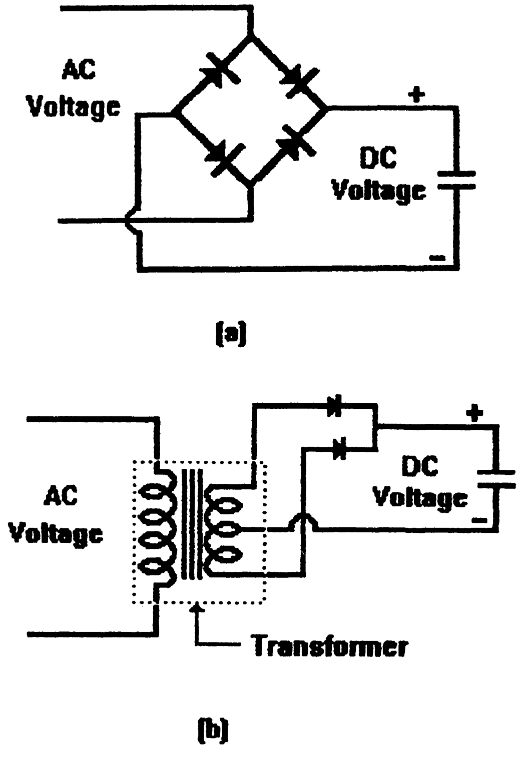

FIG. 26. Full-wave rectifiers. (a) Full-wave bridge circuit. (b) Center-tapped full-wave circuit.

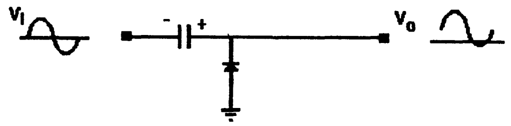

FIG. 27. dc restorer circuit. On the negative half of the input voltage the capacitor charges nearly to the peak value of the input with the polarity indicated. This capacitor voltage adds to the input voltage producing an output that is clamped above ground with the exception of a few tenths of a volt equal to the diode forward voltage.

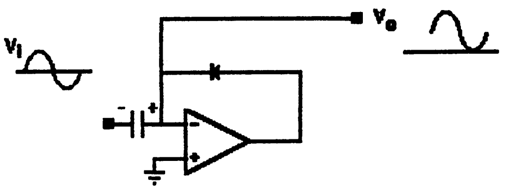

FIG. 28. Modified dc restorer. This circuit operates essentially the same as that of Fig. 27 except that the amplifier reduces the effect of the diode forward voltage to a millivolt or less.

grated circuits usually employ a Zener reference within the circuit package.

Zener diodes are often incorporated in amplifier inputs to prevent overvoltage damage from too large input signals. Figure 33 is an example of this protection application. The Zener voltage must be selected to be less than the minimum damaging voltage, but larger than the normally expected signal voltage.

5.3.4 Varactor Diode. Diodes behave as small capacitors when they are reverse biased. Often this is a detriment to circuit performance. However, since the size of this capacitance is determined by the amount of reverse voltage, specially designed diodes, called varactors, are employed as voltage controlled capacitors.

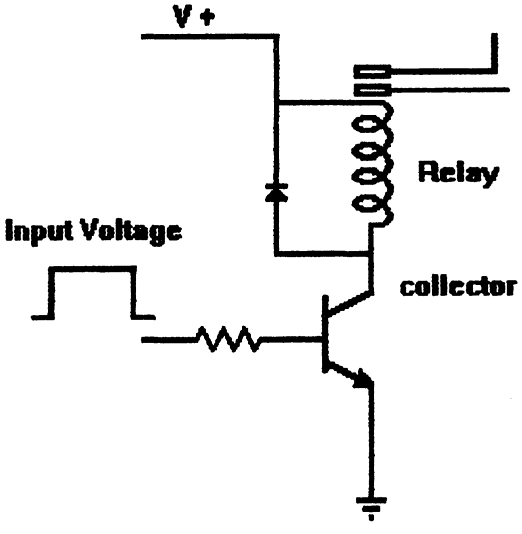

FIG. 29. Inductive spike protector. When the transistor is cut off at the falling edge of the input pulse, the inductance will cause the collector voltage to rise above V^+. The diode will then conduct and hold the voltage rise to less than 1 volt above V^+.

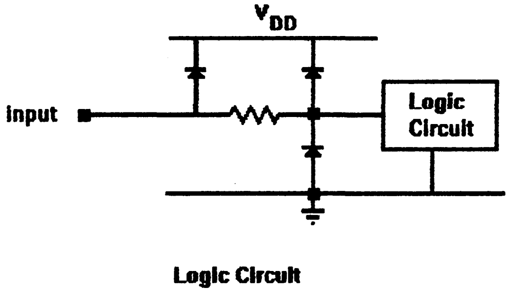

FIG. 30. Overvoltage protection. The upper diodes protect the logic circuit from positive-input overvoltages; the lower diodes protect against negative-input voltages.

Varactor diodes are the principal tuning element in most modern radio and television receivers. Figure 34 is an example of a voltage controlled oscillator (VCO). Such oscillators are used in conjunction with frequency control circuits to generate the tuning of most receivers and transmitters that operate at more than one frequency.

5.3.5 Photodiode. Photodiodes are used as light detectors, especially where nanosecond responses are required. They respond to light incident on a thin layer of intrinsic semiconductor sandwiched between *p*-type and *n*-type material. The light creates electron-hole pairs and consequently a diode current. This configuration is referred to as a *p-i-n* or PIN diode. The sensitivity of these diodes to incident light is usually less than one microampere per microwatt of incident light. See the articles on electronic properties of semiconductors for details concerning *p-i-n* structures. See also PHOTODETECTOR DEVICES.

5.3.6 High-Frequency Diodes. Gunn diodes are used as low-power oscillators to

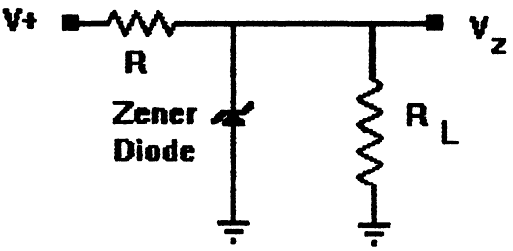

FIG. 31. Simple Zener regulator. The output voltage V_z will be equal to the Zener voltage as long as the input voltage minus the drop across R is greater than the Zener voltage.

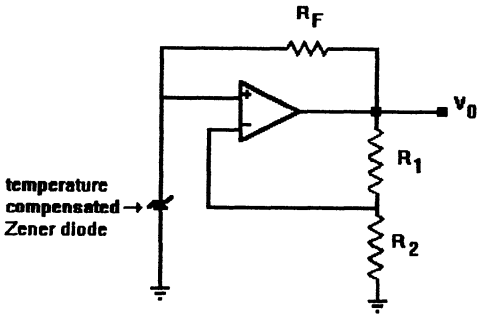

FIG. 32. Improved voltage regulator. The output voltage depends upon the ratio of R_1 and R_2. The resistor R_F is chosen to provide a Zener current that will produce a zero temperature coefficient for the temperature-compensated diode.

generate frequencies in the 5–100-GHz range. They utilize the many-valley scattering phenomenon that occurs in some III-V semiconductor compounds. See the article SEMICONDUCTORS, COMPOUND—ELECTRONIC PROPERTIES for details concerning III-V semiconductors.

Another class of PIN diodes, distinct from the photodiodes discussed above, serve as voltage-variable resistances and switches. Because of their nanosecond response times they are often used in voltage-controlled attenuators at UHF frequencies and as switches in microwave circuits. The amount of resistance that such a diode presents depends upon the amount of forward bias current passing through it. When the bias current is at the saturation point the diode has a low resistance to small high-frequency currents and acts as a closed switch.

Diodes called IMPATT diodes have on and off rise times of less than one picosecond and are used to generate frequencies in the 100-GHz range. The acronym IMPATT is derived from the "Impact Avalanche Transit Time" description of the diode operation. This diode exhibits a negative resistance region in its characteristic volt–ampere curve. When it is coupled to a cavity resonator and with the proper voltage applied, power at microwave frequencies is generated.

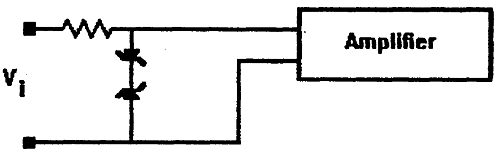

FIG. 33. Amplifier input protection. The "back-to-back" combination of Zener diode voltages is selected to begin conducting when the input voltage V_i becomes excessive for either polarity.

5.3.7 Light-Emitting Diodes. A specially designed diode called a light-emitting diode (LED) uses the recombination of electron-hole pairs in a forward-biased *p-n* junction as a source of light in both the visible and infrared parts of the spectrum. Light-emitting diodes have replaced small indicator lamps in many electronic applications and have formed the basic elements of the popular seven-segment display as well as other alphanumeric indicators.

With the advent of gallium arsenide semiconductors, laser diodes have been under rapid development for use in optical fiber communication circuits. Gallium arsenide lasers produce coherent light in the red and near-infrared regions. See LASERS, SOLID STATE for details concerning these devices.

6. TRANSISTORS

6.1 Introduction

A transistor is a three-terminal device in which the current between two of the terminals is controlled by a current or voltage applied to the third terminal. In some applications an approximately linear relationship exists between the control terminal state and the controlled current. In other cases the transistor may be used as a switch simply to provide on–off control of the current.

C
L
Transistor or Integrated Circuit Oscillator
Output

FIG. 34. Oscillator frequency control. The varactor capacitance is coupled to the resonant *LC* circuit through C_1. The resonant frequency is altered by a change in the control voltage. The resistor R must be chosen large enough to have negligible effect on the resonant circuit.

There are two basic types of transistors, the junction or bipolar transistor and the field-effect transistor (FET). Many different configurations of the FET exist, but all operate by using a small voltage applied to one terminal to control current between the other two terminals, as shown in Fig. 35. The junction transistor exists in two different forms, *npn* and *pnp*. Both use current into one terminal to control the current between the other two, as shown in Fig. 36.

6.2 Applications

6.2.1 Analog Applications. The transistor is often described as a power amplifying device. In linear applications, a low-power signal is applied to the control terminal (gate or base), which causes significantly larger current to flow through the other two terminals of the transistor. When a resistive load is connected in series with this current, a reproduction of the signal voltage is produced across the resistance at a power level several orders of magnitude higher than that of the signal source. The transistor actually converts the power of the dc supply to an amplified reproduction of the power of the signal source and consequently serves as a power amplifier.

6.2.2 Switching Applications. Transistors are very useful switching devices both in low-power, high-speed applications found in digital circuits and in the higher-power cases such as switching power supplies.

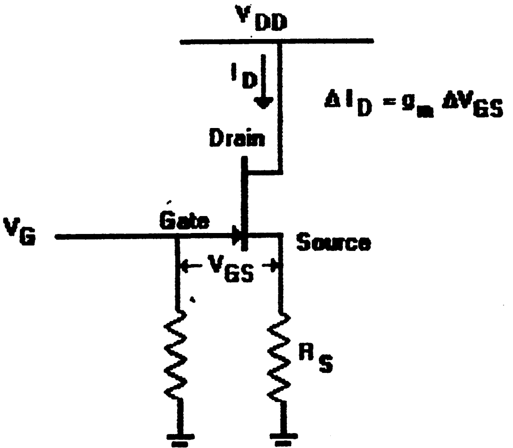

FIG. 35. A JFET transistor. The resistor R_s causes the gate to be negative relative to the source, which is necessary for the linear operation described by the equation for ΔI_D.

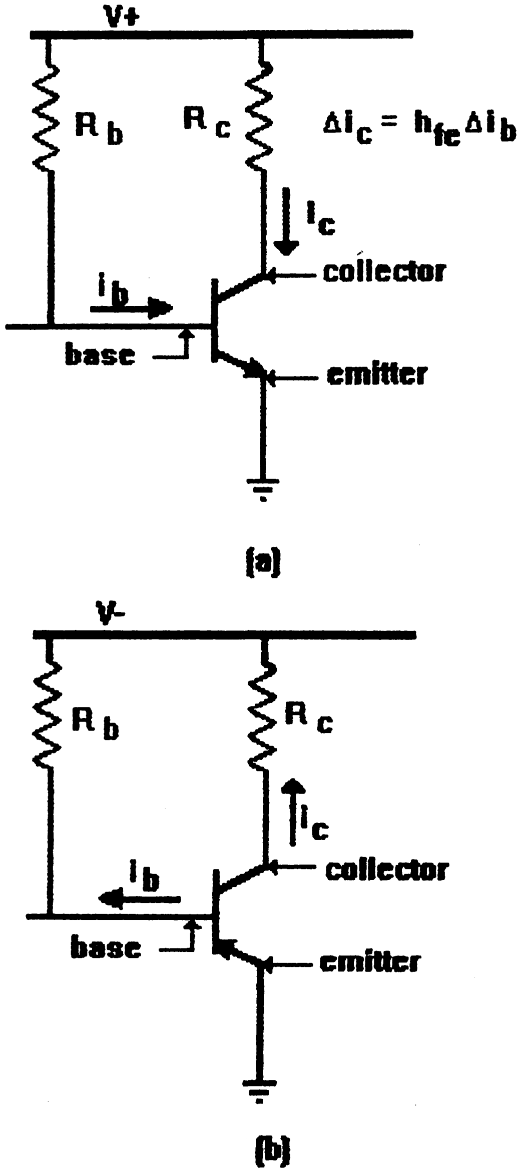

FIG. 36. Junction transistors. The equation for ΔI_C is applicable to both the *npn* (a) and the *pnp* (b) transistors.

The metal-oxide semiconductor FET or MOSFET has been the transistor design of choice among circuit designers for high-current switches. With current ratings up to 60 A, forward or on resistances as low as 0.028 Ω, and holdoff voltages of hundreds of volts, MOSFET transistors have been widely used as current switches in power supplies with ratings as high as 1000 W or more.

In recent years, most electronic designs include few transistors as discrete circuit elements. Instead transistors have become an important component of complex integrated circuits that perform many different, higher level analog and digital circuit functions. In exceptional cases where high voltage or power dissipation preclude the use of integrated circuits, discrete transistor devices still are incorporated in circuit designs.

7. TRANSFORMERS

7.1 Introduction

A transformer consists of two coils of wire that are magnetically coupled. If an ac voltage is applied to one of the coils, called the primary, an ac voltage will appear across the other coil, the secondary. Ideally, the ratio of the voltages will be the same as the ratio of the number of turns in their respective coils.

Usually transformer coils are wound around some sort of ferromagnetic core material to enhance the magnetic coupling between primary and secondary windings. For frequencies ranging up to a few kHz, this material consists of iron in the form of thin laminations bonded together. At higher frequencies, various kinds of ceramics containing ferromagnetic particles are used for core material.

The power input to the primary of a transformer will ideally equal the power absorbed by a load connected to the secondary. Realistically, most transformers are quite efficient with only a small amount of power loss in the transformer itself. Transformers are manufactured in a myriad of shapes and sizes depending upon the frequency and level of the power being transformed. Their weights range from a few grams to thousands of kilograms with corresponding volumes of a cubic centimeter to many cubic meters.

7.2 Applications

The fundamental purpose of a transformer is to change an existing ac voltage to a value more suitable for the application at hand, without incurring a significant amount of power loss. For example, a resistive voltage divider can be used to reduce a voltage for a particular purpose, but the power loss in the resistors usually far exceeds the loss from using a transformer to obtain the same reduction.

7.2.1 Power Distribution. Power generating stations use transformers to produce secondary voltages of several hundred kilovolts, which are suitable for efficient transmission of power over long distances. At the consuming end of the transmission line, transformers reduce the voltage to a more suitable value for the application of the power.

Power supplies for electronic equipment provide another example of the use of transformers to produce voltages more suitable for the applications. Most power for electronic equipment is obtained from the standard 120-V, 60-Hz lines in homes and commercial buildings. Most electronic devices require dc voltages of 30 V or less. The first step in converting the power is to use a transformer to reduce the ac voltage to a more suitable value for rectification to dc.

7.2.2 High Frequency. For frequencies of several kilohertz to hundreds of megahertz, transformers are used with a different point of view from simple voltage changing. Here, the concept of impedance matching is the dominant consideration in order to transfer a maximum amount of signal power.

High-frequency transformers may be designed to operate at a single frequency or to cover a broad frequency range, depending on the application. Single-frequency designs are found in high-frequency communications equipment, especially in the intermediate-frequency amplifiers of television and radio receivers. Usually, one or both of the windings of these transformers is tuned with a capacitor to provide frequency selectivity, i.e., to filter out unwanted frequencies.

The use of tuned transformers has diminished in recent years with the advent of surface acoustic wave (SAW) filters, which provide better selectivity and preclude the need for tuning adjustment or temperature compensation.

Broad-band high-frequency transformers are most commonly used for impedance matching between transmission-line circuits where signal frequencies may vary from 1 to 500 MHz. These transformers consist of a few

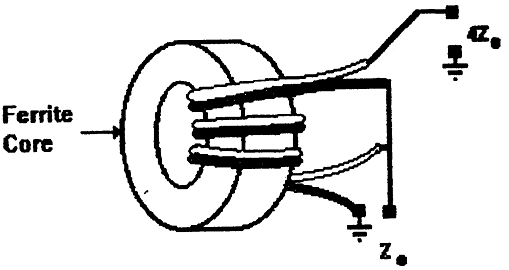

FIG. 37. Impedance matching transformer.

turns of paired wires wound around a torroidal ferrite core as shown in Fig. 37.

7.2.3 Circuit Isolation. Transformers are often used to isolate electrically a circuit connected to the secondary from the circuit connected to the primary. Since the transfer of power between the primary and secondary of a transformer is only through magnetic coupling, there is no direct electrical connection between the two windings. This isolation allows the primary and secondary circuits to have different levels of dc voltage and still be able to transfer ac power between them without disturbing their respective dc levels.

7.2.4 Variable Transformers. A special kind of transformer, called an autotransformer, has its secondary terminals connected directly to the primary. In most cases the secondary is comprised of some fraction of the primary turns that is accessed through a tap on the primary coil, as shown in Fig. 38. The secondary voltage is determined by the ratio of the number of turns between the tap and the common terminal to the total number of turns in the coil.

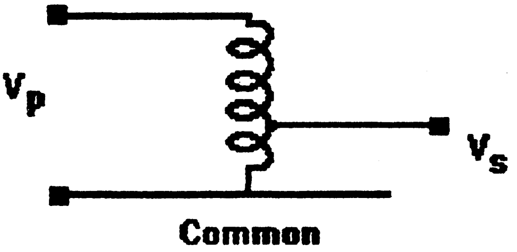

FIG. 38. The autotransformer uses a section of the primary winding as a secondary. There is no electrical isolation between primary and secondary.

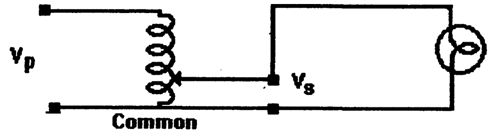

FIG. 39. Variable autotransformer. Moving the tap adjusts the secondary voltage to control the lamp intensity.

Often autotransformers will be wound in a configuration that allows the tap to be movable so the number of turns in the secondary can be varied. Thus an autotransformer can be used to control the brightness of lamps or the temperature of an electric heater as shown in Fig. 39. Autotransformers do not provide circuit isolation between primary and secondary. Consequently, their use should be limited to situations where danger of electrical shock or damage to equipment will not occur because of the lack of isolation.

Another type of variable transformer is the differential or linear transformer. This device consists of a single primary winding and two secondary coils wound on a rod-shaped core, as shown in Fig. 40. The core is movable, which allows the coupling between the primary and the secondaries to be varied. With the core centered, as shown in Fig. 40, the voltage in the two secondaries will be equal. When the core is moved to the right or left the two secondaries will have unequal voltages, the larger voltage appearing in the coil with the larger share of the core.

Differential transformers are useful for detecting small linear motions and are widely used in instrumentation systems for this purpose. Displacement ranging from 0.01 to 50 cm can be measured with accuracies of better than 0.1%.

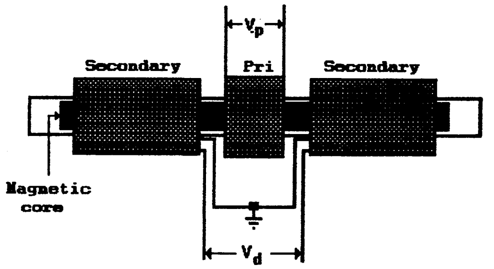

FIG. 40. Differential transformer. The two secondaries are differentially connected so that when the core is centered for symmetrical coupling, V_d is zero.

7.2.5 Constant-Voltage or -Current Transformers. A current-limiting transformer has been specially designed to operate gas-discharge devices, particularly the neon signs seen in nearly every city of the world. This transformer has a high-voltage secondary winding with a high resistance. Once the high voltage ionizes the gas, the current is limited by the high resistance of the secondary to a value that will maintain the discharge without overloading the transformer. Such transformers will withstand indefinitely a short circuit on the secondary without damage from overheating.

A cousin to the current-limiting transformer is the constant-voltage transformer. This device is designed to maintain a nearly constant secondary voltage when the primary voltage varies. Usually, this is accomplished by using a variable-reluctance core material, which is controlled to vary the coupling between primary and secondary to offset variations in the secondary voltage.

8. SWITCHES

8.1 Introduction

A switch is a device used to complete the circuit between an electrical load and its power source. Switches exist in a vast number of forms and sizes for a myriad of applications. In some cases, the load current passes through the switch contacts; in other cases, control of a load current in one switch may be done remotely by use of a second. The latter cases usually employ magnetically operated switches, called relays, or solid-state devices designed specifically for remote operation.

Applications for switches must take into account both electrical and mechanical requirements. The principal electrical requirements are the amount of current the switch contacts can carry without overheating, the amount of current the switch can interrupt for resistive and inductive loads without arc damage, and the amount of voltage the switch can withstand without insulation breakdown or arcing across contacts or terminals.

The mechanical requirements include the physical stress that must be withstood from the mounting and actuation method, the temperature and humidity extremes of the operating environment, and the number of operating cycles expected before failure.

8.2 Applications

The application areas can be divided into categories, namely, signal and control switching, low to medium power switching, heavy industrial switching, and power distribution switching.

8.2.1 Signal and Control. Switches for signal and control are subject to little electrical stress. Their main requirements are reliable operation and low noise generation. They may be either mechanical or solid state devices.

Mechanical switches are by far the most important for interfacing with human operation. Many reliable mechanisms have been designed for switches to be operated by pushing a button, turning a knob or flipping a lever. Some disadvantages exist for mechanical switches when they are used in wide-bandwidth or digital circuits, however.

One of the more important defects of mechanical switching is contact bounce. When their contacts close, almost all mechanical switches will alternate between an open and closed condition for as many as 100 times, for a period that may range up to a millisecond. Most digital circuits are capable of responding to this rapid opening and closing of contacts, which can result in serious errors when mechanical switches are used to interface with computers.

Contact bounce can be eliminated either by software methods, in the case of computer applications, or by electronic "debouncing" circuits, such as that shown in Fig. 41.

Another disadvantage of mechanical switches is their effect on high-frequency or low-level signals. The capacitance of the switch and its attendant wiring may seriously affect the high-frequency performance of a circuit. For low-level signals, the switch and its wiring may introduce noise.

In these applications the mechanical switch should be used to control a more suitable switching device that minimizes the capacitive and noise effects. An example of a combination of mechanical and solid-state switching to minimize noise in a low-level audio circuit is shown in Fig. 42. In a similar manner a mechanical switch can be used to control a relay specially designed to switch radio frequency signals.

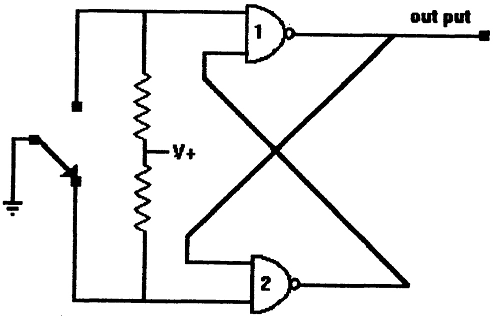

FIG. 41. Debounce circuit. The output is the logical NAND function of the inputs to gate 1. When the switch is in the lower position the output will be zero volts, a logical zero. When the switch is in the upper position the output will be approximately +V, a logical 1. These outputs will occur on initial contact of the switch terminals and remain fixed during contact bounce.

An interesting example of a switch designed specifically for interfacing with microprocessor circuits is the so-called sine–cosine switch shown in Fig. 43. This switch is capable of continuous rotation in either direction. The two rotor poles are identical, except that one pole is set 90 degrees around the shaft from the other. This results in the contacts emitting a different sequence of two bit binary numbers for clockwise rotation than for counterclockwise rotation. The software for the microprocessor must be designed to detect the rotation direction. The result then can be used to generate control signals for frequency, amplitude, position, etc.

8.2.2 Low to Medium Power. Applications for low- to medium-power switching are widespread among automobiles, households, offices, and commercial establishments. Mostly, such applications are for lighting and small electric motor control. In other than automobiles, the switches used usually carry the full load current of the devices that they control. Electrical specifications for such switches rarely exceed 15 A and 230 V. In the case of electric appliances, such as refrigerators, washers, dryers, and air conditioners, relays are usually employed to control the electric motors.

For automobiles, most of the dashboard switches are of the control type. These are used in conjunction with relays to provide high current capacity without requiring high-current conductors routed under the dash.

With the advent of solid-state switching devices, two of the most important in power control applications have been the silicon controlled rectifier (SCR) and the triac. The circuit symbols for these devices are shown in Fig. 44.

The SCR is a unilateral device like the diode with one important exception: The SCR will not conduct unless it is triggered on by a current from gate to cathode. Once triggered the SCR behaves as a diode rectifier, regardless of the presence or absence of gate current. When the anode voltage becomes equal to or negative, with respect to the cathode, the SCR stops conducting and will remain in a nonconducting state until triggered again by gate current.

The gate control property of the SCR allows it to be turned on any time during the portion of the ac cycle when the anode is positive with respect to the cathode. Consequently, the device can be used as a rectifier that will produce a variable amount of average dc current depending on when it is triggered during the positive half of the ac cycle. One application for the SCR is its use as a speed control for dc motors, as shown in Fig. 45.

The triac is similar to the SCR in that it is triggered on by a current through the gate-to-MT2 junction. The device differs from the SCR in that it is bilateral, i.e., it can conduct in either direction. Once the triac is turned on, the gate terminal no longer controls it until the voltage between MT1 and MT2 goes to

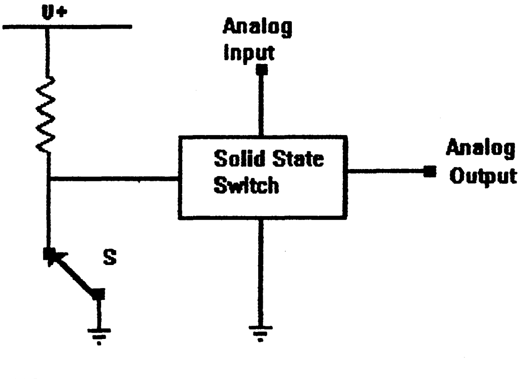

FIG. 42. The solid-state switch is an integrated circuit incorporating a MOSFET transistor in the analog signal path. These switches are turned on and off with digital signals such as that generated by the mechanical switch S.

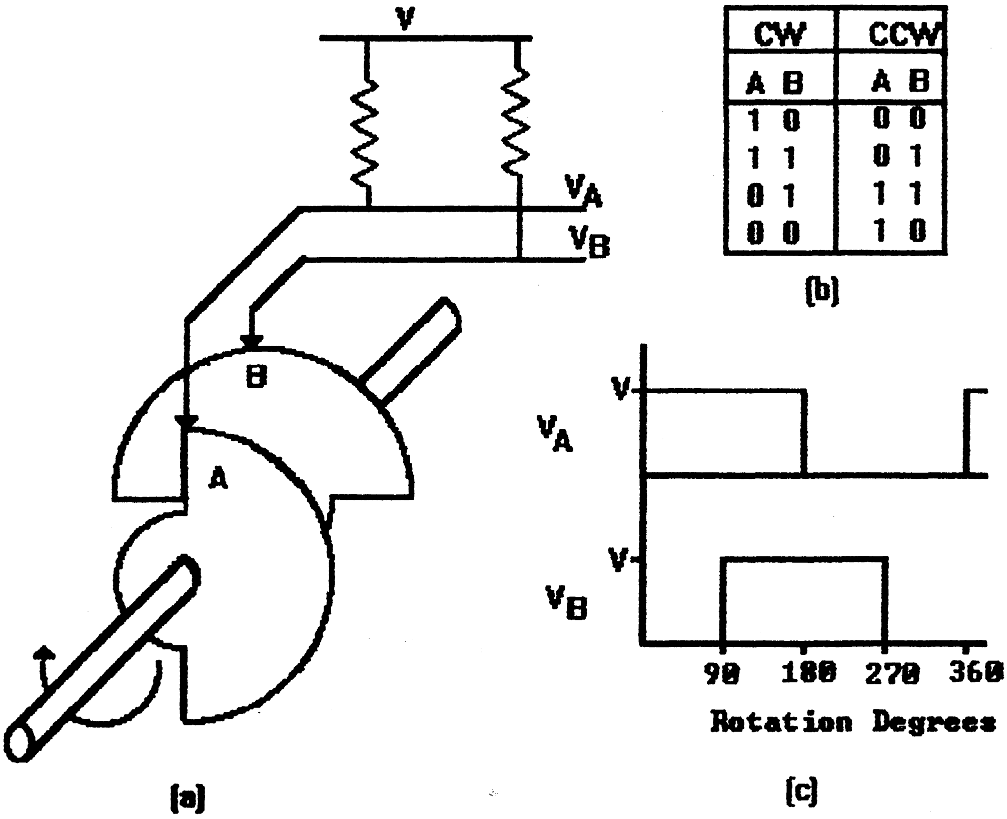

CW		CCW

zero. The device then goes to a nonconducting state and must be turned on again by gate current.

If the phase of the gate current in the triac is varied relative to the ac line voltage phase, the device can be made to conduct for a variable fraction of the ac cycle. When used in this way, the triac can control the average ac power delivered to resistive loads, such as heaters and incandescent lamps.

Another application of the triac is that of zero-voltage switching, which is used to prolong the life of expensive incandescent lamps, such as those used in traffic signals or flood lighting. The life of such lamps is materially shortened by high current surges when they happen to be turned on at or near the peak of the ac line voltage. The control of these lamps by a triac circuit, shown in Fig. 46, minimizes lamp failure due to current surges at turnon.

8.2.3 Industrial Power. Industrial electrical requirements usually include large electric motors, ranging up to several hundred horsepower, and electric heating and lighting loads, ranging up to hundreds of kilowatts. Switches for the large currents and voltages required of these loads must be specially designed. Most are magnetically operated to provide fast operation to minimize the arcing time on opening and closing. The contacts must be large and of sufficient heat capacity and thermal conductivity to prevent excessive temperature rise. Remote control of these switches is usually done from push buttons or, in some cases, directly from the output of computer ports or integrated logic circuits.

8.2.4 Power Distribution. Switching for power distribution requires the most severe specifications for switch gear. These devices must be capable of handling thousands of amperes at tens of thousands of volts. The contacts are usually immersed in oil or other fluids that will quench arcs and prevent contamination. Such switches are usually oper-

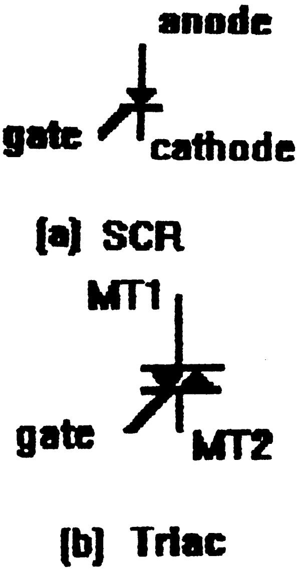

FIG. 44. (a) The silicon controlled rectifier (SCR) will conduct only when triggered by a current passing from gate to cathode. Once triggered it will conduct as an ordinary diode without further control from the gate until the anode voltage becomes negative with respect to the cathode. At this point the SCR resets and will not conduct again until the anode becomes positive and gate current is initiated. (b) The triac operation is similar to the SCR except the triac conducts in both directions. It resets to the off state each time the voltage between MT1 and MT2 passes through zero and must be triggered on again by gate current.

ated remotely from a control panel or computer, located at some central point in the distribution system, many miles from the switching site.

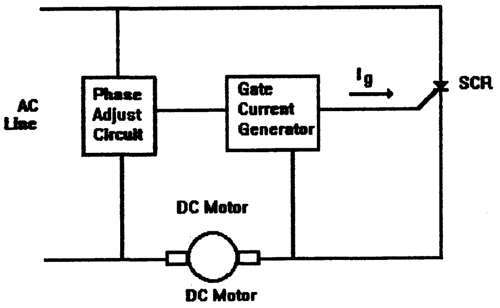

FIG. 45. dc motor speed control. The average current through the SCR is controlled by adjusting the phase of the gate current relative to the phase of the ac line.

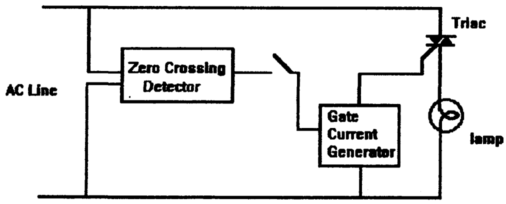

FIG. 46. Zero-voltage switch. When the switch is closed to turn the lamp on the gate-current generator will not trigger the triac until the line voltage is at or near zero.

9. FUSES AND CIRCUIT BREAKERS

9.1 Introduction

A fuse is a device that opens a circuit if the current becomes larger than a preset maximum. Its active element is a low-melting-point alloy that melts to open the circuit when the current becomes excessive. A circuit breaker performs the same task as a fuse but differs in operation in that a circuit breaker can be reset and used again, while a melted fuse must be replaced. In either case, the purpose of the device is to protect wiring or electrical equipment from damage due to excessive current.

Fuses and circuit breakers are rated according to the maximum current they will allow before opening. Current ratings vary from small fractions of an ampere to hundreds of amperes. Their response times to current overloads depend on the severity of the overload and vary inversely with the square of the overload current. Response times may range from a few milliseconds to several minutes.

9.2 Applications

For any application, the response time of the fuse or circuit breaker must be taken into account to ensure that circuit damage will not occur before the protective device can interrupt current flow. For the protection of semiconductor devices, the response times must be very short—shorter than that of most protective devices. Consequently, special fuse types have been developed to handle these short response-time requirements.

Some applications may involve large inrush currents at turnon that can be ten times larger than the normal operating current of a circuit. In these cases, the response time of the fuses or breakers used must be long enough that they will not interrupt the circuit before normal current can be established. Large inrush currents are usually encountered with the turnon of incandescent lamps and electric motors. Sometimes large inrushes occur in magnetic core devices, such as transformers and solenoids, depending upon the magnetization state of the core at turnon.

Another class of circuit protective devices, called thermal overload protectors, serve to interrupt current to a circuit, much the same as fuses and circuit breakers. These devices do not react to overcurrent, however. Instead, they operate from heat generated in their immediate surroundings, much in the same way as thermostats. Thermal overload protectors are often used in electric motors and transformers, where they are embedded in the winding or core space, and cut off current if the temperature rises beyond a safe limit. These thermal protectors usually operate mechanically and reset to the operating state when their temperature is reduced below their operating limit.

GLOSSARY

Band Pass: Range of frequencies transmitted by a circuit.

Characteristic Impedance: Termination impedance for a transmission line necessary to prevent reflection of transmitted energy back to the source.

CMOS: Complimentary metal oxide semiconductor.

dB: decibel.

Duty Cycle: Fraction of time that a switch is on during a switching cycle.

FET: Field effect transistor.

High Pass: Used to describe the behavior of a circuit that transmits all frequencies above a selected value.

III-V Compounds: Binary compound with one element taken from column III of the periodic table of elements and the other from column V.

IMPATT: Impact avalanche transit time, used to describe carrier behavior in a semiconductor structure designed specifically for generating energy in the GHz range.

JFET: Junction field effect transistor.

Low Pass: Used to describe the behavior of a circuit that transmits all frequencies below a certain selected value.

MOSFET: Metal oxide semiconductor field effect transistor.

Op Amp: Operational amplifier.

Pass Transistor: Transistor used as a series element to regulate the output of a dc power supply.

SCR: Silicon controlled rectifier.

Surface Mount: Describes the technique of mounting circuit elements on a printed circuit board by soldering them directly to the component side of the board.

Triac: Semiconductor device used for electronically controlled switching of alternating current at any selected point during the cycle.

UHF: Ultra high frequency. Frequencies ranging from approximately 450 to 950 MHz.

INTRODUCTION

Analog circuits and systems process signals that may be continuous both in time and in amplitude. Even systems that are nominally digital may exhibit behavior that can be understood only in an analog context, especially at extremes of speed. Furthermore, despite the growing use of digital systems, there remain many instances in which analog circuits can implement a given function more conveniently (although perhaps with less accuracy) and can provide substantially higher speed operation. Finally, digital systems often require analog-to-digital (A/D) and digital-to-analog (D/A) converters (ADCs and DCAs) to provide interfaces to the "real" world.

This article examines operational amplifiers first (in Sec. 1) because many of the global issues pertaining to analog circuits are conveniently illustrated in that context. Section 2 provides a brief review of the theory of signals and systems and considers in particular the issue of system stability. A cursory treatment of semiconductor devices follows in Sec. 3, with a focus on issues relevant to circuit modeling, while Sec. 4 surveys amplifier design with an emphasis on bandwidth considerations. Section 5 presents a number of techniques for performing A/D and D/A conversion, and Sec. 6 concludes this article by examining a number of miscellaneous applications, such as switch-mode power conversion.

Throughout this article conventional, rather than electron, current flow is assumed, as is the use of Système International units.

1. OPERATIONAL AMPLIFIERS

The term "operational amplifier" derives from the variety of mathematical operations that such devices may realize conveniently, as will be shown shortly. The symbol for an operational amplifier (op-amp) is shown in Fig. 1, as are the reference directions for a number of associated electrical quantities. All potentials are with respect to an implicit ground.

An op-amp produces at its output a voltage that is some multiple of the differential input voltage, that is,

$$v_{\text{out}}=A(v_+-v_-). \qquad (1)$$

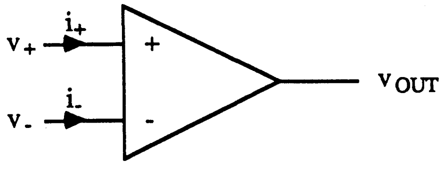

FIG. 1. Operational amplifier.

An ideal op-amp may be defined as one possessing zero input current ($i_+ = i_- 0$), infinite differential gain (or amplification factor) A, infinite speed (that is, dynamic limitations are ignored so that A is a purely scalar quantity), and infinite output current capability. By assuming these characteristics, one can expediently analyze any ideal op-amp circuit. Corrections for the failure of real op-amps to satisfy all of these conditions can also be applied if necessary.

As an example of this type of analysis, and also to illustrate the origin of the term operational amplifier, consider the collection of circuits shown in Fig. 2. Figure 2(a) is known as an inverting amplifier and may be analyzed as follows. Assume, in addition to ideal op-amp behavior, that the output voltage of the op-amp is finite as a consequence of the negative feedback connection (there is a net inversion of signals propagating around the feedback loop). If the output is finite, the infinite differential gain assumed necessarily implies a zero input differential voltage; the voltages v_+ and v_- must be equal and, in this case, equal to zero. Because the inverting input is always forced to be at zero potential in this case, it is also known as a virtual ground.
